ACKNOWLEDGMENTS

In addition to all those who chose to remain anonymous, I would like to thank the following for their part in inspiring and encouraging me, or otherwise aiding in the process of research [knowingly or unknowingly], thereby making this work possible:

The amazing plant allies; my loving wife, thanks for everything; all my family and friends not otherwise mentioned; K. Trout, for his endless thoroughness and scholarly generosity, and for proof-reading; Michael Bock, in allowing me access to his library and [at the time of writing] unpublished book; Sasha Shulgin, for encouragement and advice; Ann Shulgin, for encouragement, advice, and for proof-reading the 'Questions and Answers' chapter in an early stage; theobromus, for feeding me endless morsels of information, and providing valuable scholarly criticism and proof-reading; Rob Montgomery, for inspiration, encouragement and sharing; Giorgio Samorini and Manuel Torres, who freely gave me copies of some hard-to-find articles; Morgan and Digby for software help and good vibes; Gaston Guzmán; Jan Borovicka; Nen; Lamius; Rkundalini; Sue Baill; Ray & Liz; Ghostpipe; Hoodoo; Glass; Om-Chi; friendly; NaChaSh; Andy; OneAM; Chris; Simon; Peter L.; Steffen; Todd P.; James Peziza; Ben and Sacred Succulents; Pod; Floyd; Copan John; Nibn; P. Recher; David C.; Carl; Jonathan Ott; Christian Rätsch; Lynn Horwood; Andrew Thompson; Mulga; Torsten; Marion, for some French translation; Jadler, for some German translation; Jesai; Kyle; Jacques; Todd Pisek; Dutchie; Leigh; 'Dennis'; John W. Allen; Larry; George Fuller; Thomas Munro; Jeremy; Noah; Ronny; Day-V; the library staff of Melbourne University, Monash University, La Trobe University, Royal Melbourne Institute of Technology, Agriculture Victoria, National Herbarium at Royal Melbourne Botanic Gardens, and State Library of Victoria; Polyester Books; Greville Records; Chan-Kah (Ruinas); El-Panchan; the great men (who unfortunately I have never met) Richard Evans Schultes [r.i.p.], Gordon Wasson [r.i.p.] and Albert Hofmann [r.i.p.]; and especially all of the inspiring music which fed my head, inspired me or otherwise helped along the way (with a special mention to the pro-active Pink Fairies song 'Do it!', which kept me from giving up!).

FOREWORD

Greetings, reader! The book you are holding was born, initially, as a hobby of sorts. After developing a strong interest in the ethnobotany, chemistry, preparation and beneficial useage of psychoactive plants and other gifts from nature, it did not take long to realise that reliable information regarding these topics was anything but easy to come by. I encountered frustration at attempting to avoid the many inaccuracies and ignorant assumptions portrayed through media, government, and many mainstream publications in this field [as well as the internet, and 'underground' publications]. There is, however, a wealth of relevant literature that has been published in scientific journals and obscure books, which are unfortunately inaccessible to many. Searching for such information randomly, with no references to start from, is a time-consuming task that could not be accommodated in the lives of most working people. Due to the tendency of journal articles to become forgotten in the sands of time, there was a need for some academic excavation [and continuation of excavations begun by others] to ensure that much valuable information was not lost from public knowledge.

Also of tremendous importance are the numerous personal communications that have been exchanged with a wide array of knowledgeable folk. Many have chosen to remain anonymous, some have chosen pseudonyms, and others have stepped out into the open entirely. All have contributed valuable information regarding their own observations or experiments, much of which has never been published before. The unfortunate unwillingness of many science-related authors to publish the reports of 'amateurs' has historically resulted in many gaps in our holistic understanding. Such gaps have also arisen from the frequent lack of communication or understanding between practitioners of different scientific, academic and/or 'mystical' disciplines. In my own explorations of the realms of ethnobotany and consciousness, it quickly became apparent that here was an area of study in which all of these disciplines [and many other things beyond] are inter-related in a fascinating way. Being a lover of the gathering and analysing of obscure and interesting information, I set to work on assembling this ever-growing project, not suspecting it would take over more than a decade of my life.

In short, this book began as a private project for my own reference. After a year or so, it became clear that this would be a book that should be shared with others. So, part of the mission of this book was to retrieve a great deal of this information for public perusal, attempt to filter out old errors and make sense of points of confusion, and establish a substantial bibliography to aid the reader in further research of their own. Also, a multidisciplinary approach was taken in an attempt to harmonise fields of knowledge that are usually treated as unrelated. Further, perhaps more important, motivations for writing this book are discussed in the Introduction. This resulted in what you are now reading – a compendium of knowledge intended to aid both personal and academic research into the shamanic and spiritual useage of natural substances. I cannot claim this book will tell you everything you may want or need to know on the subject, of course – I drool to think of any single book which could, whilst simultaneously doubting such a book could be written – yet hopefully it will at least serve its stated purpose.

Information from the past is constantly being rediscovered, and fresh research is constantly being carried out by many scientists and noble amateurs the world over. Many thousands of plants are still unknown to us, both chemically and ethnobotanically, and it should be expected that we will learn of 'new' psychoactive plants and substances in the natural world with increasing frequency over the coming decades. Whilst writing, so much information has passed before my eyes, that there have been many topics and avenues of discussion I have been unable to pursue further in this volume. Also, the size of the endeavour has meant that some more recent new developments, as well as some old ones, have slipped through my net and are not reported here. Even if everything regarding these topics that is known to this point in time were compiled, the result would consist of a small library full of texts and images. In addition, there are some fields of knowledge which seem exceedingly difficult to confine to static words or images, and must remain as knowledge obtained via direct experience. As is reflected in the dazzling complexity of nature, any line of intellectual inquiry can be found to expand exponentially – a question becomes a thousand questions!

I hope this book helps you find the answers to some of your questions.

[Please note: regretfully there are some layout anomalies that could not be resolved without creating worse problems. These became apparent too late in the final editing process, and fixing them would have required reassembling the whole thing from scratch, altering the layout, and re-doing the index numbering (which due to the complex nature of the book had to be done manually rather than automatically, and took literally weeks of work). As the book has already been delayed for so many years, stress has mounted, and other aspects in life are calling to be attended to, I took the difficult decision to continue and publish the book 'as is' despite these flaws. Hopefully you'll be so busy reading you won't even notice!]

Snu Voogelbreinder, April 2009

DISCLAIMER

Unfortunately, some of the plants and naturally occurring chemicals discussed within are illegal to possess, process, or consume in many countries across the globe. It is strongly advised that the reader become familiar with the laws of their country in this regard, as failure to abide by such laws frequently results in serious disruption to the lives of individuals, who may face distressing invasion and ransacking of the home, fines, loss of income, confiscation of property and/or incarceration.

Besides this risk, some of the substances and practices described within may be risky or harmful under some circumstances, and are usually noted as such when mentioned in the text. Some individuals may also be particularly sensitive to these influences, and have adverse reactions which are not experienced by the majority. The author can not assume responsibility for any harm resulting from the use or mis-use of the information within this book. Readers are advised to act with their own responsibility in mind and to make their own informed choices.

A NOTE ON CROSS-REFERENCING AND FORMAT

For conciseness and simplicity, the properties of chemicals appearing in the text in italics [eg. this species has been found to contain *nicotine*] are mentioned in the *Chemical Index*. Titles appearing in italics refer to the title of a separate chapter of this book. Genus names listed in the text in bold [eg. **Cannabis** has also been used in conjunction with this plant] refer to an entry for that genus elsewhere in the A-Z listings of the main text [ie. part two]. Such genus names are not in bold type when found in their own entry, except in the case of species listings at the start of the section, and when introducing a species or genus description at the end of the section. Genera or species which are mentioned elsewhere in the text but without a main entry are marked individually as appropriate [eg. This fungus may be confused with Ustilago spp. (see *Endnotes*)]. Colloquial names are generally given in inverted commas when first appearing in a section of text.

In part two of this book, organisms [plants, animals] are discussed under individual entries arranged alphabetically by genus [the first part of a scientific name or Latin binomial; ie. Acacia (genus) baileyana (species)]. Each of these entries follows a similar pattern of formatting, depending on the depth of information available. A typical genus entry will be arranged as follows:

GENUS

(Family, sometimes including alternate or obsolete family names, and subfamilies where applicable)

Species names *with authors* **(and synonyms)** – and common names
[Such lists of species names consist of those important species discussed in the text, and do not comprise a list of all known species within a genus]

General discussion on uses and folklore.

Discussion on special methods of preparation and consumption.

Discussion on the nature of the effects of the consumed substance.

Discussion of the chemistry of these species and/or their close relatives, usually listed alphabetically by species. All yields of chemicals are from dry weight [d/w] source matter unless stated otherwise. Some information may seem contradictory or conflicting due to differing source material and methodology used by different researchers; the author has tried to analyse and compile the data and present it in a way that makes sense, but some confusing points remain.

Representative species with a detailed botanical or zoological description, including information on habit and habitat.

Discussion of possible confusion with other species or subspecies.

Cultivation requirements for this representative species and/or other members of the genus, in the case of plants.

INTRODUCTION

I feel it is necessary to be blunt. We have reached a point of crisis.

Whilst the human race has made huge leaps in technological advancement, most of us have failed to grow in how we relate to ourselves, other people, and the environment we live in – rather, we have largely atrophied in those areas. With the homogenisation and commodification of culture based on consumerism continuing to spread its influence, straining natural resources and smothering individual expression, many scientists and others sensitive to our environment are realising that the lifestyles and choices of much of humanity are destroying the natural balance which allows life as we know it to exist. It is unfortunate that in today's politico-economic climate these truths are incompatible with the increasingly myopic 'economic rationalism' which governs most nations. As a result, scientists who wish to remain in long-term employment often have their urgent messages stifled. The comforts of life in relatively affluent societies shelter us so much from the problems of the world, that it seems easier for most people to accept the reassurances from our governments and peers that we will continue to grow and prosper forever if we continue with current trends and ways of thinking.

For too long, we as a technological race have been blindly damaging links in ecosystems we are only beginning to understand. What we are now learning tells us that even minor alterations in such systems can have massive consequences for the system as a whole. Our economy, which seems to have become somewhat of a god unto itself in these times, dictates the actions of individuals, companies and governments, and makes environmental destruction desirable and profitable. It allows some of us to live in relative luxury, obsessing about the latest fashions and celebrities and complaining about the price of petrol, while the less fortunate may starve or be driven from their land at gunpoint. We act as though this can go on forever if we look the other way, though there are voices from all sides reminding us that we can not survive for long as a race without a healthily functioning ecology of the mind as well as of the planet. We can't control the weather, so to speak. When nature bites back hard, there is usually little we can do about it. This is the price we pay for turning our backs on nature and its ways – for treating it as something to be conquered, tamed and exploited, rather than as something to love, learn from and be part of – which we are whether we want to be or not.

Our relationships with, and awareness of ourselves, other beings, and our environment are in great need of repair. It could be said that the way we treat our environment is in direct relation to our degree of awareness. Psychedelic plants [and other psychoactive substances from nature] are largely functioning in this day and age as our emergency wake-up call. Their wise use offers direct experience of these relationships, and can help us find paths to healing the broken connections in the web of life, encompassing spiritual growth in the process. It is unfortunate that today's busy lifestyles do not leave most people with the time to truly find themselves, and consequently learn how to bring harmony into their lives. Many people become impatient with the more culturally-acceptable approaches to self-discovery [and the resultant re-discovery of the worlds we exist in], or are suspicious of spirituality that is not self-evident.

This is where the plants and other organic life-forms, which are the focus of this book, come into the picture. We must admire the way in which they manage to survive, with the relative simplicity and self-reliance that we have grown to lack in our ever-complex technological world. Of course, such organisms are also interdependent within the entire ecosystem [and thus, not truly 'self-reliant' – by the same extension, perhaps nothing can ever truly be considered 'self-reliant' unless the whole of 'reality' and all that it contains are considered as one organism], yet humans like to imagine themselves as being removed from this web – a dangerously false notion, both for ourselves and the non-human organisms we affect every moment. In humans, the notion of self-reliance often takes the form of fighting against nature, including other people, in order to survive and thrive, rather than flowing with it in order to live harmoniously.

We must also admire the powerful transformations of consciousness that can occur when the biochemistry of particular plants or animals is introduced to our nervous systems. Some of these chemicals are powerful catalysts which have the potential to reveal, sometimes in one session, that which may take years or a lifetime to discover by other means. This is not to say such 'other means' are without value, for in many ways they are ultimately more valuable, as using them can establish a self-discipline that may be difficult to achieve with psychedelics alone. Such practices are also discussed in this book. However, the psychedelics enable glimpses of facets of reality undreamt of, which can provide the impetus and foundation for a journey of healing and rediscovery that would not have otherwise come about. [I use the term 'rediscovery' because for many people, wisdom or revelations perceived in such altered states often may have the strange feeling of being things we once 'knew' but had long-forgotten.] Through befriending these life-forms, as well as through respectfully utilising their biochemicals and our own, we access a vast reservoir of learning that can not be found in any text book. In doing this, we also take the first steps in re-establishing our long-lost relationship with the planet that gives us life. It seems generally accurate to observe that people who consume psychedelics may frequently develop an increased empathy with the earth and its inhabitants, become active in attempting to protect and nurture our environment, and begin making positive contributions to society [or at least to their own mental/spiritual wellbeing] where before they did not.

It is seldom remembered that we depend on plants and other forms of life for our very survival. Without them, we would ultimately have no food, no water, no oxygen, no consciousness, no life – let alone the inspiration that can derive from a living being beholding natural beauty. With that fact in mind, it may seem a little less alien to adopt such a close relationship with other organisms, especially plants, which many people do not appear to even think of as being living things, let along possessing consciousness. I am not claiming that plants necessarily have a consciousness like our own, but I do believe plants to have their own kind of consciousness equally as 'real' as our own. Given the debt we owe them for our existence, it seems only fitting that we respect and try to learn from them with open hearts and minds.

Few people will openly admit, even to themselves, that most of us experience spontaneous alterations in consciousness in the course of our everyday lives, however subtle. It may be that we seldom pay them much attention simply because they are such a common part of life. These changes may be triggered by external causes, such as the occurrence of a traumatic or joyous event. They may be linked to inward emotional processes not directly related to the above. They may even seem to be truly spontaneous, occurring for no discernable reason. This is without even mentioning the states experienced semi-consciously during the different stages of sleep. We are constantly driven to alter our consciousness in ways that we find desirable and/or useful, rather than remaining at the mercy of pre-programmed or involuntary hormonal and neuronal reactions. For example, if we feel sad, upset or confused, we will usually try to find ways to feel happy, content, and in greater control of our thoughts. If needing to concentrate on a difficult problem and find solutions, and experiencing difficulty in doing so, we will usually try to find ways to sharpen our focus and/or broaden and add greater depth to our modes of thought. The psychotherapeutic ingestion of psychoactive plants and other substances, or the practice of exercises designed to alter consciousness are not recent or exceptional phenomena (see also Weil 1972). Drug prohibition on such a wide scale as we see today, *is* a very recent phenomenon.

If used wisely, the access of altered states of consciousness at will can be a highly useful tool for expanding awareness, or directing awareness into areas usually ignored. This is not to say expanding awareness is always as simple as ingesting a given substance. Some people display the ability to consume psychedelics repeatedly simply for enjoyment, and never experience any lasting insight. Others appear totally [or at least relatively] immune to the effects of some such substances. The successful application of altered states requires good health, hard work, dedication and purpose. It is an intention of this book to discuss the use of such plants, animal secretions and natural techniques in an overall holistic approach to life, rather than as relatively shallow recreation [which, in itself, is not without value]. Although this book carries a strong emphasis on the potential values of natural psychedelics, other natural substances which affect consciousness in more subtle ways are also discussed.

We will explore a great variety of substances with differing effects, some of which may overlap qualitatively. To outline these briefly, I will attempt a basic categorisation. Starting at the lower end of the spectrum, some substances produce an effect that may be called sedative – also included here are narcotics, soporifics, depressants, tranquillisers and hypnotics [consult the *Glossary* for definitions]. In moderate doses these substances can be very useful in facilitating meditation or trance, by relaxing the body and mind. They can help to calm the straying thoughts and fidgeting that often prevent a beneficial altered state from occurring. Stimulants can conversely help one to stay awake during meditation sessions that are long and arduous. During such sessions, exhaustion and mental relaxation may reach a point where sleep comes at an inappropriate time. Euphoriants can help one reach a state of 'ekstasis' where sudden realisations often occur, or may be used to reverse severe depressions. Aphrodisiacs may encompass different permutations of sedative, stimulant and/or euphoriant effects, and can be of use in instances where enhancement of sexual union is approached as a means towards illumination [i.e. tantric yoga]. Psychedelics [see also hallucinogen, entheogen, psychoptic, visionary in *Glossary*] are undoubtedly the most useful of all. Their potential beneficial uses have been briefly mentioned above, and are further discussed in the chapter *A Primer in Tripping*. Their properties and potential applications are particularly plastic, allowing access to the subconscious mind and indescribable states of reality. They have a strong history of successful use in

problem-solving, especially in cases where conventional means have been inadequate. Their potential for catalysing positive personal growth is vast, if the person is willing, and should never be underestimated. However, as with all drugs [and other things], they can be dangerous if used carelessly or arrogantly. Psychedelics may also encompass sedative, stimulant, euphoriant and/or aphrodisiac effects. Finally, we have the tonics and 'harmony herbs', or adaptogens, which can help restore physiological and psychological balance within the organism, promoting good health and resistance to stress and infection. Some have mild psychoactivity of their own or in combination with other herbs. Most are extremely non-toxic if used properly. These substances are often of use simply in everyday life, faced with the stresses and pollutions of the modern world. They are invaluable to those using psychoactive substances, which may exhaust the body due to the great energies being channelled, particularly if they have been used to excess, or after a powerful session.

In learning about natural psychoactive substances, it seems most fitting to first approach the ancient cultures worldwide who have worked with altered states of consciousness for thousands of years. It is rarely acknowledged what an important role psychoactive plants appear to have played in the history of our species, and the extent to which they have been [and continue to be] widely used for positive means. Humans have the potential to misuse anything with great power – as has also been done with these plants, when they have been used to influence, dominate, and even kill others. The parallel of 'drug abuse' in our modern societies, where substances are often used excessively and habitually with negative physical, psychological and social effects, is likewise the side often present in the public mind when 'drugs' are mentioned, except only in reference to illegal drugs. The official stance of the last hundred years or so has been that *any* use of illegal drugs is 'drug abuse'. This tendency to categorise all psychoactive substances into one group – or two, legal and illegal – is the major barrier towards a wider understanding of the fact that many psychoactive substances can be therapeutic and highly positive in their influence if used wisely. However, few people in our societies know how to use any drug wisely.

So we turn to the shamans of indigenous cultures, the original experts in the use of psychoactive plants and altered states. Yet we must first understand that shamanism is and has been practiced in a much wider context than that of simple consciousness-alteration. The states experienced by the shaman encompass a vast array of unlimited potentials which relate to all aspects of life, and particularly integrate a sense of spirituality or cosmic and sub-molecular awareness which bond the tribal group with each other and their surroundings, aiding psychological survival, increasing the quality of life-experience, and increasing possibility of physical survival via learned enhancement of perceptual, intellectual and physical skills (see also Fericgla 1995). This is not to say that all indigenous peoples of the world are necessarily enlightened angels as a result – simply that many such groups of people have learned to use 'shamanic technologies' in ways that are beneficial [rather than harmful or neutral in effect] to the group as a whole.

The shamans were/are often the 'doctors' and 'politicians' of the tribal group, resolving problems medical and psychological, as well as divining for information on other matters and settling disputes. Through access to 'spirit realms', as they are often called, via alteration of consciousness, shamans may acquire and master an impressive field of esoteric knowledge that constitutes the science with which they perform their duties and explorations (see Narby 1999). They are respected members of the group and considered wise because of the relative success of their cures and advice. Shamans are usually selected when young, if they show an unusual degree of potential in this field; sometimes the responsibility is simply passed on down family lines. In some groups, almost everyone is a shaman. Extended life-threatening sickness and/or insanity early in life are often deemed as good indications of a shamanic future. Whatever the origin, the 'apprentice' shaman is taken under the tutelage of an elder shaman and trained or initiated over many years in the shamanic practices of the group, encompassing also local mythologies and spiritual beliefs. They may be kept in isolation from the group for long periods, acquiring knowledge and undergoing tests in the wilderness. A notable feature of the lives of many native North Americans has been the vision quest, which involves retreating to a remote and secluded 'power spot' (a geographic location deemed to be particularly well-endowed with cosmic energies) for days with no food. This ordeal usually culminates in a vision or series of visions which may give the seeker useful and inspiring relevant information, and aid in development of connections with the 'spirit' realms [see also *Influencing Endogenous Chemistry*]. The years of initiation usually involve a combination of instruction from the elders in ritual, secret knowledge, medicinal plants etc., keeping of special diets [see *A Primer in Tripping*], abstaining from sexual contact, practicing meditation, undergoing ascetic ordeals or tests [see *Influencing Endogenous Chemistry*], consumption of different psychoactive substances of increasing degrees of potency and intensity, and learning of other means of altering consciousness and healing. These are practiced until the apprentice has gained a working relationship with a wide array of plants and mental states, and can use them positively and effectively in relation to this 'earthly' reality, which is often not seen as separate to other 'realities'. It is these means by which shamans cure the sick and produce correct divinations on matters, skills usually largely taught by the plants themselves. Much time is often spent developing empathy, recognition and communication with different plants, which are usually seen as entities in their own right. The spirit of the plant is communed with by ingesting it, or by simply living in its presence for a period of time. Shamans are often 'told' or 'shown' by the plant spirits which plant to pick from the environs to treat a specific disorder, and the prescription is usually effective (for more on these last points see also Bear & Vasquez 2000; Luna 1984).

Often, all boys at a certain age [rarely girls, it seems] are initiated in a briefer and less intense version of the above, to transit them into full 'adulthood' and to show them 'the way to live'. On other occasions, it is usually only the shaman who ingests the more potent plants, but sometimes the plants are consulted by all or any in need of guidance. More rarely, they are used almost casually, though this usually refers only to the less mind-altering substances [e.g. tobacco (**Nicotiana**), coca (**Erythroxylum**), coffee (**Coffea**), betel nut (**Areca**)]. A notable exception is the casual use of visionary snuffs, which has often been observed in some parts of S. America [see **Anadenanthera** and **Virola**] amongst tribal groups such as the Yanomamo.

Along the way, we can also learn from some of the ancient healing arts, such as those which constitute Traditional Chinese Medicine [TCM], and the Ayurvedic system from India, which have evolved over thousands of years of self-experimentation, trial and error, and practical observation of the properties and effects of many varied natural products, consumed both alone and in complex combinations. The effectiveness of these systems in treating health disorders speaks for itself, yet they have only recently gained acknowledgement and acceptance in the west as 'real' medical practices. Up until perhaps 10 years ago, herbal medicine and most other natural therapies were widely considered to be 'quackery', and many in our societies are still stuck in this erroneous belief [though exaggerated claims of efficacy often abound when such therapies encompass a financial interest]. Such methods invariably involve a holistic approach to health, and as such, TCM and Ayurvedic practitioners have become masters of restoring harmony in the organism – encompassing mental as well as physical health, in acknowledgement of the dynamic interplay that all the organs [divided into 'meridians' in TCM] and subtle energies of the body exist in. That is to say, a disorder in one part of the body may cause other organs to dysfunction; and conversely, a disorder in one part of the body may be indirectly caused by a disorder or imbalance in another part. Psychological disorders can also manifest physically, and vice versa.

Throughout our history, cultures have existed almost worldwide who employed psychoactive substances from nature to experience other aspects of reality, and to help propel their lives in positive directions. Today, few of these cultures have survived, due largely to the corrupting and genocidal influences of 'western civilisation' and the accompanying puritanical demonisation of the use of most psychoactive plants. We will quickly span the globe to gain an impression of the diversity in psychoactive plant useage, discussed in more detail throughout the book.

The Australian Aborigines, probably the oldest surviving group of indigenous cultures, are also amongst the least-known when it comes to shamanic plant useage. This much-abused racial grouping is comprised of many separate tribal clans with their own languages, beliefs, and social structures. Unfortunately, this is usually not recognised as such, and 'Aborigines' or 'Aboriginals' are often mistakenly thought of as a single, uniform culture. Due to the fact that 'aboriginal' does not necessarily refer to the Australians, I have chosen to use the term 'indigenous Australian' in the remainder of the text, where the names of relevant tribal groups are not known to me. [The same general rule will be used in other cases where inappropriate epithets have been the norm, such as the use of 'Indian' to refer to indigenous people of the Americas.] Some groups used various herbal preparations such as those known as 'pituri' [see **Duboisia** and **Nicotiana**], as well as meditational and 'magic' shamanic techniques, to enter the dreaming – a timeless and 'mythical' aspect of reality where both helpful and harmful entities may be encountered, as in all classical shamanic states. Other plant substances with psychoactive properties far greater than those of pituri have been used shamanically, but their details are kept secretive from outsiders (pers. comms.), and are probably only known by a few of the remaining shamans.

North of Australia, the inhabitants of Papua New Guinea [PNG] have used a vast array of plants with reputed 'intoxicating' properties, in ritual applications encompassing most aspects of life. Many are still unidentified botanically, or unknown to us entirely, and this area still bears plenty of fertile ground for exploration. It has been little penetrated in a thorough sense, due to fear of the reputedly aggressive culture of many of the jungle inhabitants, coupled with near inaccessible terrain. See, for example, **Galbulimima**, **Homalomena**, **Kaempferia/Alpinia**, **Castanopsis** and **Boletus**.

Inhabitants of the Pacific Islands and Pacific s.e. Asia make regular use of 'kava' [see **Piper 2**] and 'betel nut' [see **Areca**]. **Psilocybe** and **Panaeolus** mushrooms are often found on sale for tourists, though apparently the locals rarely indulge, and a traditional useage of the fungi in these areas is not known of. It has been suggested from analysis of remnant ritualistic art that the original inhabitants of Easter Island [Polynesia] used **Datura** and psychoactive mushrooms (Claypool 1977).

The rest of southern Asia is home to such familiar substances as the 'opium poppy' [see **Papaver**] and **Cannabis**, two plants with an ancient history of human cultivation, thought to date further back than cultivated food plants. It has been suggested that agriculture began as a result of knowledge gained from centuries of learning how to successfully cultivate drug plants, these two in particular. Some interesting obscurities such as 'kratom' [see **Mitragyna**] are in use today in some parts of s.e. Asia, of which the history of human use is less clear. China is traditionally known to have a repressive attitude towards intoxication, though in some periods of Chinese history this has not been the common case. Intoxicating properties of many of their medicinal herbs taken in excess are known [e.g. **Caesalpinia**, **Ephedra**, **Nelumbo**, **Peucedanum**], and early Taoists and Buddhists experimented a great deal with the properties of natural substances.

Such a keen attitude towards experimentation also accompanied the early practitioners of Ayurvedic medicine in India. Here, the Hindu religion was originally based on inspirations received from the mysterious 'soma', which is only used today in the form of non-psychoactive or weakly active substitutes. Its original identity has been proposed to have been, amongst many other suggestions, **Ephedra** spp., **Peganum** harmala [unlikely candidates alone], **Nelumbo** nucifera, **Amanita** muscaria or possibly a species of **Psilocybe** mushroom. Of all proposed to date, the most convincing arguments put forth have been in favour of **Amanita** muscaria, though not all agree with this, and the matter is still thoroughly in dispute. However, it may be that soma was never one plant, but referred broadly to plants that could bring one into contact with the divine, as well as to the state itself. The word has also been applied by some to pineal secretions [see *Neurochemistry*, *Influencing Endogenous Chemistry*] from a person in an 'enlightened' state, generally in association with yogic practices. Indeed, yoga itself is thought to have arisen from knowledge gained through early ingestion of psychoactive plants, and as an attempt to reach those same states of consciousness without the use of the plants. An array of Indian plants are recognised as having some of the virtues of soma, or to be 'rich in soma juice' – including **Cannabis** and **Desmodium**. This is interesting in light of the variety of psychoactive chemicals found in some **Desmodium** species, which are also found in the mammalian nervous system! Ritualised use of psychoactive substances is mainly confined to saddhus and aghoris, the ascetic 'monks' or sages of Hindu society, who have made use of **Cannabis**, **Datura**, 'nutmeg' [see **Myristica**] and even the cobra [see **Naja**]!

In west Asia and the Middle East, 'haoma', which may or may not have been identical to soma, was the inspirational plant central to the Zoroastrians, though its use is no longer observed, or even its existence as a real substance acknowledged. It has again been claimed to be referable to **Peganum**, which is widely used in this part of the world. **Cannabis**, 'khat' [see **Catha**] and 'opium' from **Papaver** are also popular substances in these areas. Africa has a vast tradition of plant useage, and **Cannabis** is much used there, though its date of introduction is unclear. It is the home of 'iboga' [see **Tabernanthe**], 'yohimbe' [see **Corynanthe**], **Sceletium** and **Leonotis**, as well as many more obscure plants. **Panaeolus** and other mushrooms are now thought to have been once more widely used in religious practices here, beginning at least 9,000-7,000BC in north Africa, when the land there was more fertile (Samorini 1992; Walters 1995-1996). Egyptian mummies, dating from 1070BC-395AD, have raised confusion due to the finding of minute though significant traces of *THC*, *nicotine* and *cocaine* in the hair, bone and soft tissue, clear pointers to the consumption of these drugs (Balabanova et al. 1992). Currently, no *cocaine*-containing plants are known from the area, being confined to South America [see **Erythroxylum**], and tobacco [see **Nicotiana**], the best-known and richest source of *nicotine*, is also generally considered a contribution of the Americas. Could there have been ancient trade-links, or lost plant species present to explain these discrepancies?

The early Christians may possibly have used psychoactive mushrooms, as suggested by some examples of Christian art in frescos and architecture (Fabbro 1999; Samorini 1998) and some interpretations of historical texts (Allegro 1970). However, Allegro's speculations are widely accepted as leaping beyond the available evidence, and Samorini's scholarly observations make no assumptive claims. The 'manna' of the bible has been proposed to have been 'ergot' [see **Claviceps**], or at the very least, another powerfully-psychoactive substance, by researcher Dan Merkur [see his books 'The Mystery of Manna' (1999) and 'The Psychedelic Sacrament: Manna, Meditation, and Mystical Experience' (2000), both from Park Street Press, which unfortunately, I have not read yet]. It is not unlikely that early Christian teachings, particularly of those sects driven underground, such as the Essenes, were originally derived from insights gained through the use of psychoactive plants. Even if this was not the case, it is clear that they had access to the same kind of knowledge through some means of consciousness exploration.

Russia and Siberia have a sparser environment with less potential for psychoactivity, though plants that have been used include **Lagochilus**, **Ledum** and **Amanita** muscaria, the latter widely so. Extending into Europe, records of shamanic plant use are now scarce or non-existent. 'Pagan' cultures once flourished across Europe, though with the advent of Christianity as a major force there, most such groups were extinguished or repressed failing conversion to the new form of Christianity. Knowledge of plant and animal properties became a dangerous asset, as such knowledge could cause a person to be considered a witch. As a result of this, herbalists and 'magicians' alike learned to work in secret, and often lived secluded in wilderness. Plants and creatures known to have been used by European 'witches' include **Datura**, 'darnel' [see **Lolium**], **Hyoscyamus**, **Amanita** muscaria and toads [**Bufo**]. Intoxicating plants, such as **Hyoscyamus** and **Laurus**, have been thought by some to have been used at the Oracle of Delphi in ancient Greece [see **Laurus** for discussion of modern theories]. These, and many related substances, were used more casually by the Greeks, Romans and other cultures, diluted in beers and wines [see *Methods of Ingestion*]. Ergot [see **Claviceps**] has been suggested to have been the basis for the 'kykeon' potion consumed at the Greater Mysteries of Eleusis, an initiation which many famed philosophers are known to have undergone. Psychoactive plants such as **Amanita** muscaria, **Ferula**, **Datura**, 'mistletoe' [Viscum spp. and others], 'wolfsbane' [Aconitum spp.] and 'larkspur' [Delphinium spp.] [see *Endnotes* and *Methods of Ingestion*] frequently play integral roles in the interpretation of many Greek myths (Heinrich et al. 1999a, 1999b; Ruck & Staples 1999).

Celtic shamans, including druids and bards, of Britain and Europe were likewise driven underground in the advent of Christianity, and their more esoteric plant practices are practically unknown today. Reclusive and secretive witches, wizards and sorcerers, many of whom may have simply been herbalists or alchemists rather than spell-casting diabolists, later became keepers of some of this local knowledge of natural substances and their magical use. The druids used mistletoe [only that growing on oak; see *Endnotes*] and many mildly psychoactive herbs [such as **Anthemis**, **Scutellaria**, **Verbena** etc.], but may have used **Amanita** muscaria and **Psilocybe** mushrooms also. It is now thought that 'smoking cults' were common in more ancient times across Europe, making use of plants such as **Hyoscyamus**, **Cannabis** and **Papaver**. These were apparently superseded by the 'drinking cults' [who made use of alcoholic beverages fortified with psychoactive herbs], better known today as a component of early European history (see Rudgley 1995). Scandinavian peoples of the Viking tradition used a number of plants to help induce their pre-battle 'berserker' state of rage, as well as in feasts and celebrations, diluted in beer, such as **Ledum** and possibly also **Amanita** muscaria and **Psilocybe** mushrooms (for clues to the latter, see also Kaplan 1975).

The 'Eskimos' [Inuit and other groups] apparently had little or no psychoactive plant useage, due to the barrenness of their surroundings. The conditions in their part of the world are so extreme, it would be expected that some kind of altered state would result in daily life, without encouragement from psychoactive substances. There are some obscure examples, however [eg. see **Oplopanax**]. Travelling south in the Americas, we encounter the use of **Amanita** muscaria again, as well as **Datura**, tobacco [see **Nicotiana**] and a wide array of psychoactive smoking mixtures, collectively called 'kinnikinnick' in some areas [eg. see **Arctostaphylos**, **Eriogonum** and **Artemisia**]. Further south, into Mexico and other countries of Central America, brings us to the home of the ancient Aztecs, Mayans and other cultures, who dwelled in a virtual garden of delights [and horrors!] of psychoactive substances. Between them, these cultures made extensive use of medicinal and psychoactive plants, such as 'balché' [see **Lonchocarpus**], tobacco, **Psilocybe** mushrooms, 'peyote' [see **Lophophora**], 'morning glory' [see **Ipomoea** and **Turbina**], and **Datura**. The barbaric behaviour of the Aztecs in regards to ritual human sacrifice [some current belief has it that the Mayans probably did not share this practice after all] may draw objection from many, or lead to suggestions of evidence that drug use produces unbalanced minds and evil deeds. However, the possible psychology of culture and circumstance in the matter is a topic beyond the scope of this book [see also *A Primer on Tripping*], and it seems sensible to simply mark this as one probable historic example of the destructive use of drugs and interpretation of visionary states, due to the gory outcome – depending on which ideological tunnel you look through.

This cornucopia of psychotropes continues southward into the Amazon, where 'yajé' or 'ayahuasca' [see **Banisteriopsis**], **Virola**, **Anadenanthera**, tobacco [see **Nicotiana**] and poison arrow frogs [see **Phyllomedusa**] are used, amongst many other substances. The complex pharmacopoeias of the peoples of this large area are noteworthy, though unfortunately they are vanishing. Deforestation, pollution and 'westernisation' of indigenous peoples continue to diminish the extent to which traditional knowledge can be passed on to concurrent generations, whilst 'unknown' plants disappear before they can even be classified. Other parts of South America, such as the Andes, see much use of 'coca' [see

Erythroxylum], **Brugmansia** and **Trichocereus**. The Incas, and cultures before them, made use of these plants, as well as **Anadenanthera**.

Clearly, there is a strong shamanic tradition amongst the human animal – having survived through centuries of oppression and persecution from dominant power structures, only to face being lost entirely in the modern age. It appears, to many people, bad enough that today there is a concerted effort [stemming largely from the U.S., on behalf of the rest of the world] to eliminate 'illegal' psychoactive plants from the face of the earth. As experienced shamans grow old, they now face the difficulty of finding suitable candidates from the younger generation to whom they can pass on their knowledge. The allure of 'western civilisation', and all of its toys and trappings in developing nations is a primary factor in the manifestation of this problem, which might not seem so unjust if indigenous people entering city life were not guaranteed a position at the absolute bottom of the social ladder, not to mention those factors which kill, intimidate or drive indigenous people from their traditional homelands against their will.

It is at this point that we encounter a unique situation in cultural history. 'Westerners' from all walks of life are rejecting the ethics of consumerism, and embracing those of experiential spirituality and grass-roots community. They are seeking that which has for too long been denied to them. Amongst these people are the new shamans, a fact acknowledged and welcomed by many of the 'old school'. That the meeting cultures are totally removed from each other is of little importance. Nor is the lack of contact with an actual shaman to learn from gravely important [although it can certainly help], as their scarcity demands that the new shamans once more learn directly from the plants themselves. It is not the form, but the underlying content that is significant, and this is something that transcends and transforms cultural barriers.

In modern societies, the task of the shaman may require some redefinition, along with the metamorphosis in form. The problems faced by shamans in tribal societies, though not totally removed from our concerns, are often quite different to those met in the modern developed world. Shamans still must go within, and interact in the 'spirit realms' of mind, to reach the source of their healing potential, and inner strength and vision. However, rather than healing solely individuals, they are faced with the greater task of healing humanity as a whole. This process must always start at home to have any lasting effectiveness. Thus, shamans must first heal and transform themselves before they help others. Although many modern self-appointed shamans lack much true ability in their chosen field [admittedly, partly due to the lack of experienced and proficient 'real' shamans to give guidance, and partly due to culturally ingrained traits and beliefs which tend to prevent ease of shamanic efficacy], the modern shamanic/spiritual resurgence is still in its infancy. Hopefully with conscientious practice this art and science may redevelop to the new heights required in these troubled times. I believe we need to take in the accumulated wisdom of human history and create a synthesis which can reunite us in understanding, and carry us beyond the destruction and unhappiness which have followed us around for the last few millennia. It is humbly hoped that this book and its multidisciplinary approach may contribute to the future development of such a synthesis. It should be mentioned that this book is not a manual on how to be a shaman – far from it. This book contains much useful information regarding the chemical technologies involved in shamanic practices. Much can still be learned by the use of these natural technologies without one becoming a 'true' shaman – an undertaking which is extremely difficult for the average westerner without tutelage by a truly talented shaman, and totally altering the way we have been taught to think.

With this current resurgence, we have an opportunity to rediscover our roots, and to guide humanity towards a more harmonious existence – ideally, the whole in equilibrium. Whether we currently realise it or not, the old ways are dying, and we are entering a new, and hopefully improved, chapter in human consciousness. The future of our race, and of the planet, depends on it.

To quote from Paul Hawken (1976. The Magic of Findhorn. p.164. Fontana/Collins) – "Roc [Robert Ogilvie Crombie] sees mankind as enacting the biblical edict to exercise dominion over everything without understanding the spirit of the world. Dominion does not mean to dominate by force, to make things do what you think they *ought* to do. Neither does it mean to force or exploit something, or to distort its impulses for self-gain through manipulation. To have dominion means to understand completely, to have sympathy, to love, to enter into a state of wholeness and perfect harmony with all of creation."

SNU VOOGELBREINDER, 1998

QUESTIONS AND ANSWERS – SOME MISCONCEPTIONS DISCUSSED

The following section has been necessitated by the widespread public ignorance surrounding the nature of 'drugs'. We live with the unfortunate fact that the general public, as well as [in most cases] the officials who claim to be keeping us informed, are actually grossly mis-informed about psychoactive substances, or are knowingly suppressing the dispersal of frank, factual information. Such official figures and institutions tend to use the falsehoods so gained, under the guise of 'drug education' and 'public safety', to persecute and demonise users of illicit drugs, exaggerate and/or falsify potential dangers whilst mentioning positive effects in only the vaguest and most misleading terms [generally making positive effects sound like symptoms of mental and physical illness], and otherwise stifle the sense of need for informed public debate. Some may not even realise they are doing this, blind to the socially- and scientifically-destructive results of such bias. As some who read this book will have come from such a background, this chapter has been prepared in an attempt to inject what I believe to be a more honest perspective into an otherwise publicly clouded issue. Although discussing some drug issues in general, the primary emphasis here is held on plant psychedelics, unless specifically noted otherwise.

Aren't illegal drugs dangerous and addictive substances?

This question alone may be fraught with potholes, as the illegal drugs are clearly not in that legal status because of their relative health risk. If they were, then drugs such as alcohol and tobacco [see **Nicotiana**] would surely be illegal also – these latter substances being known to be just as damaging and addictive, if not more so, than most of the drugs currently prohibited. As a clear example, **Cannabis** ['marijuana'] and *THC* [its main active ingredient] are known to be clinically safer than Aspirin™. Indeed, in 1988 in the US, DEA [Drug Enforcement Administration] judge Francis Young [who was apparently quite conservative], after reviewing all the evidence from both sides of the argument and taking medical testimonies for 15 days, concluded that "marijuana is one of the safest therapeutically active substances known to man." This observation was conveniently ignored, however, as is routinely the case with any finding that makes marijuana appear less than a danger. [For more on this topic, and the roots of the illegalisation of marijuana, see the entry for **Cannabis**.] Known naturally-occurring psychedelics [excluding those plants of the family Solanaceae] have never been shown to be either addictive or physically dangerous in doses that would realistically be consumed, and generally have a very wide margin of safety. Some powerful plants from the Solanaceae such as **Brugmansia** and **Datura** could certainly be said to pose a public health risk, if risk of harm is the real issue, and they have been used in western societies most often by teenagers 'looking for a high'. Yet these plants and their active constituents are not illegal to possess or consume. Also, the effects from plants such as these are frequently unpleasant and frightening, besides being potentially lethal, with a low margin of safety and high risk of death or injury by misadventure. From this, one could conclude that the current drug laws are not intended to protect public health, but to hinder the pursuit of relatively safe and useful types of consciousness-alteration that are not approved of. Rather than protecting anyone, current government attitudes towards such illegal drugs and states of consciousness appear determined to make pursuing them as dangerous as possible by promoting disinformation, fear, uncertainty, and the threat of incarceration. Curiously enough, such 'disapproved' experiences tend to be those that are usually pleasurable, and more importantly, have a tendency to expand processes of thought and perception. Such substances, simply put, also happen to compete successfully with the legal drugs – particularly alcohol – which make fortunes for corporations and governments alike.

While this book was being written, there had been news reports of deaths connected to a new 'anti-smoking' drug that had entered the market. It is strange that totally new chemical creations, whose pharmacological properties and potential side-effects are still relatively barely known, are routinely released for mass consumption after only a short period of human testing, whilst a natural drug such as **Cannabis**, which has been used without much incident as a source of medicine, relaxation and inspiration for thousands of years by an even greater number of people [with NO reported deaths from its use that have any scientific credibility], remains firmly illegal to grow, possess, or consume in almost every corner of the globe, legally stamped as a dangerous drug having 'no therapeutic value'.

Even substances said to be carcinogenic by health authorities sometimes reveal seemingly hidden motives for suppression, upon closer inspection. Essential oil components such as *asarone*, *estragole* and *safrole*, precursors to psychedelic amphetamines, were claimed by the US FDA [Food & Drug Administration] to be carcinogenic and hence unsafe for human consumption, and more or less banned to the public. Essential oils rich in such desired precursor compounds have subsequently become difficult to obtain in some cases [see also **Sassafras**]. Yet the dosages of these chemicals used to reveal carcinogenic activity were greatly incomparable to any degree of realistic human consumption. These compounds were generally applied to test animals daily, often by injection, in massive amounts until tumour growth was induced, rather than giving regular and 'realistic' oral doses, and observing to see if tumours resulted. Humans apparently even lack the enzymes required to metabolise *safrole* into the toxin which is actually believed to be the responsible carcinogen in test rodents [which do contain these enzymes] (Shulgin pers. comm.), although *safrole* itself may still act directly as a carcinogen in high doses. Many common and otherwise innocuous compounds may be carcinogenic in large enough quantities [including ethanol], and in comparison these essential oil components appear to pose relatively little public health risk (eg. see Ames et al. 1987). In any case, most people would never directly ingest essential oils, particularly not in large amounts.

It is also often noted that the effects of whole herbs or crude extracts thereof are usually not equivalent to the effects of purified or selective extracts [such as standardised pills or essential oils], and that toxic effects manifested by one portion of a plant's chemistry may be effectively counteracted by another portion. Hence, it also seems premature to make such judgements on the toxicity of herbs based simply on the ambiguous knowledge surrounding single chemicals in the laboratory [and usually in non-human, non-primate animals or parts of animals], rather than on more empirical, holistic and practical evidence.

Psychedelics cannot logically be illegal simply because of the fact that they are psychoactive, because the three most heavily-consumed legal western 'recreational' drugs [not including Valium™ (*diazepam*) and other pills which are widely abused by 'normal' people of all class-groups, or betel nut (see **Areca**), which is widely used in south-east Asia], *caffeine*, *nicotine* and alcohol, are all psychoactive in different ways, the latter sometimes excessively so [being commonly associated with domestic and social violence, sexual assaults and road fatalities]. However, let's look briefly at each, as on closer inspection they all may be seen to be very suited to mass-consumption in a worker/drone society. *Caffeine* and *nicotine* are short-acting cerebral stimulants, each qualitatively different to the other, ideal for getting started first thing in the morning, and for brief drug-breaks at work. They don't really noticeably alter consciousness very much in low doses, and may actually improve the performance of monotonous or repetitive work. Alcohol acts as a 'social lubricant' in low doses, and produces initial euphoria; at higher doses, it is more intoxicating and can greatly impede cerebral and motor functions, as well as causing nervous system depression [sometimes to the point of death]. In both dose ranges, it is considered ideal for after-work or weekend recreation, to wind down from the busy mode and have some fun. It can also sometimes be a means of social bonding, and reinforcement of the common work-ethic, with after-work drinks and work-parties. In higher doses, which are not officially approved of [but often encouraged in practice], there is even the opportunity for 'proving' machismo or social status by demonstrating the ability to consume more alcohol than anyone else. Generally speaking alcohol does not expand consciousness, either, for the majority of people who consume it. In rare cases where it does, the individual will usually quickly forget whatever revelation it was they had. Rarer still is the person who can use alcohol to open the mind and still remain relatively lucid. Rather, for most people large amounts of it deaden consciousness and keep it at the most base level of awareness. It should be noted that as just hinted there are important exceptions, when alcohol is sometimes consumed by competent shamans in a shamanic setting. In these cases, the power of the shaman is such that the effects of the alcohol are usually not apparent to observers. *Nicotine* is also used in such cultures [in the form of potent tobacco – see **Nicotiana**] but rarely in the extremely tame forms or doses used in 'civilised' societies.

It must also be acknowledged, of course, that due to the widespread social acceptability of these legal drugs, and the mighty influence held by the tobacco and alcohol industries in particular, any move to illegalise or further restrict access to these drugs based on a realistic recognition of their dangers [as would be required if drug prohibition is really necessitated by the dangers of drugs] would be met with the fiercest opposition. Governments know this, as well as being aware of the vast amounts of money they make from these industries, and as a result the anti-drug laws are morally bankrupt, as well as being irrational in every sphere except that of politics.

If you are a member of the rat race with little free time or opportunity to realise your own dreams, these aforementioned drugs seem to be relatively ideal [short of mind-control] for keeping you in acceptance of

that lifestyle. This appears to be because when used in such a socio-political context, and as the major legal options for pursuing consciousness alteration, they can help to limit the possible horizons of any expanding consciousness, and reinforce the common group-notion that "everything is just fine the way we're going". The drugs don't *cause* such a mindset, but can subtly reinforce the mindset already in place when alternatives are denied. Most people do not even think of these substances as drugs, a blanket term used to designate either 'legitimate' medicines or [more often] illicit or illegal substances which affect the mind. *All of these things are drugs*, and it could even be argued that we drug ourselves every time that we eat – and especially, that our brains and bodies are full of natural drugs through every moment of our lives. We are walking drug factories! That this does not appear clear to most people is partly the reason for the lengthy discourse you are now reading. Also, as this book will show, we can rarely find a neat dividing line between drugs of medicinal virtue and drugs which affect the mind – and drugs from both false groupings can be dangerous under some conditions, or quite safe under others.

Psychedelics however, although still drugs, operate on a completely different level to most recreational and/or functional stimulants, sedatives and inebriants. It becomes apparent to anyone who investigates psychedelics seriously and personally [that is, experientially] that rather than deadening or distorting consciousness, or simply producing crude 'intoxication' and/or 'hallucinations', they can actually enliven consciousness and show that other aspects of 'reality' exist in overlap and can offer valid experiences of deep significance. They can offer us a realisation of almost unlimited horizons for expanding our awareness and capabilities. If used wisely, they can help us understand and utilise the concepts of possibility, choice and consequence with more purpose and intelligence, hopefully to work towards a better world for all. As has been said in the *Introduction*, this is certainly not to say that psychedelics are the only route to such ends, but in a time when most people are impatient with gradual change [and indeed, when there may not even be time for us to wait for gradual change] and seem psychologically 'stuck' in repeating unconsciously self-destructive thoughts and actions, they are certainly a powerful and well-needed catalyst, remedy, or if I may repeat from the *Introduction*, a 'wake-up call'. So, it might be said that these drugs are illegal because of their propensity for creating an awareness of truths that engender a moral denial of the authority wielded by current corporate, governmental and most importantly, dominant *human* power structures, and of an entire conditioned form of thinking and living. In other words, psychedelics show people that the Emperor has no clothes, and those with power have gone to great lengths to try to ensure we don't fnd out for ourselves.

Psychedelics offer such potential for expanded awareness of self and its place in the cosmic whole [or even the awareness of no self but the cosmic whole], that those who partake of such drugs subsequently often choose to not remain loyal to a system that stunts their personal growth, the health of society, and of the planet itself. Indeed, they may actually choose to work actively against such a system, hopefully with their hearts and minds rather than with hate and weaponry. Psychedelic drugs, by means of their potential and likely effects, can be seen as a factor diametrically opposed to power structures based at their core on domination, greed, deception, manipulation and the perpetuation of ignorance, and in many cases, the oppression or suppression of those without adequate economic means, who often justifiably hold such anti-establishment sentiments.

Psychedelics cannot reasonably be illegal for creating a public threat – even if many users of psychedelics turn against 'the system' in varying ways, this does not make them terrorists. Most users of psychedelics appear to be overwhelmingly peaceful, intelligent, well-intentioned and otherwise law-abiding citizens [though not, of course, in all cases, as with any group of individuals]. Violence from such people is rare, and generally occurs only with those already predisposed to violence. Incidences of assault and robbery, burglary, and other theft related to illicit drug-users have only significantly been linked to users of 'powders' such as heroin, *cocaine* and *amphetamine*s. Such antisocial behaviour is mostly made possible by the inherent high addictive potential of these drugs, coupled with high price, which is a result of criminalisation. In the long-term, these factors [probably also including neurochemical changes brought about by constant use of such drugs] often appear to motivate a dissolution of the user's moral standards and powers of judgement to the point where they may think nothing of breaking in to their best friend's house to find something to steal and sell, as obtaining the drug becomes virtually all that matters. It should be noted that this is not always the case, as many users of such substances do not necessarily exhibit these behavioural characteristics. These are often people who exercise some degree of control over their habits, possess stable financial means to support same, and make an effort to remain healthy, active and sane. Some people may be geneticall predisposed to addiction/intense habituation, and in such cases the person could perhaps just as easily become addicted to sweets, television, religion, shoplifting, hang-gliding or heroin, depending on individual tastes.

Keeping certain drugs illegal seems to be a profitable game for governments. When examining the relationships between illicit drugs and most governments of the world, the existence of entrenched corruption, and in some cases actual conspiracy to traffick illegal drugs, becomes rather difficult to deny (eg. see De Rienzo et al. 1997; Herer & Jiggins 1995; Lee & Shlain 1992; Shulgin & Shulgin 1997; Stevens 1987). Many incidents have been uncovered and continue to show up in newspapers for all to see, yet the public has a very short memory for the implications of such things and tends to dismiss them as isolated and unusual incidents. The following brief selections are a matter of public record, obtained by researchers through Freedom of Information requests and journalistic investigations.

The CIA is known to have been involved in long-term secret projects – which it is claimed the US Presidents did not even know about – involving the testing of psychoactive drugs [including LSD, *psilocybin*, *mescaline*, and many drugs never tested before on humans] on unsuspecting individuals as well as sometimes themselves, for the purpose of researching processes of brainwashing, hypnosis and other forms of 'mind-control'. Other, non-drug techniques were also explored, however these will not be discussed here. Those involved knew after a while though, from their own experiences, that the psychedelics generally did not leave any real psychological scars, and, if anything, healthy subjects tended to develop a more global, compassionate consciousness, not in keeping with any CIA or national security agenda. Some subjects, however, developed difficulties or committed suicide, due to existing psychological imbalances, or simply due to the fact that subjects did not know they had been given a psychedelic drug, and thus could not rationalise what they were experiencing [actually, recently revealed evidence strongly suggests that the most famous suicide by a CIA LSD-user may have actually been murder, due to his desire to go public about their unethical experiments]. Later, either purposely or inadvertently, factions from the CIA began gradually leaking these drugs, especially LSD, into the mainstream throughout the 1950's and 1960's. The intended purpose of these leaks can only be guessed at. Signs that the experiment [if that is what it was] was getting out of control [or going according to plan?] in the late 1960's might likewise be connected to the sudden increased availability and use of heroin and *methamphetamine* observed near the end of that decade, and the subsequent rise in the level of street crime, incidence of violent revolutionary groups [many of which, it has become known, were apparently put together by the CIA and FBI, or at least infiltrated by their agents and agitators] and apparent dissolution of the 'hippie dream'. [However, these factors could probably have arisen by themselves without covert encouragement, and could be the subject of a lengthy and complex discussion not entirely warranted here.] The CIA and the US military complex have also conducted testing of both psychedelic and 'chemical warfare' compounds on exposed, un-informed US citizens in subway stations, by releasing such substances into the air in gaseous form. We are told such experiments no longer occur, though it is unlikely we would be told about it if they do still take place in any form. Some sources state with conviction that the experiments are no longer taking place as such because they have progressed beyond research and development to the 'operational' level. Only a small portion of information requested, in relation to government-funded 'mind-control' projects, has actually been released to the public, and it is known or at least believed that many of the files in question have been destroyed. If this is all we have been allowed to know in this matter, it is somewhat chilling to imagine what we *haven't* been told. Here we see a historic example of drug-abuse of the highest order.

Police the world over have been and continue to be caught on many occasions dealing in illegal drugs obtained from 'busts', and I have known people who lived in areas where it was common knowledge amongst heroin-users when and where they could buy their drugs from certain members of the local police force. It is also not unknown for seized drugs to be consumed by the officers who seized them. Hardly a year seems to go by without reports of police officers being convicted of selling and/or using illicit drugs, not to mention aiding in their successful importation and distribution. This perhaps pales in comparison with the covert importation of heroin from Indo-China by factions of the US military and CIA during the Vietnam War, the evidence that the CIA introduced cheap 'crack' *cocaine* to predominantly black ghettoes [though there are other stories about who was responsible], or the numerous *cocaine*- and weapons-related dirty dealings by the US Government and military in Latin America.

Evidence strongly suggests that industrial and pharmaceutical giants in the US have, in cooperation with government officials in prominent positions, been involved in suppressing, outlawing and spreading misinformation regarding both **Cannabis** and, to a lesser and more recent extent, *ibogaine* [from the iboga shrub – see **Tabernanthe**]. Closer analysis of these situations reveals that such behaviour appears to be associated not with some desire to help society, but with the fact that these natural plants and drugs compete strongly with products manufactured and endorsed by factions of the above groups, further complicated by the controversial psychoactive properties of these natural substances, and the perceived benefits of prohibition to governments, law enforcement agencies and society in general. These complex allegations have not had the opportunity to be brought up in a court of law [for reasons outlined below], yet are very strongly implied when the available evidence is examined in detail,

especially in the case of **Cannabis**. See the entries for those two plants for more discussion on particulars.

There is the case of *tryptophan*, a popular, cheap and effective antidepressant [a naturally-occurring amino acid, which of course can not be patented], banned shortly before the introduction of Prozac™ [fluoxetine], which subsequently cornered almost the entire antidepressant market. This synthetic drug was also rushed into circulation without the proper long-term testing requirements being met – and many adverse and common side effects have since been reported. *Tryptophan* was supposedly banned due to a string of deaths and other complications traced to impurities in some contaminated batches. The problem was identified and removed, but *tryptophan* is still difficult to obtain except as a minor component of some dietary supplements. Prozac, however, with all its faults, remains a widely prescribed drug for virtually anyone who requests it, despite recent studies showing it to be no more effective than a placebo. Coincidence or conspiracy? [See *Neurochemistry* for more discussion regarding the banning of *tryptophan*.]

Regarding Prozac, this commonly used drug has a mode of action similar in some ways to that of the illegal drug MDMA [3,4-methylenedioxy-*methamphetamine*, a.k.a. 'ecstasy'] and its long-term toxicology is unknown. Although MDMA has been the focus of much government-funded research which has supposedly shown it to be neurotoxic, most if not all of this research has been faulty in terms of unsound scientific methodology and questionable conclusions, such as with **Cannabis**. [Meaningful human data is still sketchy at best, and although apparently quite safe for the majority of consumers, some people advise that MDMA, if used, should be used infrequently and in moderate doses.] In addition, most of the deaths resulting from 'ecstasy' ingestion appear to be related to the dance party environments in which it is often taken [of course in combination with the effects of the drug], interactions with other drugs, or the fact that a pill sold illicitly as 'ecstasy' could and often does contain a variety of sometimes potentially dangerous substances and no MDMA at all. This last factor is another illustration of how drug prohibition can lead to more danger in experimenting with psychoactive drugs, because people don't know what they are getting, or how much. Interestingly, Prozac has not been researched nearly as much as MDMA yet is routinely prescribed to an increasingly large portion of the population, despite much evidence that it can produce drastic behavioural side effects (see Concar 2002).

The current recognition of the anti-scientific effects of industry sponsoring research brings into doubt the true state of knowledge regarding many new drugs. "Academic researchers backed by biomedical companies are much more likely to produce pro-industry findings than are independent groups... industry-backed studies are much more likely to compare drugs with placebos or poorly chosen drugs rather than the best competitor, boosting the chances of getting positive results" (Matthews 2003). Some recent studies claiming a range of natural remedies to be ineffective often have such a bias at their core, as well as using selective and often ill-informed logic to support their claims – the presumed motive being to suggest the superiority of various new synthetic drugs and of 'conventional medicine', and reduce demand for 'alternative therapies' and competing natural products which can not be patented [and are thus far less profitable]. Often the test methods devised are simply inappropriate for evaluating the activity [or lack of activity] of medicinal plants or other natural remedies, and are likewise slanted to give the best chances for a synthetic product to display its positive effects. Once such reports find their way to mainstream media, the distorting powers of journalists [who often do not appear to understand what they are reading in the case of scientific or 'scientific' papers, and simply accept and repeat the gross points from the conclusion or abstract, usually spliced with a sensationalist spin] ensure that what most people may read or hear about regarding such matters is already a distortion of a distortion. The same goes for government-sponsored research into illegal psychoactive drugs.

Consider also in Australia, the recent case of kava [see **Piper 2**] becoming regulated, and the herb stripped from the market, to be replaced almost immediately by pharmaceutical extracts in over-the-counter form. Most people familiar with the herb itself agree that these extracts are weak and produce inferior effects, compared to good quality, properly prepared kava. The excuse for legal regulation given at the time was a vague reference to kava-abuse by some groups of indigenous people in northern Australia, in which case it had been serving as a substitute for alcohol. Hardly a situation demanding of such drastic national measures, especially as many people can't stand the taste of the kava beverage, and that with moderate use it is quite safe. The current domination of most of the global commercial kava supply by pharmaceutical companies has also had the added asocial effect of causing shortages, and driving up the price.

Australian Customs somehow has the power to 'ban' and sometimes burn books found on importation that they deem to be unsuitable [and yes, this power is sometimes exercised]. They apparently have the power to decide what books they want to ban on the spot, without any public banning notification or legal processes. Thus the censorship whims of government employees are currently being casually applied to many factual and rather harmless books on psychedelic substances, and people's experiences with them. This is hardly the kind of thing we associate with living in a free and fair society.

The influential US organisation Partnership for a Drug Free America [PDFA] is sponsored by a long list of influential corporations and 'moral outrage' groups, including alcohol, tobacco and pharmaceutical companies – and one of their stated goals is to foster intolerance of illegal drugs and those who use them. [On a side-note, the PDFA used to be situated at a 666 Third Avenue, but relocated due to negative and embarrassing address-associations brought up regularly at pro-**Cannabis** rallies – though their parent organisation, an advertising corporation, has remained at that address.] They are notorious for spreading misinformation and outright fabrications regarding the dangers and effects of illicit drugs, with a strong bias against **Cannabis**. When 'caught' lying, they have failed to offer retractions or corrections to the public, or to anyone else, yet continue to be a respected institution. It is an unfortunate fact also, that groups attempting to approach governments to discuss these issues, with view to possible law reform, are blatantly ignored and treated as though their concerns and opinions were irrelevant or ridiculous. Public opinion has been so successfully shaped by selective misinformation that it still appears relatively easy to ensure that reform of drug laws is not seen as an important enough issue to even consider putting into action. Most 'anti-drug' groups, which are almost invariably backed and fostered by governments, consistently refuse to have public debate with **Cannabis**- or other drug-legalisation groups, and sometimes mockingly and falsely accuse them of the same cowardice [easier for them to do and be heard, as drug law reform activists do not have a voice in mainstream media – except perhaps in some of the more egalitarian and liberal nations of Europe]. Why shy away from open discussion, unless they know their arguments will not stand up to open scrutiny? [And I don't mean the *Donahue*-type scrutiny many people seem to prefer when it comes to examining controversial issues!]

It is next to impossible to even bring many of these allegations of mass-corruption to court. When the wrong-doers are protected by a wall of wealth, influence and/or government secrecy, such charges simply are not taken seriously, without the evidence even being considered. Also, such cases will usually not even be heard unless they can be raised in conjunction with a relevant case that is already pending hearing. Even then, almost no judge will pass a verdict that could effectively end their career by displeasing powerful people, and the few who might have the courage to do otherwise [if available facts seemed to call for it] would not be likely to be allowed near such a case in the first place. Few people are able to raise the kind of money needed to carry such complex issues thoroughly through the legal system, and again, economics fall in the way of justice. This is particularly mirrored in the case of asset-seizure from 'suspected' drug-traffickers, as practiced rampantly in the US and recently adopted on a more realistic scale in Australia, where there is strong potential for the greed of financial gain in underpaid police forces to override the fair balance of justice. What is needed to constitute 'suspicion' of being involved in trafficking illegal drugs is a very grey area, open to much subjective plasticity and amazingly, sometimes not requiring definitive proof. In some documented cases it is known that drugs have been planted in order to obtain an asset-seizure. Even if the defendant is subsequently not proven to be guilty of any crime their seized assets [which usually include cash, house, land, and all other possessions of value], unbelievably, are often not returned. Examples such as these make our democracies appear, in part, closer to dictatorships when it comes to drugs and money. Of course, many police and government officials are honest and would not knowingly take part in the corruption of justice; however, few would deny that their dishonest counterparts are numerous and powerful.

So, the supposed reasons for the prohibition of certain drugs and plants seem pretty flimsy and full of hypocrisy. Reducing harm hardly seems to be a top priority. What, then, does it mean to say something is dangerous and addictive? Addiction can conceivably result from anything that provides some degree of pleasure and becomes part of one's routine – which, as mentioned above, can range from eating sweets, to driving fast, to sex, to science-fiction novels, to smoking crack [which is, admittedly, much more addictive than most other fun things you might do]. If the routine can not be broken without strong cravings and some kind of noteworthy physical/psychological withdrawal symptoms taking place, then for that person in those circumstances the routine had become an addiction. In an extreme sense, it could be argued that we are all addicted to food and water! It is important to know that there can be many types of 'addiction', and that whilst some addictions can be harmful, some may be benign or even necessary. Psychedelics are not addictive [if anything, the more strongly-acting ones have the opposite effect], although anti-drug crusaders sometimes choose to believe that they are – because some people like the experience and choose to do it again! Of course, the same logic could be applied to anything that people may do more than once because they liked it the first time. **Cannabis** can be strongly habituating over time, particularly when smoked with tobacco, but is not [pharmacologically-speaking] addictive; that is, psychological symptoms of addiction may be observed if a regular supply is interrupted [mostly mild craving and some irritability – more so if smoking with tobacco], but physical

symptoms of addiction are absent. Tobacco [containing *nicotine*] and alcohol [ethanol] are addictive in all senses of the word [as are *caffeine*, heroin, *methamphetamine* and *cocaine*], although some people fare better than others in using these drugs but apparently avoiding addiction.

What, then, is dangerous? Contrary to what anti-drug propagandists would prefer us to think, anything is potentially dangerous or even deadly at a high enough dose or when used under appropriate [rather, inappropriate] conditions. Drinking enough water can kill you, though it may take a concerted effort to consume that much in a short enough time [presuming that you're not dancing all night in a hot, crowded nightclub after having taken some purported MDMA]. Many people die each year from overdosing on prescribed or over-the-counter chemicals – sometimes from a normal dose – which are approved for use; these deaths far outnumber those resulting from illegal drugs. Illegal drugs [a term which, along with the terms of more technical legal classifications, generally implies that they have no known or possible medical usefulness – often blatantly false] are not approved and said to be more dangerous, but the psychedelics [ie. **Cannabis**, **Psilocybe** mushrooms, **Lophophora**, **Banisteriopsis**, **Salvia**] have a wide 'therapeutic window' of safety, it being practically impossible to overdose to the point of injury. For matters of psychological safety, see below. Heroin, *amphetamine*s and *cocaine* can be physically dangerous in dose ranges not far removed from the normal 'recreational' dose [especially allowing for the sometimes surprising individual hypersensitivities that may be observed in some people who try such drugs]. For these substances the arguments become even more complex, but that is also the case with **Nicotiana** [tobacco] and alcohol, on the other side of the legal fence. However, street drugs like heroin, *amphetamine* and *cocaine* do not really concern the intentions of this book, though the occurrence of *amphetamine*s [in doubt] and *cocaine* in some plants is discussed [see **Acacia** and **Erythroxylum**].

Still, though, people are afraid of psychedelics – a fear probably rooted mostly in some of the following – a) negative media and government propaganda, b) stereotyped thoughts of 'crazy, spaced-out hippies and drug freaks' as a threat to the safety and wellbeing of all 'decent people', (c) personal bad experiences due to using psychedelics in inappropriate ways, and (d) fear of the unknown or 'occult'. For more on this line of thought, see both the section below and the *Primer on Tripping*.

The debate on the legal status of psychedelic drugs can be expounded over many more pages, but has been done admirably elsewhere (particularly see Forte ed. 1997; Ott 1993, 1997; and Shulgin & Shulgin 1997). We end this section with a suitable quote from Stuart Mill's 1859 essay "On Liberty" -

"The only purpose for which power can be rightfully exercised over any member of a civilised community, against his will, is to prevent harm to others. His own good, either physical or moral, is not sufficient warrant."

Can't psychedelic drugs make you go insane?

Again we enter some turbulent waters, as there is no concrete definition of what constitutes insanity, and definitions of sanity can sometimes seem to define a common kind of insanity or collective mental disorder, when analysed in detail. To make matters worse, most psychiatrists and/or psychologists appear to have little or no real understanding of the mental conditions in which their patients may mostly reside. Schizophrenia, for example, is defined by a wide array of symptoms which can not be consistently diagnosed or defined as one specific disorder, yet many psychiatrists still act as though they know what it is. Their inability, in many cases, to understand the mental state of the patient, and the heavy reliance on 'antipsychotic' medications [which usually make matters worse in the long run, and may substitute one psychic aberration for another] are reflected in both the largely unsuccessful results of treatment (see also Farber 1993 and Mender 1994) and the rising incidence of such disorders, which may also be very much a mental reaction to these troubled and hectic times. It should fairly be stated, however, that some people with serious mental disorders may need to rely on psychiatric medication to abate their symptoms, as little else seems to help make their lives liveable. Regardless, such medications should not be regarded as cures, or even necessarily as therapeutic in the long run.

I feel, as do many others, that for such scientists to experience a variety of psychedelic states themselves is probably the only way in which they could relatively safely hope to gain a greater insight to the conditions of their patients. The two broadly conceived states, 'insanity' and 'psychedelic inebriation', bear many similarities in the short term, and parallel many of the symptoms experienced as schizophrenia. This does not really mean that to ingest a psychedelic is to go insane. It means that such ingestion can allow the individual to access some of the same realms but with a short-term, reversible nature. There is also the important difference of knowing that one has ingested a powerful drug, which can lend a greater sense of security to the experience. People with mental disorders are usually either born that way, or the characteristics develop during the first 20 years or so of life. The long-term exposure to such 'abnormal' phenomena with no backing network of social understanding or acceptance of their implications, often results in what we would call 'insanity'. Negative feedback from the person's family and friends, and sometimes members of the public, only serves to further convince the person of their insanity. They live in a state that they can not rationally comprehend, and are thus forced to adopt unusual belief systems in an attempt to make sense of it all [see *A Primer in Tripping* for more on the influences that can play a part here].

However, some rare individuals are born or develop into this state and show the ability to function within it effectively, as opposed to becoming overwhelmed and confused – in short, although having a radically different experience of 'reality' to most people, being 'mentally well' as opposed to 'mentally ill'. Such people develop a balanced awareness of these phenomena in relation to the world around them, and often devote their energies to healing others and the world, be it directly through shamanic healing, or by more abstract means such as art and spiritual practise. Often such people go through the early years of life struggling with these forces until they gain an understanding – sometimes they are hit with it suddenly at a later point in life. In both cases, the individual's handling of the situation will determine whether the long-term result is relative 'insanity' or 'wisdom'. There are, of course, many points in between...

To return to the original question, I have known a small number of people [including myself] who have managed to temporarily make themselves what some would classify as 'insane' or mentally ill, partially as a result of psychedelic experience(s). In most cases, I believe this result was ultimately mentally self-inflicted. I have observed a common tendency for people to blame the drug, rather than their own deeply-buried psychodramas, when something 'goes wrong' in such a fashion. In the course of a psychedelic experience that seems too strong or disorientating for the user, there come many mental opportunities to just 'give-up', and believe that they have gone mad and will never come down. There may be ample opportunities to get so drawn into believing a possibly delusional idea or series of ideas [see *Primer in Tripping*] that they completely restructure their perceptions and beliefs in such a way that they do not emerge from this self-created 'psychosis' for some time, if ever. In such cases, the outcome is very much reliant on the choices of the person involved. However, it would be unfair not to acknowledge the fact that a fragile psyche may occasionally be shattered by a particularly strong psychedelic experience. Even most people who have taken psychedelic drugs have no idea just how deep these states can go, as few explore deeply enough or for long enough to truly 'have the pants scared off them'. A 'seasoned tripper', confident with some 100 LSD experiences behind him, may still be 'blown away' by a single, ample dose of *DMT*. The power of the mind is vast, and 'reality' seemingly infinite, and this can be a terrifying thing for the unprepared to witness. For some, terrifying enough to traumatise for life. There are also sometimes reports of individuals who have become 'burnt-out', or suffered long-lasting 'LSD-psychoses' due to abuse of psychedelics, and often other drugs as well, including alcohol. People who are already suffering mental problems, or have a family or personal history of them, should probably not use psychedelics, as their existing or underlying symptoms can be exacerbated. As it is possible to induce one's own insanity, it is also possible to heal one's self from these negative states. However, for those genetically predisposed to mental disorders, this may merely mean adapting to circumstances so that one is able to cope [or ideally, to focus the phenomenon and use it constructively], rather than a full elimination of the symptoms.

If someone is undergoing such difficulties in relation to drug experiences, it is advisable for trusted friends to step in and offer some non-dramatic assistance. Usually, all that should be required is personal support and protection from harm in a reassuring atmosphere, until the person returns to stability. In most cases, this will be a very short time. I believe that usually, psychiatric intervention should only be considered as a very last resort [that is, if the effects of the drug have subsided but the person is still in a highly disturbed state more than a week or so later – and if you can't find a proficient shaman]. Being confined to a mental institution is not conducive to good mental health, and counselling from doctors not sympathetic to the real effects of psychedelics is likely to do more harm than good. These things may be even more psychologically harmful or distressing if the patient is still strongly under the effects of the drug. See Strassman (1984, 1995) and *A Primer in Tripping* for further discussion on adverse reactions to psychedelic drugs.

Many otherwise harmless inspired geniuses or eccentrics have been incarcerated in mental institutions, because they could not be understood by psychiatrists or others – or, because someone with enough power wanted them put away as a nut – and thus confined and drugged for purposes of 'public safety'. If we were to closely examine the 'average' person, in most cases we would find them to be crammed full of repressed and/or deeply ingrained neuroses, fears and insecurities. Persons leading a less 'conventional' lifestyle, exhibiting these same traits more openly, may sometimes be handed over to psychiatric 'care' because they appear to represent more of a threat to the norm. This does actually happen [in some countries more than others], though less so now than in the recent

past. Yet the greed, powerlust, backstabbing and inflated egotism of many of the men and women who influence the world economically and politically goes unrecognised as a disease – a severe mental aberration (see Forbes 1992).

So, again we do not have a black-and-white answer. Psychedelic drugs themselves can not make a person insane. They can, however, bring the psyche to a point where 'insanity' can be explored, and some few choose [whether consciously or subconsciously] not to return from it. The choice can be from one moment, or it can grow in conviction over time. Once this choice has been made, it can sometimes be difficult to undo. This is an important reason why the use of psychedelics, or for that matter, any type of psychoactive drug, is ultimately a personal choice, that if undertaken should be with full knowledge of the potential risks involved. When exploring the mind and beyond, one must take full responsibility for the consequences.

Lastly, I stress again that the neurochemistry or genetics of some people are just not cut out to handle psychedelics – they may already be teetering on a fine edge, and a psychedelic drug could be the catalyst that pushes them over unsuspecting. Anyone interested in psychedelics who suspects they may be potentially unstable enough to experience severe difficulty in coping, or who has a previous family or personal history of 'mental disorders', should definitely think twice before actually ingesting anything of that nature. If such a person is still undeterred and curious, it may be advisable to sample a small amount to determine if there might be problems, similar to testing to see if one has an allergy to any substance, before proceeding with caution [but preferably not fear].

Aren't drug users merely escaping into a world of fantasy and delusion?

That is what our governments, and most other people with no direct experience, would have us believe. In contrast, anyone who has seriously investigated psychedelic drugs via personal experimentation will agree that this is certainly not the case. The potential for escapism may appeal to some who approach these substances, but such people usually turn away unsatisfied, or scared out of their wits, because these drugs do not offer escape. In contrast, they tend to amplify reality, and to magnify one's own problems and their causes to the point where they can not be avoided. This is one major reason why psychedelics are used as shamanic sacraments, as well as in some types of psychotherapy. Other, more recreational drugs, may afford some degree of escapism for a while, but if they are used habitually for such means, the walls will eventually come crashing down, so to speak. You can't run away from yourself forever. This is apparently a fact of life [but for some rare exceptions], and this is one reason why I strongly suggest that psychoactive substances be used, if at all, with intelligence and respect.

As to what constitutes delusional fantasy, there can be no completely successful argument that we are not hallucinating all of this right now. Whether or not an idea is a delusion depends largely on the judgements of others, who may be unequipped to do so and simply dismiss it on the basis of 'common sense' [which as will hopefully be shown, appears to be simply another potential delusion]. If common sense was always listened to there would be practically no important breakthroughs in science, or growth in understanding. Indeed, many such leaps initially make mince meat of common sense, and thus human concepts of 'reality' expand once again – not that the every-day person usually finds out about such changes in parameters. The notion of 'common sense' as having any practical meaning suggests that we already know everything, which is clearly not so.

It currently still appears impossible to prove that there is any one true 'reality', or that we can always distinguish which is which. Psychedelics have shown many people how alternate realities can overlap, for example. This is particularly vivid with substances such as *DMT* and *salvinorin A*. People ingesting strong doses of these drugs have been known to enter realities seeming as real or more real than the one most of us consider to be 'consensus reality', or to inhabit more than one plane of reality at the same time, and to exist in them for extended periods [subjectively, even days or longer] before returning to the 'original' reality [after perhaps 10mins 'normal' time, 'objective' time being an illusion anyway], and reverting to a cohesive state of usually more heightened awareness, once the amazement has worn off! This is all due to largely uncomprehended [ie. scientists have observed and named many of the mechanisms, but don't really understand why or how they lead to such incredible subjective effects] and relatively minor adjustments in neurochemistry. The keys, the locks, the doorways, are all present in the human body.

It is particularly in the field of psychedelic exploration that we become aware of how little is known about anything. Anyone who has been keeping up to date with the sciences, including quantum physics and chaos mathematics, will appreciate that the institution of science in general is finally, and perhaps reluctantly, acknowledging that 'reality' is much stranger stuff than most people had thought; the remaining few who were already aware of this being composed largely of shamans, artists, mystics and the insane.

"'Reality' is the composite report of sentries. Eyes see; ears hear; nose smells; tongue tastes; hands touch. Each sends complicated coded messages to the brain, but consciousness receives only simplified summaries. Our reality is illusion: we don't know for sure what's out there" (Frankel & Whitesides 1997). Many animals perceive the world in a very different way to us, yet we do not consider their conscious experiences of sensory data to be illusions or fantasies simply because we can not perceive these things. So it is with psychedelic states, which allow us to perceive things we are normally closed to.

Consider also these interpretations of consciousness and modern physics – "We construct our own individual realities; each individual universe construction also contains an indefinite number of other universes, with all variations and all other possibilities[...]in constantly changing patterns, each individual universe forms all others, and each universe is connected to each other and all others[...]each reality is constantly forming and affecting all other realities beyond time[...]for each of us, an indefinite number of universes exists simultaneously [each universe may be a slight variation of the next one, or may be entirely unrelated][...]the 'ordinary' reality we perceive is not one universe – it is the harmony of phases of movements of an indefinite number of universes[...]there is an indefinite number of harmonies constructing an indefinite number of possibilities" (Toben et al. 1975 – emphasis in original text). 'Reality' may, in one analogy, be viewed as a multidimensional fabric, from which complex harmonic ripples emerge, to form self-organising patterns of perceived matter. This may be the 'veil of illusion' or 'maya' referred to in Hindu religion. I suspect, however, that it's not nearly as simple as that [or so simple that we miss the point entirely!].

Here is a simple and fairly obvious observation to contemplate, regarding the 'reality' of matter. Nothing is really physically solid, since individual particles [ie. electrons, protons, neutrons] are separated by a relatively huge space, though their vibrations and energy fields appear to interact to form a more or less cohesive form, such as a piece of wood. You can hit someone over the head with it, and it will still result in pain and perhaps a wound, but the wood is not solid in the sense that we usually would, according to 'common sense', consider it to be – nor is your unfortunate victim for this experiment, nor even yourself. Even the particles are of questionable solidity, and scientists haven't been able to figure out what these are actually made of. It seems quite amazing that despite these apparent facts we still perceive solidity and form, and that these apparent forms can move or be moved from one space-time coordinate to another without disintegrating. Strange that people can be so doubtful of miracles when closer examination of our universe and our experience of it seems to reveal an enormous bundle of the miraculous that we take for granted!

Also of interest is a condition known as 'Charles Bonnet Syndrome', in which psychologically 'normal' and 'sane' people are known to experience vivid and realistic 'hallucinations', though such persons are usually aware that these are hallucinations. Strangely, only a small proportion of reported cases involve any personal meaning in the visions, whereas so-called 'hallucinations' triggered by psychedelic drugs are often pregnant with personal meaning. The condition has so far mostly been observed in people with poor eyesight or vision defects [such as cataracts], though most such people do not experience symptoms of Charles Bonnet Syndrome (Gold & Rabins 1989; Teunisse et al. 1995, 1996).

Consider some more observations of physics – "There is life in everything – on the submicroscopic level, everything is moving, changing, vibrating, growing, dissipating; [time and space are] not absolute – in a strong gravitational field relative to that of the observer, time goes slower and dimensions contract from the point of view of the observer[...]a particle has no fixed size because gravity distorts space and time[...]mathematicians can describe the limits of space-time, but they can't describe what is beyond – they only know there *is* a beyond[...]every part contains the whole – one electron is all electrons, one particle is all particles" (Toben et al. 1975). This last observation is also suggestive of the holographic concept of reality implied by the brain studies of Karl Pribram, and put forth largely by Pribram and the noted physicist David Bohm. See also McKenna & McKenna (1975), Miller et al. (1990) and Wilber ed. (1985), for in-depth discussions on the details and implications. The basic idea relates to a well-known property of holograms – that if broken, one fragment is observed to contain the information constituting the whole image. As the old saying goes, "all is one"! This has become such a cliché in modern times that many people seem able to repeat it without even thinking about what it might mean.

So, who can even really say at this point what reality 'is'? What exactly are 'fantasy' and 'delusion' when dealing with things practically no one really understands? It is noteworthy that people using psychedelics purposefully, or people dreaming, have been able to access information they otherwise could not have known, but which, upon later research and verification, turns out to be accurate. Due to the spontaneous and often secretive nature of most such occurrences [at least partially due to legal complica-

tions, with many of these drugs being prohibited substances in most countries], this is rarely witnessed by 'authorities' with any capacity to judge and report on the validity of such claims, and the majority of such cases go unreported. For reasons of personal privacy, many users of psychedelics would probably prefer it that way. Those who have experienced this [both myself and many others – see also Harman & Fadiman 1966; Masters & Houston 1966; McKenna 1993; Rätsch ed. 1990; Stafford 1992] know beyond a doubt that the potential is there for great learning, as mentioned in the *Introduction*. Forward-thinking psychotherapists and allied researchers were only just beginning to glimpse the vast potential of psychedelic substances for expansion of awareness and successful self-psychoanalysis (eg. see Frederking 1955) before all human research was banned, including personal use [October 6, 1966 in California for LSD and other psychedelics]. Psychedelics can also be of enormous value to artists and the creative process – many great artists have either been directly inspired by the use of psychotropic substances, or by equivalent endogenous spontaneous 'mystic states' [see Grey 1998 for a wonderful insight into this subject]. It has recently been postulated that the 'hallucinations' resulting from ingestion of chemicals or plant preparations [such as *DMT* and ayahuasca – see **Banisteriopsis**] may originate from amplification of 'information transmissions' from the DNA of one's own body and surroundings (Narby 1999). Even though it is a theory which could be difficult to prove or disprove for some time [if ever], if shown to be true, illegalisation of such sacraments and persecution of their users, effectively a violent denial of our connection to all life, would be widely seen to constitute a monumental crime against humanity, one which passes by largely unrecognised. I personally regard this latter point to be the case regardless of whether Narby's eloquent ideas hold true. See also Forte ed. (1997).

For further reading on matters of 'reality', see also Abraham & Shaw (1982-1988), Barbour (1999), Brooks (1999), Brown & Novick ed. (1993), Buchanan (1997), Capra (1983), Chown (1998a, 1998b, 2000), Concar (1998b), Grey (1990, 2001), Hameroff (1994), Harvey (1978), Henbest (1998), Kaku (1994), Murray (1993), Narby (1999), Seife (1998), Spinney (1998), Watson (1973), Weil (1972), Wilber ed. (1985) and Wilson (1977) [practically all works by Robert Anton Wilson are recommended, both 'fiction' and 'non-fiction' (these definitions tend to lose meaning with some of his books)]. Although classified as a science-fiction novel, Heinlein (1961) offers profound insights into human concepts of reality and spirituality, as well as offering some interesting [and, if 'grokked fully', quite mind-blowing] alternatives. Likewise, almost anything by Philip K. Dick is recommended reading in this regard, though too much at once may result in some depression and paranoia!

Aren't shamans and witchdoctors frauds?

No doubt some are, but this should be considered the exception, not the rule. Fraudulent so-called 'shamans' may be found perhaps in greater numbers today than in the past, in areas such as the Amazon, where native and non-native peoples alike, sometimes with little or no background in working with shamanic plants, are cashing in on tourist demand for ayahuasca ceremonies and/or shamanic workshops. There is little room to further explore those points [see also **Banisteriopsis**], so we will return to the original question.

Some shamans who probably do not deserve that status claim to possess abilities beyond their grasp, in order to capitalise on, or to exert influence over, others in a tribal group. The term 'witchdoctor', as often used derisively in 'civilised' lands, is perhaps more suited to describe this kind of person, essentially a 'quack' taking advantage of a flair for showmanship, higher intelligence put to devious ends, and the gullibility of others. Such people generally wouldn't be able to get away with it indefinitely, and when discovered as frauds would have had to flee or face the anger of the tribe. Honest shamans are usually somewhat more modest when it comes to boasting of their prowess, and earn their status because others confer it to them, in recognition of the effectiveness of their advice or healing capabilities. In many cases, though, the means of curing and/or of contacting 'spirit realms' for divine information are not visually or rationally apparent to the unawakened anthropologist, hence the large grounds for doubt of such abilities in the general collective 'western consciousness' [which brings us back to 'common sense']. Indeed, the very methods by which most anthropologists usually operate function to prevent them from ever learning anything substantial about the people whom they are attempting to study [see Narby 1999, for a good discussion of this point]. Quantum physics has something to say about this too, with its recognition of the fact that observers affect that which they are observing, simply by the act of observing with the senses or with instruments.

Shamans may be 'shown' in visions which plants to collect and administer to the sick patient as an effective treatment. If this were not based in some kind of 'reality' then shamans would probably inadvertently kill or harm as many people as they cured. In some cases treatment may also consist of what could be called psychosomatic means [eg. 'sucking out' a malignant spirit from the sick person], which aid in the healing process presumably through deep trust and belief in the shaman's healing powers – presuming, that is, that the shaman does not know something about the nature of illness which we don't, a premature and probably foolish assumption. There is nothing fraudulent about psychosomatic medicine, if it works, and given how little we know, it is unwise to insist that 'unseen forces' do not exert any influence. It is unknown to us whether these methods are truly psychosomatic in function [the mind has a remarkable influence on health – eg. see Rogers et al. 1979], or whether 'real' shamans are actually doing something here we do not comprehend, or [most likely] a combination of the two. At least in the case of healing songs often used by proficient shamans, we know that sound waves can exert physiological effects on different parts of the body, and that music can strongly affect state of mind – especially if the patient is already in an altered state of consciousness. It is now becoming more known that we are capable of directing our body to heal itself, by cultivating and utilising a greater realisation of self-awareness. This was drawn to attention in the western world largely by experimental monitoring of eastern spiritual adepts who can regulate their body temperature, heart rate, brainwaves, pain perception, consciousness and some aspects of physiological morphology at will, aided by meditational practices and focusing consciousness inwards to specific body parts or organs (eg. see Anand et al. 1961; Das & Gastaut 1957; Kasamatsu & Hirai 1963; Wenger et al. 1961; Yatri 1988).

So, if seemingly 'metaphysical' explanations are unpalatable, even if a shaman resorts to symbolic performance to help heal the patient, in many cases s/he will be doing this with full immersion and belief in the shamanic healing process, and with the knowledge that if the patient believes in it as well, it will most likely have a positive effect on attitude, leading to a boosted immune system and hopefully a state of 'wellness'. Ultimately, though, regardless of the explanation, a shaman is judged by results – if these are not forthcoming, then the shaman is accorded no such respect. Clearly, if all shamans were frauds, then shamanism would never have lasted as long as it has.

CATEGORIES OF PSYCHOACTIVE CHEMICAL COMPOUNDS

The naturally occurring chemicals which affect the nervous system can be divided for convenience into groups related to their chemical structures. Here these will be outlined briefly, in the form of a very basic guide, to be read in conjunction with the next chapter. For more specific information on the properties of italicised compounds, as well as their chemical structures, refer to the Chemical Index located in the appendix. Text books on organic chemistry should be consulted for more informative discussion on the physical properties of these groups of compounds.

Alcohols and solvents

These are simple compounds which are part of a larger broad category, the carbohydrates and lipids. Alcohols are reduction products of several different types of sugars [saccharides]. Although ethyl alcohol [ethanol] is a well-known inebriant, it can be made from a wide variety of plants which would not otherwise be considered psychoactive, and will not be discussed in depth here. There are several excellent books and articles available which cover this topic (eg. Buhner 1998; Müller-Ebeling et al. 2002; Pendell 1995; Rätsch 1999b). Some shamans use alcohol in various forms sacramentally. Even when large amounts are consumed, such shamans claim to transmute the alcohol into a non-toxic substance, so that they do not appear to be inebriated. It could indeed be said that they convert it into 'fuel for the journey'! For most people, though, alcohol may be a hindrance rather than an aid towards the expansion of consciousness, as well as being very toxic when used in excess.

Solvents are generally liquid or gas compounds obtained from a variety of sources, eg. petroleum distillates, and may be inhaled for psychoactive effects. These chemicals are not discussed further in this work [except for the purposes of phytochemical extraction], due to their inherent toxicity, and the long-term destructive nature of their effects on the nervous system [as well as the bodily organism as a whole]. They are often easily absorbed through inhalation of vapours, or through skin contact. [More generally a solvent is simply any medium that dissolves something else.]

Alkaloids

For most of the course of investigations into plant chemistry, attention has focused on the alkaloid group for their potential as bioactive compounds. As a result, in the mass screening of plants for psychoactive or therapeutic compounds, those not shown to contain alkaloids were routinely discarded. The hastiness of this approach is now slowly becoming appreciated, as other chemical classes have shown great therapeutic potentials in recent years. However, the alkaloids remain some of the most powerful chemical agents in use. Here, they will be divided into several groups relevant to this study. Alkaloids are usually recognised by their carbon-ring; as a rule they contain nitrogen, and are usually basic on the pH scale in their natural state, hence known also as bases.

Indole alkaloids

The indoles include many of the most important compounds discussed in this book – some of the best known indoles certainly offer the most useful altered states that can be obtained through substance-ingestion. Their effects are broadly categorised as psychedelic, with mental excitation yet physical sedation [with some exceptions]. Others are more tranquillising, some reputed to be aphrodisiac, some producing physical stimulation. In general they affect a variety of neurotransmitter-systems, mainly *serotonin*, but also *norepinephrine*, *dopamine* and others [see *Neurochemistry* chapter]. Here we find the *tryptamine*s, including *DMT* [N,N-dimethyltryptamine] and its close relatives *5-methoxy-DMT* [5-MeO-N,N-DMT] and *bufotenine* or 5-OH-DMT [5-hydroxy-N,N-DMT], all found in a wide variety of plants as well as in some amphibians [and debatedly in some fungi]; *psilocybin* [O-phosphoryl-4-hydroxy-N,N-DMT] and *psilocin* [4-hydroxy-N,N-DMT] from a relatively large number of higher fungi, particularly amongst the family Agaricaceae subfamily Strophariaceae [eg. see **Psilocybe**]; the ergoline- and clavine-type alkaloids, such as lysergic acid amide [LSA; LA-111; *ergine*], *ergonovine* [ergometrine] and *elymoclavine* distributed amongst certain 'morning glory' species of the Convolvulaceae [eg. see **Ipomoea**] and simple fungi such as 'ergots' [Clavicipitaceae; see **Claviceps**]; the β-carbolines, including *harmine*, *harmaline* and *tetrahydroharman*, which may also be expanded to include substances like *yohimbine*, *reserpine* and *mitragynine*, spread through several diverse plant families; and the iboga- and *vobasine*-type alkaloids, including *ibogaine* and *voacangine*, generally amongst plants of the Apocynaceae ['dogbane' family; eg. see **Tabernanthe**].

Phenethylamine alkaloids

This group contains compounds largely stimulant in effect, some with more psychedelic effects of high-standing, such as *mescaline*. They are primarily found in the families Cactaceae [cacti] and Leguminosae [legumes, such as **Acacia** and **Desmodium**], though their distribution spreads further in the plant kingdom. In general, they affect primarily the *norepinephrine* and *dopamine* neurotransmitter systems in the brain [see *Neurochemistry*], though *mescaline* also strongly affects *serotonin* receptors. Broadly, this group contains stimulants such as *ephedrine*, *cathinone* and *amphetamine*; as well as more interesting compounds such as *mescaline*, and the amination-products of some of the phenylpropenes discussed below, these amination products including MDA [3,4-methylenedioxy-*amphetamine*] and TMA-2 [2,4,5-trimethoxy-*amphetamine*]. The *phenethylamine* 3,4-dimethoxyphenethylamine [*DMPEA*; a neurochemical common in cacti] and its N-methylated [but not β-hydroxylated] derivatives have been shown to inhibit MAO degradation of *tyramine* and *tryptamine* [see next chapter] in rat brain (Keller & Ferguson 1976a) – this is now thought by myself and others to possibly explain the psychoactivity of some ritually-used cacti not containing active amounts of *mescaline*. As many naturally-occurring simple *phenethylamine*s have not been found to be active orally, some are presumed to be active with MAO-B inhibition (Shulgin pers. comm.; pers. obs.). The use of *phenethylamine*-type drugs generates free-radicals in the body; to prevent potential oxidative damage, and to reduce adverse after-effects, antioxidants should also be taken with such drugs (Leibovitz 1993).

Tropane alkaloids

The tropanes are mostly contained in plants of the family Solanaceae [eg. see **Datura**, **Brugmansia**, **Atropa**], and are quite toxic, though used in small doses for certain medical purposes, eg. to produce mydriasis and to combat motion-sickness. Some of these compounds produce a very powerful delirious hallucinatory state, accompanied by loss of motor-coordination and memory loss, associated with the powerful anticholinergic effects [see *Neurochemistry*] of these drugs. After-effects can include temporary blindness and temporary 'insanity'; larger doses can lead to death due to respiratory paralysis. These substances are difficult to work with, and possess a particularly malevolent nature; they are generally favoured by practising witches. The major examples are *atropine*, *hyoscine* and *hyoscyamine*. Some other tropane alkaloids, such as *cocaine* [see **Erythroxylum**], are local anaesthetics as well as central nervous system stimulants and euphoriants, affecting *dopamine* and *norepinephrine* systems in the brain [see *Neurochemistry*].

Isoquinoline alkaloids

These alkaloids may be derived biosynthetically in plants from basic amino acids such as *phenylalanine* and tyrosine [see *Neurochemistry*], and display a wide array of pharmacological effects. Many are found in plants of the family Cactaceae, such as *gigantine* and *pellotine* [which are 1,2,3,4-tetrahydro-isoquinolines – THIQs]; some are represented in **Peganum** harmala of the Zygophyllaceae, such as vasicinone; and many are found in the poppy family, Papaveraceae [eg. see **Papaver**], including such well-known alkaloids as *morphine* and *codeine*, which affect the brain's neuropeptides [see *Neurochemistry* chapter]. Isoquinoline-type alkaloids have been reported to possess anticholinergic and antihistamine properties (Capasso et al. 1997). Some THIQs have been shown to inhibit MAO and COMT enzymes; some isoquinolines found in the Papaveraceae, such as berberine, coptisine, chelerythrine and sanguinarine, inhibit the enzyme AChE [acetylcholinesterase; see *Neurochemistry*] (Bembenek et al. 1990; Deitrich & Erwin 1980; Ulrichová et al. 1983).

Pyrrolidine and piperidine alkaloids

Our representatives in this group are generally central nervous system stimulants affecting cholinergic neurotransmission [see *Neurochemistry* chapter], and many display high toxicity. Examples are *nicotine* [eg. see **Nicotiana**], *lobeline* [eg. see **Lobelia**], *coniine* from **Conium** maculatum ['hemlock'], and *arecoline* from **Areca** catechu ['betel nut']. Alkaloids such as piperine and piperidine are best known from **Piper** spp.; piperine acts as a CNS-depressant [see also **Piper 1**] (Bruneton 1995). Recently, piperidine alkaloids have been found in some fir [Abies spp.], pine [Pinus spp.] and spruce trees [Picea spp.] [see *Endnotes*] (Stermitz et al. 2000).

Isoxazole alkaloids

These are a small group of chemicals that have been detected in some fungi, most notably the 'fly agaric' mushroom, **Amanita** muscaria, and are represented here primarily by *ibotenic acid* and *muscimol*. They are *GABA*-agonists in the central nervous system [see *Neurochemistry*, and *Chemical Index*], and produce a peculiar dissociative-visionary state in the consumer.

Purine alkaloids

The chemicals of this class represented here are stimulants, found most notably in tea [**Camellia** sinensis] of the Theaceae, coffee [**Coffea** spp.] of the Rubiaceae, 'kola nuts' [**Cola** spp.] of the Sterculiaceae, some **Ilex** spp. of the Aquifoliaceae and 'guarana' [**Paullinia** cupana var. sor-

bilis] of the Sapindaceae. The best known of these stimulants are *caffeine*, *theobromine* and *theophylline* [they are also referred to chemically as xanthines]. Simple purines such as guanine and *adenosine* are the basis of nucleic acids fundamental to life, such as DNA and RNA. *Caffeine*-type purines exert their stimulant effects largely by inhibiting the actions of *adenosine* receptors [see *Neurochemistry*].

Quinolizidine alkaloids

This final class of alkaloids are concentrated in the Leguminosae [eg. see **Lupinus**], and are quite toxic. Their psychoactivity in humans is debatable and accompanied by potentially dangerous side-effects. Common examples are *cytisine* and lupanine. These, as well as N-methyl-*cytisine*, show a marked affinity for nicotinic *acetylcholine*-receptors, while the related 3β-OH-lupanine, sparteine, angustifoline and multiflorine showed a greater affinity for the muscarinic *acetylcholine*-receptors [see *Neurochemistry*] (Schmeller et al. 1994). A little-studied sub-division of these chemicals is found in 'club mosses' [**Lycopodium** spp.]; another example is *cryogenine* from **Heimia** salicifolia, less toxic than many other quinolizidines.

Pyrones, lactones, phenols, terpenes and iridoids

Here is a very broad grouping of compounds which can overlap to varying degrees. Firstly, I will mention compounds found in 'kava' [**Piper** methysticum – see **Piper 2**], the kava-pyrones or kava-lactones. Generally speaking, they are anaesthetic, tranquillising, anticonvulsant and produce inebriation without hindering clear-thinking. Examples are *methysticin*, *kawain* and *yangonin*. Iridoids include the sedative *valtrate* from 'valerian' [**Valeriana** officinalis] and the euphoric iridoid-lactone *nepetalactone* from 'catnip' [**Nepeta** cataria]. There are sesquiterpene-lactones that intoxicate in varying ways, such as *lactucin* from wild lettuce [**Lactuca** spp.] and *tutin* from **Coriaria** spp. The phenols and terpenes are widely found in the oils of aromatic plants. Some, such as *borneol*, *camphor*, and limonene affect the nervous sytem in ways little studied in humans, and are known to have toxic potential. Others, such as thujone from **Salvia** officinalis, **Tanacetum** vulgare, **Thuja** occidentalis and **Artemisia** absinthium, and cannabinols such as *THC* from **Cannabis** spp., have unique psychoactive properties which are well-known. The mint family, the Labiatae, is abundant in interesting diterpenoids, the most interesting by far being the neoclerodane diterpenoid *salvinorin A* from **Salvia** divinorum, which displays tremendous psychedelic power unlike any other compound yet discovered. Triterpenes are structurally similar to the steroidal saponins, which are discussed below.

Coumarins

Coumarins are aromatic lactones which are fairly common in the plant kingdom, especially the ubiquitous coumarin itself [1,2-benzopyrone], which is the parent compound of all coumarins. They include umbelliferone, angelicin, xanthotoxol, aesculetin [or esculetin – see **Aesculus**], *scopoletin* and the aflatoxins [see **Aspergillus**]. Some, such as coumarin and *scopoletin*, are hypotensive and can show hypnotic effects at high doses (see MacRae & Towers 1984b for a review of natural coumarin pharmacology). Some coumarins have been shown to inhibit the enzymes MAO and XOD [xanthine oxidase]. Metabolism of coumarin is inhibited by grapefruit juice [see **Citrus**] (Runkel et al. 1997; Yun et al. 2001). Coumarin has shown liver toxicity in dogs and rats, but not in humans, for whom it is relatively non-toxic. Coumarin is often found as an adulterant of vanilla extracts, and as an additive to tobacco [see **Nicotiana**], to add flavour and aroma (Hall 1973; Marles et al. 1987). Some synthetic coumarins, such as warfarin [used as a rat poison], act as powerful anticoagulants, and are highly toxic.

Phenylpropenes

These phenolic compounds are treated separately here both for their primary CNS effects, and for their potential to be converted in the body to *amphetamine*-type *phenethylamine*s. They are found in many essential oils, and are generally sedative in effect [with other therapeutic activities also], yet with addition of a molecule of ammonia they become *amphetamine*s and display stimulant and some psychedelic activity (Braun & Kalbhen 1973; Shulgin et al. 1967; Shulgin & Shulgin 1991). They are listed as follows, with their corresponding potential metabolites:

- *estragole* and *anethole* → 4-MA [4-methoxy-*amphetamine*]
- *eugenol*, *methyleugenol*, isoeugenol and *methylisoeugenol* → 3,4-DMA [3,4-dimethoxy-*amphetamine*]
- *osmorrhizole* and *isoosmorrhizole* [nothosmyrnol] → 2,4-DMA
- *safrole* and *isosafrole* → MDA [3,4-methylenedioxy-*amphetamine*]
- *myristicin* and isomyristicin → MMDA [3-methoxy-4,5-methylenedioxy-*amphetamine*]
- *croweacin* → MMDA-3a [2-methoxy-3,4-methylenedioxy-*amphetamine*]
- *asaricin* and *carpacin* → MMDA-2 [2-methoxy-4,5-methylenedioxy-*amphetamine*]
- *elemicin* and isoelemicin → TMA [3,4,5-trimethoxy-*amphetamine*]
- *asarone* → TMA-2 [2,4,5-trimethoxy-*amphetamine*]
- *apiole* → DMMDA [2,5-dimethoxy-3,4-methylenedioxy-*amphetamine*]
- *dillapiole* and isodillapiole → DMMDA-2 [2,3-dimethoxy-3,4-methylenedioxy-*amphetamine*]
- *exalatacin* → DMMDA-3 [2,6-dimethoxy-3,4-methylenedioxy-*amphetamine*]
- and *1-allyl-2,3,4,5-tetramethoxybenzene* → TA [2,3,4,5-tetramethoxy-*amphetamine*].

Flavonoids

This group of plant constituents often contribute flavour and colour to herbs and foods. They usually occur as glycosides, and are very widespread. Some, such as *apigenin* from chamomile [see **Anthemis**/**Matricaria**], and chrysin from 'passionflower' [see **Passiflora**], show antidepressant and anxiolytic effects, at least in part due to binding with benzodiazepine [BZ] receptors in the *GABA*-neurotransmitter system [see *Neurochemistry*]. In general, they are wide-spectrum enzyme inhibitors (Bruneton 1995), and some [such as *apigenin*, chrysin, genistein, kaempferol, isorhamnetin] show a degree of MAOI activity, particularly inhibiting MAO-A [and to a lesser extent, MAO-B] (Hatano et al. 1991; Sloley et al. 2000) [see *Neurochemistry*, and **Hypericum**], which is enhanced by interaction with other similar compounds. Some, such as hyperforin, inhibit the re-uptake of important neurotransmitters (Chatterjee et al. 1998), increasing their duration of synaptic circulation.

Xanthones

Xanthones and xanthone glycosides are closely allied to the phenols and flavonoids, and are mostly found in the plant families Guttiferae [eg. see **Hypericum**] and Gentianaceae. Their pharmacology is still little known, but some, such as *mangiferin*, decussatin, bellidifolin, gentiacaulein and isogentisin, have demonstrated MAO-inhibiting activity in vitro (Harborne & Baxter ed. 1993; Hostettmann & Wagner 1977; Suzuki et al. 1981).

Peptides

Peptides are small chains of amino acids [see *Neurochemistry*], characterised by a bond [the 'peptide bond'] between the amino group of one amino acid, and the carboxyl group of the next. They may be considered 'mini-proteins'. Many have varied psychoactive or other physiological effects. Some peptides act as hormonal substances in the nervous system, such as β-*endorphin* and *oxytocin*. Many species of frogs [see **Phyllomedusa**, *Endnotes*] contain potent peptides such as caerulein and *dermorphin*, and *apamin* is a similarly potent peptide from honey bees [see *Endnotes*] with excitant and neurotoxic effects.

Cyanogenic glycosides and glucosides

These compounds, present in many plant tissues, break down enzymatically to release hydrogen cyanide or hydrocyanic acid [HCN] when the plant cells are ruptured, or from hydrolysis. Other chemicals released in this process include sugars and other compounds such as benzaldehyde (Conn 1973). HCN smells of bitter almonds [see **Prunus**] and is a potent respiratory depressant, lethal in humans at 50-250mg. However, HCN is highly volatile, and much of it is quickly lost in crushed and/or heated plant material. For this reason, plants known or suspected of containing cyanogens should be crushed after harvesting, then dried, and even briefly aged for good measure. Small amounts of HCN, when smoked in plant form, can give a mild, subtoxic inebriation, though this is not recommended, due to a low window of safety. According to The Merck Index, in low doses HCN may cause headache, vertigo, nausea and vomiting. Higher doses are lethal. In most cases of reported plant occurrence, the actual identities of the parent-cyanogens found in plants have not been pursued, though HCN was detected as the tell-tale metabolite.

Steroidal and triterpenoid saponins

This last group of compounds are important for their varied therapeutic and adaptogenic effects, and are found in many of the tonic plants discussed in this book, such as ginseng [**Panax** spp.] and sarsaparilla [**Smilax** spp. – see **Endnotes**]. Some of them can be converted into useful steroid hormones (Coppen 1980). Saponins are a class of glycosides, which exhibit frothing when mixed vigorously with water. Consult individual plant entries, as these compounds are too numerous to name briefly here.

If more interested in the chemistry of these compounds, the reader should consult more detailed sources on organic chemistry.

NEUROCHEMISTRY

To greater appreciate this study, it is invaluable to have at least a basic understanding of our nervous systems and how they appear to operate. Obviously, the state of current knowledge in this area is vast and intricate, while still not by any means complete, and can not be adequately resolved in the space available here. It should also be noted that our current accepted understandings of brain function are still woefully inadequate, when it comes to explaining the phenomenon of consciousness. I will attempt to give the reader a brief overview of the nervous system, with special reference to areas most important to this study. This will include focus on some areas of neurochemistry which are usually not discussed, due to the unanswered questions raised by them – particularly, the presence of *DMT* and other psychoactive substances in the brains and blood of normal people. Also, many areas are 'glossed over' here, or not covered at all. Technically inclined readers should also consult their local university library for greater depth of information on the nervous system, bearing in mind that some of the information you read here will be omitted from most standard textbooks written for study purposes.

Neural Anatomy

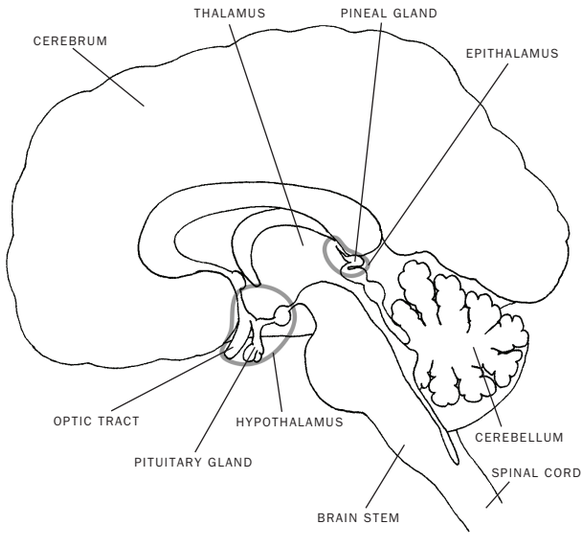
Our nervous systems can be divided into two parts – the 'central nervous system' [CNS] and the 'peripheral nervous system' [PNS]. The CNS is broadly divided into the brain and the spinal cord; the spinal cord is the centre for communication between the brain and the PNS. It is a mass of spinal nerves which exit through notches between each vertebra in the spine. The brain is divided into the main mass, the 'cerebrum', which is split down the middle into two hemispheres or lobes – the right hemisphere controlling the left side of the body, and vice versa. The right side of the brain is associated with spatial orientation, and abstract, artistic thought-patterns; the left hemisphere is associated with verbal language and rationalistic thought-patterns. The smaller 'cerebellum' ['little brain'] sits behind the cerebrum, and is said to be primarily a movement control centre; its hemispheres control the same side of the body instead of opposite, as in the cerebrum. The 'brain stem' connects the spinal cord to the cerebrum and cerebellum, and regulates vital functions. There are also 12 pairs of cranial nerves arising from the brain stem, most of which innervate the head. The PNS is divided into the 'somatic nervous system' and the 'visceral', or 'autonomous nervous system' [ANS; includes sympathetic and parasympathetic nervous systems]; the former comprises nerve cells that connect with skin, joints and muscle, and those of the latter connect with internal organs, blood vessels and glands.

Back to the CNS, however, as this part of the nervous system is of primary importance here. The brain and spinal cord are covered with a tough layer called 'dura mater'. Beneath this is found the web-like 'arachnoid layer', which connects in turn to the 'pia mater', a thin membrane adhering closely to the brain; along this run blood vessels which enter the brain itself. The walls of the brain capillaries have a layer that constitutes what is known as the 'blood-brain barrier' – this limits the passage of some substances into the brain from the bloodstream. The space in between the pia mater and the arachnoid layer [the 'subarachnoid space'], is filled with what is known as 'cerebro-spinal fluid' [CSF]. This fluid also fills the 'ventricular system' [the cavities inside the brain]. It enters the bloodstream at points in the subarachnoid space, and disruption of its flow can cause brain damage.

Experimental data show that 'hallucinatory phenomenon' often occur when the inhibitory functions of the 'higher', and more recently evolved parts of the brain [the 'neocortex'], over the older 'lower' brain structures [the 'limbic system' and the 'reptilian complex' in the centre of the brain] are decreased.

Endocrine [ductless] glands

In the centre of the brain in the brain stem, lies the tiny 'pineal gland', in the 'epithalamus' of the 'diencephalon' along with the 'thalamus' and 'hypothalamus' [see diagram]. The pineal translates light and dark periods into physiological functions coinciding with day-night rhythms, as well as translating sensory stimuli into informational neurotransmitter-substances. It has no blood-brain barrier and can release chemicals directly into CSF. It inhibits premature sexual development; stabilises and synchronises electrical activity in the CNS; promotes normal sleep and dreaming patterns; modulates proper immune function; inhibits and modulates the 'adrenal glands' [via the 'pituitary gland'] and the 'thyroid gland'; and lowers arterial blood pressure. The pineal is connected directly by neural pathways [the 'SCN' – super chiasmitic nucleus – via the 'superior colliculi', and to the inner ear via the 'inferior colliculi'] to the optic nerves. It appears to be an actual remnant eye in primitive vertebrates, and acts as a true photoreceptor with cornea, rods and cones. It is particularly prominent in the 'tuatara', a rare New Zealand reptile. The hypothalamus includes the pituitary gland [which, along with the adrenal glands, is regulated by the pineal] and is involved in nearly all aspects of behaviour, as well as temperature regulation, movement, feeding and proper function



control of the other endocrine glands.

Other endocrines are located along a downward plane from the pineal and the pituitary. Just below the larynx is the thyroid gland, which consists of two lobes on either side of the windpipe, connected just below the 'Adam's apple'. It is influenced by the 'gonads' [sexual glands] and controls growth of body tissues and normal metabolism, as well as normal mental and physical development. The 'parathyroids' are four tiny glands connected to this system. The 'thymus gland' sits above the diaphragm, next to the heart, which itself shows many of the characteristics of a gland. The thymus is involved with childhood growth, and inhibits the gonads until puberty. It is important in controlling the immune system, and is linked closely to the circulatory system. The 'pancreas' is found in the solar plexus area; it controls digestion and induces the liver to secrete sugars into the blood for energy. There are two adrenal glands, one on top of each kidney, and these regulate the body's reaction to stressful situations, with the "fight or flight" syndrome. The gonads [ovaries in females; testes and prostate gland in males] secrete the hormones necessary for sexual functions.

The Neuron

Now we turn to the 'neuron', or 'brain cell', which will conclude the focus of our anatomical discussion. The main body of the neuron is termed the 'soma' [usually about 20μm diam.]; radiating out of it are thin tubes called 'neurites', which are divided into 'axons', the main neurites, which are long [up to a metre or more] and occasionally branch off at right-angles; and 'dendrites', which are short [up to about 2mm long] and branch out mainly from the soma. At the centre of the soma is its nucleus, which contains your chromosomes, which contain your DNA [deoxyribonucleic acid], in which is inscripted your entire genetic blueprint. DNA forms itself into an uninterrupted double braid, and will be briefly discussed again later. DNA is 'read' by a process known as 'gene expression'. 'Messenger ribonucleic acid' [mRNA] is a chain of four different nucleic acids arranged in sequences, which is assembled as a transcript of the DNA expression to carry the message into the 'cytoplasm' [everything inside the soma except the nucleus]. Once there it is translated into protein synthesis by 'ribosomes' [dense globules which cover the 'smooth endoplasmic reticulum' (smooth ER), membrane-enclosed structures that float in the cytoplasm (one type of several, collectively called 'organelles')], from amino acids. Having mentioned organelles, another important type of organelle is the 'mitochondria', which consumes pyruvic acid [from sugars, digested fats and proteins] and oxygen from the 'cytosol' [the salty, potassium-rich fluid that fills the soma and contains electrically-charged atoms ('ions') in solution] and uses them to provide the energy to produce *adenosine* triphosphate [ATP], the energy source of the cell, which is then pumped back into the cytosol. These features are common to all body cells.

Axons, found only in neurons, extend from the soma and end in a swollen disc called the 'axon terminal'. The point where the terminal contacts other cells is called the 'synapse'. The axon terminal is filled with tiny bubbles called 'synaptic vesicles', which store and release 'neurotransmitters', chemical agents which will be discussed later. They also contain 'secretory granules', which contain soluble protein. The synapse consists of two sides, pre- and post-, the post-synaptic side being the soma or dendrite of another neuron; the space between the two is the 'synaptic cleft'. When the axon terminal receives an electrical impulse through the axon,

it induces its synaptic vesicles to release their neurotransmitters, which are received by 'receptors' at the post-synaptic cleft and re-translated into an electrical impulse. This is how neurons communicate with each other to operate the nervous system, and the bodily organism as a whole; this also controls the way in which we perceive our reality, through our thoughts and sensory inputs. The dendrites constitute the 'antennae' of the cell, and are covered with thousands of postsynaptic sites housing receptors to receive neurotransmitters from the synaptic cleft. We will return to the important topic of neurotransmission later. It should be mentioned briefly here that the eye contains 'photoreceptors' which translate light information into neural activity; these neurons synthesise and concentrate 5-methoxyindoles [see below], as does the pineal gland to which the optic nerve is connected.

Ions and electricity in the brain

Now we turn to the purpose of ions in the neuronal cell, mentioned earlier as being dissolved in the cytosol. The most important ions here are Na+ [sodium], K+ [potassium], Ca_2+ [calcium] and Cl- [chloride]. Changes in the concentrations of these ions on either side of the cell membrane through 'ion-channels' and 'ion-pumps' affect the electrical charge of the neuron, which has a resting voltage ['resting potential'] of about -65 millivolts. A functioning nervous system must have this negative resting voltage. If the cell becomes less negative it is said to be 'depolarised'. The resting neuronal membrane is most permeable to K+, elevations of which can cause depolarisation, though this is largely controlled by the blood-brain barrier. However, excessive elevations of K+ can still adversely affect cells in the body. An 'action potential', or positive cell voltage, occurs when the nerve cell depolarises rapidly past a threshold to peak at a positive voltage, before falling back to the negative resting potential. This is, in effect, what you are watching when you see an EEG ['electroencephelogram'] machine drawing peaks when hooked up to electrodes on the scalp. The frequency, or rate, that these action potentials occur if stimulus is continuous is directly related to the magnitude of the depolarising current. The action potential is passed along the axon as an electrical pulse, and terminates at the axon terminal, there initiating neurotransmitter release into the synapse. The stimulus to produce the action potential may be caused by any sensory input, ranging from a pin-prick on the finger to light waves reaching photoreceptors in the retina of the eye. It should be mentioned that as well as synapses that work with neurotransmitter chemicals, there also exist 'electrical synapses', where ions are passed directly from presynaptic- to postsynaptic-membranes. However, these are relatively uncommon in brain cells except in early embryonic stages of our lives.

The brain activity measured by an EEG can be divided into different frequencies:

'gamma waves' [30-c.80Hz] – occur in the 'background' of other wave activity, and though their function in consciousness is still unclear, it is thought they may be important in coordinating and organising neural activity

'beta waves' [14-29Hz] – the normal alert mind; usually apparent in the middle and front of the brain; related to sensory motor functions

'alpha waves' [8-13Hz] – associated with deep relaxation; mostly in the back of the brain

'theta waves' [4-7Hz] – observed in some sleep states, and deep stages of meditation; most prominent between ages 2-5

'delta waves' [1-3Hz] – observed in deep sleep, early infancy and in the enlightened mystical state of 'samadhi'

Neurotransmission

Broadly, the known neurotransmitters are certain amino acids, amines [alkaloids] and peptides [made from proteins]. Amino acid and amine neurotransmitters [NTs] are released from synaptic vesicles, whilst peptide NTs are released from secretory granules. When the neurotransmitter reaches the postsynaptic membrane, it binds to its receptor-site in a way analogous to fitting a key into a lock. Receptors can also be affected by chemicals which mimic the structures of NTs, but which are not native to the CNS. Such exogenous chemicals may then exert their effects by activating the postsynaptic receptor; by blocking the postsynaptic receptor [so that no NT can bind], but not activating it; by blocking re-uptake sites, thus maintaining a high level of NT in the synapse [see below]; or by other means less understood. Similar chemicals may exert different effects due to the complex variations in receptor-binding profiles, affecting different receptor subtypes in different ways in different areas of the nervous system. This is without even considering effects on ions, enzymes and other essential elements of nervous system funtion. However, an important fact to note here is that exogenous psychoactive drugs, when introduced into the brain, can generally only trigger responses that are already built into the capacity of the nervous system. With this in mind, a 'psychedelic trip' seems less an alien experience imposed on one's own nervous system, than a slight re-tuning or altered calibration, due to affecting receptors in novel combinations. This, at least to me, makes the curiosity of the presence of *DMT* [and related psychoptic alkaloids – see below] in the brain, as apparent endogenous neurochemicals with which the brain is most familiar, all the more fascinating.

There also exist receptors on the presynaptic membrane, called 'autoreceptors', which generally regulate the concentration of NT in the synaptic cleft by inhibiting further release or synthesis. Apart from synaptic neurotransmission, recent evidence suggests that 'volume transmission' can occur, ie. the transport of NT molecules to synapses relatively far away from the point of release, via the CSF. After synaptic interaction, or neurotransmission has taken place the NT is cleared from the synapse either by presynaptic-reuptake [followed by re-storage or enzymatic destruction], or destruction by enzymes in the synapse. The input received at the postsynaptic receptor is again translated into an action potential, initiating a chain of biochemical events that in effect are a translation of the original message. The chain of events that follows involves complex interactions with other neurons, enzymes, proteins, ions and 'second-messenger compounds', and is too complex to be covered further here. In many instances, these interactions are poorly understood, at best.

Enzymes

Enzyme activity in the body is essential in catalysing chemical reactions which metabolise the substances discussed here. One of the most important is adenylate cyclase, which catalyses the conversion of ATP to cAMP [cyclic *adenosine* monophosphate], a 'second messenger' chemical which mediates hormonal response. Adenylate cyclase is activated by β-adrenoreceptors, some *serotonin* receptors, some *histamine* receptors, and D1 *dopamine* receptors [these are discussed below]. cAMP is broken down to non-cyclic 5'-AMP by enzymes called phosphodiesterases. Phosphodiesterase-inhibition potentiates and prolongs β-adrenoreceptor stimulation. Cytochrome P450 enzymes [mostly in the gut] metabolise a wide array of drugs, and exist in various isoforms, including [with selected examples of substrates] 1A1 [acetaminophen], 1A2 [*caffeine*, *theophylline*], 2A6 [coumarin], 2C19 [*diazepam*, progesterone], 2C9 [ibuprofen, warfarin], 2D6 [*5-methoxy-DMT*, *5-methoxytryptamine*, *pinoline*, *codeine*, dextromethorphan, haloperidol, desipramine], 2E1 [acetaminophen, ethanol], 3A4 and 3A5 [*diazepam*, *ergotamine*, haloperidol, methadone, vincristine, lidocaine, cyclosporin]. Most inhibitors of P450 enzymes that have been found so far are synthetic pharmaceuticals, with the exception of grapefruit juice [see **Citrus**], which has been shown to inhibit types 1A2, 2A6 and 3A4. Another major enzyme is monoamine-oxidase [MAO], which exists in two forms, A and B. It oxidises amines to prevent them from reaching vital organs when inappropriate. MAO-A is found in small intestine, liver, some peripheral nerves and in the brain; its preferential substrate is *serotonin* and other indoles, but it also acts on *dopamine* and *norepinephrine*, as well as other amines to a lesser degree. MAO-B is found mostly in the brain and blood; its preferential substrates are *tyramine*, *dopamine* and *norepinephrine*, as well as *tryptamine*, but it also acts on *serotonin* and other indoles to a lesser degree. The body also contains its own endogenous MAOIs, sometimes referred to as *tribulin* [and including *isatin* – see *Chemical Index*], though these are little-known indole bases derived from uncertain metabolic routes, not enzymes. The potential of MAO-inhibition [MAOI] is discussed in the next chapter. While on the subject of oxidation [or oxidisation], it should be mentioned that whilst oxygen is essential for the life of our cells, sometimes particles that become unstable due to the loss of an electron ['free-radicals'] cause damage to other cells by 'scavenging' their electrons, causing a chain-reaction of oxidative damage. This situation may be brought about by stress, smoking, pollution, eating food cooked in overheated or rancid oil, and other unhealthy influences. Free-radicals are destroyed by anti-oxidants, which are represented by many vital nutrients and other chemicals.

Other enzymes will be mentioned under the NT system in which they operate.

Amino acids

Amino acids in the body are generally derived from food sources, as they are found in all plants and animals, and are the basic building blocks from which the nervous system synthesises its neurotransmitters – in foods, they are joined together to form proteins. The 'essential' amino acids are those which can not be manufactured by the body, and must be obtained from food – these are isoleucine, leucine, lysine, *methionine*, *phenylalanine*, threonine, *tryptophan* and valine. The amino acids discussed here are a representative selection of a larger group.

L-Alanine aids in obtaining energy from glucose, and maintaining skin condition. It can aid in treating diarrhoea.

L-Arginine helps in detoxification, release of growth hormones, and maintaining a healthy immune system. It is used in energy production. Good sources are nuts, carob, chocolate, brown rice, oatmeal, raisins, sunflower and sesame seeds, and whole wheat.

L-Carnitine is made in the body from L-lysine, iron, vitamins B1 and B6. It aids in weight loss through its role in fat metabolism, and increases energy production, as well as enhancing the antioxidant activity of vitamins C and E. It can aid in some cases of mental retardation and muscle weakness.

Choline is primarily important as a precursor to *acetylcholine*, and is also used in the body as a fat metaboliser, due to its emulsifying effect.

It aids the liver in eliminating toxins, and it has been taken to treat memory loss, movement disorders, artherosclerosis and liver cirrhosis. It has been shown to improve performance in intelligence tests, and has a calming effect. For most efficient metabolism to *acetylcholine*, it should be taken with vitamins B5 and B1. *Choline* can be synthesised by the body from phosphatidylaminoethanol, which has N-methyl groups added until phosphatidylcholine [PC] results; PC is the main store of available *choline* in the body. This process occcurs mainly in the liver, with the products then distributed through the bloodstream, though it also occurs in the brain. Good sources are soy beans, bean sprouts, egg yolk, milk, lentils, peanuts, split peas, green beans and fish.

Glutamic acid [L-glutamate] is the precursor to L-*glutamine*, and shares many of its properties. Taken together, they detoxify excess ammonia in the body. It is essential to the body for energy. May comprise 20-35% of food proteins. It is derived from *pyroglutamic acid* via the enzyme 5-oxoprolinase; *pyroglutamic acid* is also found in vegetables, fruits and molasses.

L-Glutamine is the most abundant amino acid in the CNS, and can be synthesised in the body from *glutamic acid*. It excites nerves, and may itself serve to relay sensory information. It can increase mental and physical alertness, treat epilepsy, benefit impotence and senility, and reduce cravings for sugar and alcohol. It improves nutrient absorption.

L-Histidine is the precursor to *histamine*, and is useful in treating dermatitis and rheumatoid arthritis. It is important for protecting skin from UV rays, tissue growth and repair, and production of red and white blood cells. It controls gastric acidity, and is important for proper digestion as well as healing of ulcers. It has been shown to potentiate opiate-induced catalepsy. Also, administered alone [i.p.] it causes bizarre behaviour and some catalepsy in rats, produced by interaction with the H1 *histamine* receptor.

L-Leucine regulates blood-sugar levels, promotes tissue healing, suppresses pain, and regulates energy availability. It should be taken in combination with L-valine. An excess can produce hypoglycaemia. It has been shown to have a sedative effect in chicks.

L-Lysine is essential for all protein. It helps calcium absorption, tissue production, and antibody production. It also aids in fat metabolism, and in obtaining energy from glucose. A lysine deficiency results in irritability, loss of energy, lack of concentration, retarded growth and hair loss. Good sources are dairy products, lima beans, yeast, eggs and soy products.

L-Methionine acts as a methyl-group donor for other chemicals, by reacting with ATP to form S-adenosyl-*methionine* [SAM], the main methyl-donor in creating substances such as *5-methoxy-DMT*. Its activity may be due to its metabolism products, L-cysteine and L-homocysteine, which may also aid in production of such N-methylated indoles, and increase activity in the brain. L-*methionine* is also involved in fat metabolism. Good sources are apples, Brussels sprouts, cabbage, cauliflower, chives, cottage cheese, egg, garlic, milk, pineapple, soy beans and watercress.

L-Phenylalanine is found in proteins at levels of about 4%, and is a precursor for catecholamines. It is used to elevate mood in treatment of depression [DL-*phenylalanine*, a mixture of the natural and synthetic forms, is used as a painkiller for cases of menstrual pain, migraines and arthritis, as it apparently aids in production of *endorphin*s, and prevention of their destruction]. It also plays a part in forming melanin, the skin pigment. Phenylketonuria [PKU] is a disorder in *phenylalanine* metabolism occurring in some people, where the amino acid is instead converted to phenylpyruvic acid, phenyllactic acid, phenylacetic acid, phenylacetylglutamine and/or O-hydroxyphenylacetic acid. This disorder is characterised by severe mental retardation and presence of an unusual 'mousy' odour. Good sources of *phenylalanine* are soy products, cottage cheese, almonds, peanuts, lima beans, pumpkin and sesame seeds.

L-Proline is inhibitory in the CNS; it is also used in energy metabolism, and maintenance of skin and connective tissue.

L-Taurine appears to act as a minor neurotransmitter with depressant effects. It is antiepileptic, and anti-arrhythmic to the heart. It aids in cholesterol degradation and fat absorption.

L-Threonine is important in liver and fat metabolism, and formation of collagen and elastin. It can help control epileptic seizures.

L-Tryptophan usually makes up 1-1.5% of natural proteins. It was withdrawn from the health supplement market in 1988 after a contaminated batch from Japan [resulting from an impurity caused by an untested shortcut introduced to the manufacturing process] caused deaths in consumers [the now infamous 'eosinophilia-myalgia syndrome']. Due to the psychoactive potential of this amino acid, and due to the fact that Prozac™ was introduced and promoted as an antidepressant soon after *tryptophan* was withdrawn, it seems at least possible that it was not re-introduced after the problem was resolved because both a) it is a *DMT* precursor, and b) it is a safer and natural antidepressant, and thus serious competition for Prozac™ sales. Also, a popular 'underground' publication by Gottlieb (1992 – though other versions have been around for decades) told how one could ingest 5-8g of *tryptophan* on an empty stomach to produce "drowsiness, euphoria and mental changes similar to mild dose of *psilocybin*" [the comparison to *psilocybin* an exaggeration]. When available, it was used as an antidepressant and sedative-hypnotic to promote sleep. It is essential in the production of niacin. Good sources are cheese, milk, bananas, dried dates, cashews and peanuts.

L-Tyrosine is found in proteins at about 3% concentration. It can be formed from *phenylalanine*, and is precursor to the same neurotransmitters, as well as 'thyroid hormone' [TH]. It is also used in making melanin, and helps control appetite and body fat levels. *Caffeine* can lower its plasma levels. Highest concentrations are found in yoghurt.

L-Valine is a stimulant, and an important component of muscle tissue protein.

Neurotransmitters and their intermediary products

Here we will discuss the key known neurotransmitter systems.

The Serotonergic system is usually stated to be the most important of all [if such a ranking has any true meaning whatsoever], and is based on *serotonin* [5-hydroxy-*tryptamine*; *5-HT*]. It uses L-*tryptophan* as its precursor, which may be either converted to the indole alkaloid *tryptamine* [by aromatic L-amino acid decarboxylase], or to *5-hydroxytryptophan* [*5-HTP*] [by tryptophan hydroxylase]; alternately it may be converted to kynerenine [via formylkynurenine] by tryptophan 2,3-dioxygenase. In mammals, *tryptamine* is usually not used in the biosynthesis of *5-HT*, but may still be used as a precursor to other endogenous tryptamines [see below]. Vitamin B3 deficiency in the body will tend to cause conversion of some *tryptophan* to this vitamin, producing hepatotoxic metabolites such as formate and quinolinic acid [an NMDA-receptor agonist – see below], as well as kynurenines and kynurenic acids [kynurenic acid is an agonist of NMDA, quisqualate, and kainic acid receptors], in the process; thus, taking *tryptophan* with a B3 supplement is recommended. Also, if taken without adequate carbohydrates, much of the *tryptophan* will be converted to glucose. *Tryptophan* and kynurenine have recently been shown to stimulate the expression of nerve-growth-factor [NGF] in mouse experiments. Kynurenines and kynuramines can also be produced in the body from *tryptamine*, *5-HT*, *5-HTP* and *melatonin* [see below]. *Tryptamine* given intravenously produced mild perceptual distortions, accompanied by pupil dilation, increased blood pressure, heavy limbs, sweating, dizziness and nausea. In the rat cerebral cortex, it depresses the firing of most neurons; in mice and cats it produces excitation. *5-HTP* is a slight sedative and an antidepressant, similar to its parent *tryptophan*, but more active. In large doses, it has produced excitation in animals. It is converted to the neurotransmitter *5-HT* by aromatic 5-HTP decarboxylase [which requires vitamin B6 and copper, as does the *tryptophan* to *tryptamine* decarboxylation; vitamin C and folate also help]. *5-HT* is a slight sedative and can promote a content mood and decrease aggression [some antidepressants such as Prozac™ work partly as selective *serotonin* re-uptake inhibitors (SSRIs), which prevent *5-HT* from being re-absorbed into the axon terminal, and thus, keep high levels of the neurotransmitter circulating in the synapse]; it does not cross the blood-brain barrier, and therefore must be synthesised in the CNS from more lipid-soluble precursors [such as *tryptophan* and *5-HTP*]. It causes bronchoconstriction in asthmatics, vasoconstriction, smooth muscle contraction, reduced cerebral blood flow and decreased body temperature. It can cause nausea in high amounts, as well as reducing sex drive. It is also involved in the perception of pain. *5-HT* depletion generally causes hypersensitivity to psychedelics that affect these receptors [ie. LSD, *DMT*, *psilocin*, *mescaline*]. Also, prolonged ingestion of an SSRI can cause hypersensitivity to LSD, DOM and *ibogaine*, though not significantly with *5-MeO-DMT*. *5-HT* fires in a slow, regular pattern.

There are many *5-HT* receptor subtypes – 5-HT1 types [divided into 1a, 1b, 1d, 1e and 1f subtypes] in the brain are generally inhibitory; 5-HT2 types [divided into 2a (2), 2b (2f) and 2c (1c)] in smooth muscle and platelets, as well as brain, are excitatory in CNS and cause vasodilation and contraction of gut, bronchi and uterus, as well as decreasing cAMP activity; 5-HT3 types, in CNS as well as sensory and digestive nerves, are excitatory and can cause pain and vomiting; 5-HT4 in CNS, heart and GI tract increases cAMP. There are also 5-HT5, 6 and 7 types that are still little known – however LSD is also known to be an agonist at these sites. 5-Substituted tryptamines are mostly selective for 5-HT1a and 1b receptors; 4-hydroxy-tryptamines are selective for the 5-HT2a receptor. *5-MeO-tryptamine* shows a high affinity for the 5-HT3 receptor. Indole psychedelics are believed to work by binding to their preferred receptors and inhibiting *5-HT*, combined with an array of secondary NT effects. *Tryptamine* is also now known to have its own receptor sites [T receptors].

After transmission, *5-HT* is either reabsorbed, or metabolised by the enzyme monoamine-oxidase [MAO] to 5-hydroxyindoleacetaldehyde, which oxidises to 5-hydroxyindoleacetic acid [5-HIAA], in which form it is excreted from the body. 5-HIAA was shown to have CNS sedative activities in newly hatched chicks. MAO also degrades other *tryptamine*s. *5-HT* may alternately be converted to *melatonin* [N-acetyl-*5-methoxytryptamine*] [with

N-acetyl-*5-HT* as an intermediary, by N-acetyl-transferase (NAT), hydroxyindole-O-methyltransferase (HIOMT) and SAM], the major chemical of the pineal gland, which regulates the body's reaction to light, inducing sleep when light levels are low or absent. *Melatonin* is also a NT and has its own receptor site, the ML-1 *melatonin* receptor. *Melatonin* is a strong antioxidant; it also protects DNA in white blood cells from radiation, and decreases MAO activity in the pituitary and hypothalamus. Pineal *melatonin* rises 2-12-fold at night. Incidentally, HIOMT activity is increased by psychoactive chemicals such as *DMT*, *mescaline*, *ergine*, *DMPEA* and *amphetamine*; its activity also peaks in January and July, and troughs in March and October.

Methyltetrahydrofolic acid [MTHF] can act as an alternative methyl donor to S-adenosylmethionine [SAM] in catalysing the O-methylation or N-methylation of the indoles [see below], although SAM usually works best as donor.

Tryptamine and *5-HT* are also sometimes converted to any of a range of other indole alkaloids, whose individual activities are discussed elsewhere. These include *5-MeO-tryptamine* [*melatonin* deacetylated = *5-MeO-T*; or, *5-HT* + HIOMT = *5-MeO-T*], *N-methyltryptamine* [*NMT*][*tryptamine* + indole-N-methyltransferase (INMT) = *NMT*], *DMT* [*NMT* + INMT = *DMT*], *5-MeO-DMT* [*5-HT* + INMT = N-methyl-*5-HT*, + INMT = *bufotenine* (*5-OH-DMT*), + HIOMT = *5-MeO-DMT*; or, from *5-MeO-T* by two actions of INMT, as above, with 5-MeO-*NMT* as an intermediate], *5-OH-DMT* [from *5-HT* by two actions of INMT, with 5-OH-*NMT* as an intermediate], *norharman*, *harman*, *tetrahydroharman*, *harmalan*, tryptoline [1,2,3,4-tetrahydro-β-carboline (THβC)][*tryptamine* condensed with acetaldehyde = THβC], *pinoline* [6-MeO-THβC], *6-MeO-harmalan* [tentative], *adrenoglomerulotropin* [1-methyl-*pinoline*], 2-methyl-THβC [*NMT* condensed with acetaldehyde = 2-Me-THβC], 6-OH-THβC, 6-OH-1-methyl-THβC and *tetrahydroharmol*. Many of the β-carbolines have MAOI activity, and some inhibit AChE activity and muscarinic *acetylcholine* receptor binding [see below]. As described above, they may be formed from condensation with tryptamines and acetaldehyde, catalysed by INMT, SAM and 5-methyltetrahydrofolate [5-MTHF]. Indole-N-methylation has been shown [in guinea-pig brain] to also create 2[β]-methylated β-carbolines and 2,9-dimethylated β-carbolines, with SAM as a methyl-donor. Some endogenous β-carbolines have been proposed to be neurotoxins, possibly involved in initiating or precipitating Parkinson's disease. However, their occurrence in the mammalian nervous system has not yet been adequately demonstrated. These are of the 2,9-dimethyl-β-carbolinium cation type, such as 2,9-dimethyl-norharmanium cation [see **Phalaris** for more discussion]. β-Carbolinium cations have been shown to inhibit *dopamine* reuptake, and the enzyme tyrosine hydroxylase. The 6-hydroxylating mechanism has been proposed to possibly produce 6-OH-*DMT* and/or 6-OH-N-acetyltryptamine, but this remains to be shown in humans; in rabbit liver, incubated *DMT* produced *NMT*, *DMT*-N-oxide, 6-OH-*DMT* and 6-OH-*DMT*-N-oxide. However, in rat brain it produced *T*, *NMT*, *DMT*-N-oxide, THβC, 2-methyl-THβC and indoleacetic acid. In human blood, *DMT* is partly converted to N,N-dimethylkynuramine [DMK], of unknown activity; kynuramine inhibits α-adrenoceptors, and along with 5-OH-kynuramine, 3-OH-DMK and 5-OH-DMK, antagonises *5-HT*.

The Catecholamine system in general is associated with arousal, alertness and excitement, and is based on *dopamine* [*DA*], *epinephrine* [*Ep*; adrenaline] and *norepinephrine* [*NE*]. Their synthesis begins with L-*phenylalanine* and/or L-tyrosine. L-*phenylalanine* may be made into *phenethylamine* [*PEA*] by the enzyme aromatic L-amino acid decarboxylase, or into tyrosine by phenylalanine hydroxylase. *PEA* has *amphetamine*-like effects when administered i.v. in large doses, or with an MAO-inhibitor. It has a high turnover rate, and relatively short half-life in the body [1-5 min.]. After action, it is degraded by MAO-B to phenylacetaldehyde [a sedative], or by dopamine β-hydroxylase [an enzyme which requires calcium and vitamin C] to phenylethanolamine [a weak stimulant]. Tyrosine is converted by tyrosine hydroxylase [which inhibits cAMP] to 3,4-dihydroxyphenylalanine [L-*DOPA*], which decreases brain *5-HT* and causes mental and physical excitement, mimicking the effects of *DA*; or alternately may be converted to either o-, m- or p-*tyramine* [2-, 3- or 4-hydroxyphenethylamine], which induce *DA* and *NE* release, as well as inhibiting *DA* re-uptake. In higher doses or with an MAO-inhibitor *tyramine* can cause hypertension. *Tyramine* may be converted by dopamine β-hydroxylase to octopamine, which acts as a minor neurotransmitter in the sympathetic nervous system [released with *NE*], raising the blood pressure; its CNS effects are debatable. This compound may be converted by N-methyltransferase to synephrine, a decongestant and stimulant which is an agonist at α- and β-adrenoceptors and raises blood pressure in the sympathetic nervous system; in mice it appears to have antidepressant activity without *amphetamine*-like stimulation. *Tyramine* can also be converted to *PEA* or *DA*; octopamine to *NE* or phenylethanolamine; synephrine to *Ep* or N-methylphenylethanolamine; and vice versa, for each. *DA* [from either *DOPA*, via DOPA decarboxylase, or *tyramine*, via ring DOPA hydroxylase] is excitatory, producing pleasure, as well as increasing sex drive and promoting orgasm. It increases heart output, and in larger amounts produces vasoconstriction and hypertension. It fires in a rapid, irregular pattern, and its release is calcium-dependent. High amounts inhibit tyrosine hydroxylase. *DA* may be converted to *NE* by dopamine β-hydroxylase, which in turn may be converted to *Ep* by phenylethanolamine-N-methyltransferase [*DA* may sometimes be converted to 3,4-dimethoxyphenethylamine (*DMPEA*), which has no intrinsic psychoactivity, but inhibits MAO activity on *tyramine* and *tryptamine* in the rat brain]. These are excitatory and are associated with the arousal of the "fight or flight syndrome", and in high amounts can cause hypertension. *NE* is found in the pineal gland, as is *DA*, as well as other parts of the CNS; it stimulates activity of the enzyme N-acetyltransferase [causing *melatonin* synthesis for later use – thus, an active lifestyle during the day can help normalise *melatonin* production], as well as that of cAMP. *Ep* is made primarily in the adrenals, as well as in the brain, and acts peripherally as a hormone, and as a NT in the CNS. It is associated with regulating temperature, food and water intake, and cardiovascular and respiratory control. Nicotinic acid may reduce its levels.

There exist α-1 [with a, b, c and d subtypes], α-2 [a, b, c and d], β-1, β-2 and β-3 adrenoceptors, which are affected by *Ep* and *NE*; *Ep* affects mostly β-types, and *NE* affects mostly α-types; *DA* affects α-types to a lesser degree, as does phenylephrine. α-1 activity is excitatory, and produces peripheral vasoconstriction. It facilitates the action of *DA*, *acetylcholine* [*ACh*] and testosterone. α-2 activity is inhibitory, and antagonises α-1; agonists of this receptor have hypnotic, anaesthetic and analgesic effects. It also produces peripheral vasoconstriction, and inhibits *ACh* and adenylate cyclase activity. α-Adrenoceptors also cause pupil dilation and uterine contraction. β-1 activity causes tachycardia and palpitations, as well as decreased GI motility; these receptors are found primarily in the heart. β-2 activity is excitatory and promotes nervousness. It produces vasodilation, bronchodilation and uterine relaxation. β-3 is little known. β-receptors also increase available energy by stimulating production of glucose for the brain, and fatty acids for skeletal muscle.

DA receptors are divided into D1 [subdivided into 1a (1) and 1b (5) subtypes] and D2 [subdivided into 2a (2), 2b (3) and 2c (4)] types. D1 receptors stimulate the enzyme adenylate cyclase, which stimulates cAMP. In the parathyroid gland, D1 receptors are involved in the release of parathyroid hormone. Little is known of their CNS effects. D2 receptors produce the excitatory effects typical of *DA*, and excessive stimulation may cause psychedelic effects, or schizophrenic-like syndromes in those already susceptible. Octopamine also has 4 known receptor subtypes – OA1, OA2A, OA3 and fat-subtype OA-receptor. Also known to be associated with [though quite distinct from] noradrenergic receptors located on mitochondrial MAO are the I1 and I2 imidazoline receptors. To my knowledge, the primary endogenous ligands for these receptors have not yet been discovered or confirmed, although *imidazole-4-acetic acid* [see below] would seem to be a candidate. I1 receptors are known to mediate hypotensive effects, though little is known about the properties of these receptors, apart from possible inhibition of *NE* release, stimulation of insulin secretion, and modulation of ion flux.

After transmission, these amines are either reabsorbed, or enzymatically degraded. Methyltetrahydrofolic acid [MTHF] can act as a methyl donor to catalyse the O-methylation or N-methylation of the catecholamines. *DA* may be attacked by MAO to produce dihydroxyphenylacetic acid, then by catechol-O-methyltransferase [COMT] to homovanillic acid [HVA]; or by COMT to 3-methoxytyramine, then by MAO to HVA. *NE* may be degraded by MAO to dihydroxymandelic acid, then by COMT to 3-methoxy-4-hydroxymandelic acid [VMA]; or by COMT with S-adenosyl-L-*methionine* [SAM] to normetanephrine, then by MAO and aldehyde dehydrogenase to VMA; or by MAO and aldehyde dehydrogenase to 3,4-dihydroxyphenylglycol, then COMT and SAM to 3-methoxy-4-hydroxy-phenylglycol. *Ep* is sometimes oxidised to form *adrenochrome* [immortalised in an exaggerated fashion by Hunter S. Thompson in "Fear and Loathing in Las Vegas"], an unstable product which, when given intranasally or sublingually, produces 'LSD-like' effects that are not very visual, and adrenergic effects. This may be further converted to *adrenolutin* [to which it is converted in blood plasma], which has similar effects, or to dihydroxy- and trihydroxy-indoles, such as 5,6-dihydroxy-N-methylindole [DNMI], which has anti-anxiety effects. Similarly, *DA* and *NE* can be oxidised to form dopachrome and noradrenochrome, respectively, which are little known but probably have similar effects to *adrenochrome*. In this vein, *NE* can also be converted to 5,6-diacetoxy-N-isopropylindole [DIN], which produces disruption, and later promotion, of sleep as well as improving mood during waking hours. *Ep* is protected against oxidation to *adrenochrome* by vitamin C, which also catalyses the conversion of *adrenochrome* to dihydroxy- and trihydroxy-indoles. *Adrenochrome* levels are also reduced by L-cysteine. Fresh haemoglobin, or high oxygen intake, catalyse the reaction of *Ep* to *adrenochrome*. 2-OH-4,5-dimethoxyphenethanolamine has been proposed as a possible endogenous 'psychotogen', and is psychoactive, but its presence in mammals remains to be demonstrated.

Some of the catecholamines can also be metabolised in the body by condensation with aldehydes [such as acetaldehyde, a metabolite of alcohol] or pyruvate, to form tetrahydroisoquinolines [THIQs] of largely unknown human activity – *PEA* can give rise to THIQ [which can

cause symptoms of Parkinsonism], 1-methyl-THIQ [prevents symptoms caused by THIQ] and 1-benzyl-THIQ; *DA* can give rise to norsalsolinol [6,7-dihydroxy-THIQ], *salsolinol* [6,7-dihydroxy-1-methyl-THIQ; potent *dopamine* uptake-inhibitor, increases *5-HT* in the striatum, inhibits COMT & MAO] and 6,7-dihydroxy-2-methyl-THIQ. Some stimulate catecholamine release, and some also have shown very weak tyramine hydroxylase and MAO-B inhibiting activity. High levels of these endogenous THIQs are thought to be correlates of alcoholism, phenylketonuria [see above], Parkinsonism and diabetes.

The Cholinergic system is based on *acetylcholine* [*ACh*], formed from *choline* and acetylcoenzyme A [AcCoA][an intermediary product in metabolism of carbohydrates, fatty acids and some amino acids; present in all animal cells], by the enzyme *choline* acetyltransferase [ChAT][which has a high *glutamine* content] using glucose and acetylcarnitine as acetyl-group donors. *ACh* synthesis is inhibited by omission of Na+. *ACh* is essential in the PNS for controlling muscle contractions, and thus, movement. If present in excess at the skeletal-neuromuscular junction, it can cause relaxation instead. In the CNS, it is important in modulating learning, memory, mood, REM sleep, energy conservation, attention span and behavioural arousal; it generates theta-EEG rhythms. *ACh* also inhibits high-affinity *choline* carriers, as a regulatory factor.

There are two main types of cholinergic receptors – nicotinic [subdivided into c-10 (muscle type), c-6 (neuronal type; ganglionic) and neuronal α-bungarotoxin binding site (neuronal type; α-bungarotoxin-sensitive)] and muscarinic [M1, M2, M3, M4 and M5]. Nicotinic receptors produce rapid and typically brief excitation. They induce release of *Ep* and *NE*, and initiate muscular contraction. Their blockage produces skeletal relaxation. Presynpatic nicotinic receptors modulate *DA* release in the striatum. Muscarinic M1 receptors produce excitation which is slower in onset and more prolonged. M2 receptors are inhibitory. M3, M4 and M5 are little known. Muscarinic receptors slow heart-rate, produce vasodilation, constrict the pupil and relax the lens of the eye, increase the tone of GI smooth-muscle contraction, contract the urethra and bladder, and increase secretions in salivary glands, sweat glands, intestinal enzyme-secreting cells, parietal cells in stomach, and mucous glands in bronchi. In the CNS, they are responsible for promoting and/or regulating short-term memory, vomiting, and resting body tremors. Their blockage can cause relaxed eye muscles [resulting in lack of ability to focus], pupil dilation, increased heart-rate, reduced secretions, reduced gastrointestinal tone, delirium and hallucinations – and sometimes death from respiratory paralysis.

After transmission, *ACh* is broken down by either acetylcholinesterase [AChE] or butyrylcholinesterase [BuChE, or pseudocholinesterase]. AChE is predominant in brain and muscle, and hydrolyses only *ACh*; BuChE is a second-rate enzyme found in the serum, and hydrolyses *ACh* as well as other esters of *choline*. High concentrations of *ACh* inhibit AChE. *ACh* metabolism results in acetic acid and *choline*, which can be reutilised.

The Histaminergic system is based on *histamine* [*Hi*], produced from L-histidine by the enzyme histidine decarboxylase [HDC], which also acts on N-methylhistidine at a lesser rate. *Hi* is an important mediator in regulating gastric acid secretion in the gut, and is also involved in motion sickness. An intestinal barrier prevents more than 99% of *Hi* from reaching the circulation. It has weak direct effects, but strongly potentiates excitatory signals. It is excitatory in the CNS [at least in part due to its ability to stimulate *NE* release], facilitating arousal, sensitisation and blood flow, as well as powerfully stimulating cAMP. It may aid in memory retention. Given i.v., it dilates cerebral arteries; it can cause increased heart rate and tachycardia; it activates suppressor cells and reduces antibody secretion. Centrally administered, it elevates plasma levels of corticosterone, *vasopressin* and *adrenocorticotropin* [*ACTH*] [discussed later] and the opioid peptides β-*endorphin* and β-lipotropin. *Hi* release is induced by *morphine*, *codeine*, dynorphin, β-*endorphin* and α-neoendorphin. Its production is enhanced by vitamin B12; vitamin C has an anti-*histamine* effect.

H1 receptors mediate inflammation, which is observed in the case of an allergic reaction or a nettle sting [see **Urtica**]. Antagonism of this receptor results in sedation, analgesia and impaired vigilance. H2 receptors mediate anti-inflammatory action, and their antagonism may result in antidepressant activity. H3 receptors regulate *Hi* production.

After use, *Hi* is metabolised in any of a number of ways. In the brain, it is usually converted to t-N-methyl-imidazoleacetic acid [t-Me-ImAA], by the enzyme histamine N-methyltransferase [HMT], which produces t-N-methylhistamine from *Hi*, which is oxidised by MAO-B to t-N-methyl-imidazoleacetaldehyde, and further stripped by either aldehyde dehydrogenase [ALDH], aldehyde oxidase [ADO] or xanthine oxidase [XO] to t-Me-ImAA. It may also alternatively be converted along a similar route [starting with indolethylamine N-methyltransferase (IMT)] to pi-Me-ImAA. N-methylhistamines strongly inhibit HMT, as do quinine-type antimalarial drugs, *5-HT* and its methylated-derivatives, and the catecholamines *DA*, *tyramine*, *PEA* and 3-methyltyramine. Another route of destruction, usually in the gut and elsewhere in the periphery, uses the enzyme diamine oxidase [DAO; found in the intestine, kidney and plasma] to produce imidazoleacetic acid [*imidazole-4-acetic acid*; ImAA; IMA], which has hypnotic and possibly analgesic activity in rats and mice; some seizure activity has also been observed, and it also attenuates arterial pressure. It potently inhibits neurons in the cerebral cortex, and mimics some actions of *GABA*, also inhibiting release of DAO. It enhances benzodiazepine-binding to *GABA*a receptors [see below], binds to *GABA*c receptors as an antagonist [and possibly a weak partial agonist], and also binds to I1-imidazoline receptors [see above]. ImAA has been detected in brain, CSF, and plasma, though its formation and function in the nervous system are still poorly known. *Hi* may also be converted to γ-glutamylhistamine by γ-glutamyltransferase, or to N-acetylhistamine by acetylcoenzyme A and N-acetyltransferase [NAT].

The GABAergic system is based on *GABA* [*γ-aminobutyric acid*], an inhibitory neurotransmitter produced from L-*glutamic acid* [glutamate] by glutamic acid decarboxylase [GAD], with vitamin B6 as a co-factor in the reaction. It may also be produced from *glutamine*, which can be made from *glutamic acid* by glutamine synthesase and NH_3. *GABA* release is calcium-dependent, and it aids in the metabolism of carbohydrates in the CNS. It is involved in control of spinal reflexes, decreases the firing rate of neurons and inhibits excitatory neurotransmission. Through this activity it also acts as an antispasmodic muscle-relaxant. It is released in males at orgasm, and reduces anxiety and active sexual response, though it promotes active sexual response in females. Despite its inhibitory effects, it can paradoxically have disinhibiting effects on behaviour. *GABA* inhibits *NE*-induced stimulation of N-acetyl transferase activity in the pineal. *Glutamic acid* and *glutamine* also have their own activity within this system, their excitatory actions being opposite the inhibitory actions of *GABA*. Also acting in this system are L-*aspartic acid* [aspartate] and *glycine*. *Aspartic acid* can be synthesised from *glutamic acid*, with aspartate aminotransaminase and oxaloacetic acid, and like L-*glutamic acid*, is excitatory in nature. *Glycine* is found in all body tissues, and is also obtained from the breakdown of proteins, peptides, nucleotides and nucleic acids; it can also be formed from carbohydrates by 3-phosphoserine and serine; in the CNS it can be made from serine by serine hydroxymethyl transferase and tetrahydrofolic acid. It is inhibitory, and aids CNS functions. Both *aspartic acid* and *glycine* are dependent on potassium and calcium for their release. *GHB* [*γ-hydroxybutyric acid*] is also found in the brain in small amounts, though found in highest levels in the thalamus, hypothalamus and substantia nigra of adult humans. It appears to be produced from *GABA*, through the action of GABA-aminotransferase, with succinic semialdehyde as an intermediate metabolite, which is then converted to *GHB* by means as yet unclear. It is metabolically destroyed by reconversion to succinic semialdehyde, and then to succinate via the action of succinic semialdehyde dehydrogenase [SSADH]. Some people have a genetic lack of SSADH, which produces an abnormal increase in *GHB* levels, with symptoms of the disorder including "severe psychomotor retardation, ataxia and convulsions." *GHB* acts as a hypnotic tranquilliser and mild anaesthetic, with euphoriant and inebriating properties. It binds to its own *GHB* receptors, which are associated with some *GABA* receptors, and also shows partial binding to *GABA*b receptors. Its uptake is inhibited by *harmaline* [most potent], 2-OH-cinnamic acid, citrazinic acid and 3-(2-furyl)acrylic acid. N-acetylaspartylglutamate [NAAG], first discovered in the mammalian nervous system in 1965, has only recently been accepted as a neurotransmitter; this is surprising, as it is known to be the most abundant peptide neurotransmitter in the CNS. It is a highly selective agonist of mGluR3 receptors, and is also a low-potency agonist of NMDA receptors [see below]. It suppresses excitotoxicity, inhibits *GABA* release in the cortex, and reduces cAMP levels. NAAG is synthesised from N-acetylaspartate [NAA] and *glutamine*; NAA may also be a neurotransmitter. After use, NAAG is hydrolysed back to NAA and *glutamine*, and further hydrolysed to *aspartic acid* and acetate.

There are several types of *GABA* receptor – the inhibitory receptors, *GABA*a, *GABA*b [subdivided into b1-α, -β, -Δ and b2], benzodiazepine [BZ] 1 and 2, and barbiturate [BARB]; and the excitatory ion-channelled *glutamate* receptors [iGlu], N-methyl-D-aspartate [NMDA][subdivided into *glutamate* and *glycine* sites], quisqualate [quisqualic acid; α-amino-3-OH-5-methylisoxazole-4-propionic acid; AMPA] and kainate [kainic acid; activated by *aspartic acid*, *glutamine* and *glutamic acid*], and G-protein or metabotropic *glutamate* receptors [mGlu; subdivided into mGluR-1, -2, -3, -4, -5, -6, -7 and -8]. Activation of the *GABA* receptors by an agonist increases the binding-capacity of agonists for the BZ receptors. *GABA*a antagonism enhances CNS cholinergic activity, and *GABA*b antagonism does this as well as producing an antidepressant action. BZ receptors are affected by benzodiazepine-type drugs [eg. *diazepam* (Valium™)] and some plant flavones. A natural ligand has not been positively singled out, although *diazepam*, nordiazepam and N-desmethyldiazepam have been identified in human brain and plasma [possibly of plant origin]. They increase *GABA* function by preventing its reabsorption, which inhibits cholinergic neurons. BARB is affected by barbiturate-type drugs [eg. phenobarbitol], and a natural ligand has not been found; it increases the affinity of *GABA* for its receptor and increases the duration of its activity. NMDA receptors may be important in learning and memory processes. NMDA antagonism produces analgesia, amnesia, disinhibition, agitation

and a dissociative state with hallucinations. Excessive antagonism leads to respiratory depression, increased blood pressure and unconsciousness. Examples of NMDA-antagonists include the synthetic hallucinogenic anaesthetics PCP and ketamine. NMDA activity stimulates post-synaptic release of arachidonic acid [see *anandamide* below]. Antagonists of postsynaptic *glutamate*-receptors in the hypothalamus [an NMDA-complex coupled to a nitric oxide/cGMP signalling pathway] block the light-induced suppression of *melatonin*.

GABA is either reabsorbed after transmission, or broken down by the enzyme GABA-aminotransferase [GABA-α-oxoglutarate transaminase; GABA-T] with α-oxoglutaric acid [and vitamin B6 as a co-factor] to succinic semialdehyde, which is oxidised to succinic acid by succinic acid semialdehyde dehydrogenase, which then enters carbohydrate metabolism. *GABA* uptake is inhibited by ketamine, β-alanine, guvacine, nipecotic acid, and even *GABA* itself. *Glutamine*, after use, is usually converted back to *glutamic acid* by hydrolysis. *Glutamic acid* is broken down to α-ketoglutaric acid, by the enzyme glutamic acid dehydrogenase, or it may be reabsorbed, and converted to *glutamine*. A dysfunction of glutamic acid dehydrogenase can result in signs of neurotoxicity, due to increased CNS levels of *glutamic acid*, which in high concentrations is known to cause neuronal death from over-excitation [excessive and prolonged depolarisation].

The Opioid system is based on a group of peptides which, in general, produce analgesia, sedation and sometimes a feeling of well-being. One of these, β-*endorphin*, has been proposed to be important in learning and memory processes, but data are ambiguous and inconclusive. Pro-*enkephalin* is the precursor to *methionine-enkephalin*, leucine-*enkephalin*, octapeptide, heptapeptide, peptide E, peptide F, BAM 12, BAM 18 and BAM 22; prodynorphin is the precursor to leucine-*enkephalin*, dynorphin A, dynorphin B, α-neoendorphin and β-neoendorphin; and proopiocortin is the precursor to *ACTH* [*adrenocorticotropin*; discussed later], as well as α-, β- and γ-*endorphins*, which can also be made instead from β-lipotropin. More recently, endomorphin-1 and endomorphin-2 have been found as endogenous brain opioids. The *endorphin*s and *enkephalin*s are the best known of all of these. Tyrosine seems to be essential for the opiate-like effects of β-*endorphin* and *methionine-enkephalin*, which α-*endorphin* mimics. The latter peptide has been said to possess some *amphetamine*-like effects. β-*Endorphin* release from the posterior lobe of the brain is inhibited by *dopamine*. Opioid peptides impair the release of *ACh*, *NE* and *DA*, and inhibit testosterone, LHRH and LH [see below]; their actions are facilitated by *5-HT*. They are distributed throughout the CNS; *endorphins* are also found in the pituitary gland and in the adrenals. Their release is calcium-dependent. *Enkephalin* release is triggered partly by *GABA* receptors.

μ-Opiate receptors are most potently affected by β-*endorphin*, followed by *morphine* and the endomorphins, *methionine-enkephalin* and leucine-*enkephalin*, respectively. They cause slowed pulse, constricted pupils, respiratory depression, analgesia, and withdrawal syndrome if dependence is allowed to occur. Agonists of μ-receptors antagonise the effects of *DMT* and LSD in low doses; higher doses enhance the effects. δ-Opiate receptors [subdivided into δ-1 and δ-2] are affected most strongly by leucine-*enkephalin*, followed by *methionine-enkephalin*, β-*endorphin* and *morphine*; it has similar actions to the μ-receptor. κ-Opiate receptors are sensitive to dynorphins, neo-*endorphins*, and *salvinorin A*; they elicit some degree of analgesia and diuresis, cause weak respiratory depression, and can produce 'dysphoric pseudo-hallucinations'. They down-regulate μ-receptor mediated analgesia in opiate-naive rats, and potentiate it in opiate-dependent animals. Agonists at this receptor also elevate corticosteroid levels, modulate immune response, decrease pilocarpine-induced seizures and neurotoxicity, and mediate 'aversive' effects of Δ-9-*THC*. (-)-Naloxone, which is a synthetic μ-κ-antagonist, enhanced the effects of *DMT* and LSD in low doses. Activation of opiate receptors also boosts *norharman* [β-carboline] levels.

After release, peptides are broken down by peptidase enzymes, and the fragments diffuse into the extracellular space. *Morphine* and *codeine* have also been found in human milk, urine and CSF, though their metabolic origin is unclear.

The Anandamide system has only recently been discovered, and relatively little is known about it [compared to the other major systems]. *THC* and other cannabinoids from **Cannabis** bind to cannabinoid receptor sites to produce their effects, which may also involve interaction with the opioid and dopaminergic systems. The central receptors which mediate psychoactive effects are known as CB1, and peripheral receptors as CB2, although CB1 receptors are also found peripherally. Activation of CB receptors inhibits the enzyme adenylate cyclase, decreases cAMP levels, produces analgesia for some types of pain, protects against brain ischaemia, ameliorates some symptoms of Multiple Sclerosis, enhances cerebral blood flow, and stimulates feeding in newborns. Agonists of CB1-receptors also inhibit *glutamine* transmission. Some CB1 receptors are also located on presynaptic nerve terminals, and their activation inhibits release of *serotonin*, *acetylcholine*, *norepinephrine*, *GABA* and *glutamine*. Their effect on *dopamine* release is contradictory, with in vitro rat brain studies showing inhibition, and in vivo studies showing stimulation. CB1-mediated sedation is potentiated by D2-receptor agonists, and activation of D2-receptors enhances *anandamide* release in the striatum. *Anandamide* [N-arachidonylethanolamine; AnNH] is one of the endogenous ligands for CB receptors [though with a 30 times greater affinity for the CB1 receptor], and is a long-chain fatty acid amide and neurotransmitter. It partly mimics the effects of **Cannabis**, and is produced from arachidonic acid and ethanolamine, with N-arachidonylphosphatidylethanolamine as an intermediary product, via hydrolysis by the enzyme phospholipase D. It has also been shown to weakly bind to vanilloid VR1 capsaicin receptors [see **Capsicum**], possibly modulating pain response. A second CB ligand in the brain was later discovered, *sn*-2-arachidonylglycerol [2-AG], which is 170 times more prevalent in the brain than *anandamide*, and is a full agonist of CB receptors. 2-AG seems to be present in lower levels in CSF. It is produced from phosphatidylinositol(4,5)-bisphosphate by the action of phospholipase C, resulting in 1,2-diacylglycerol [DAG], which is transformed into 2-AG by the action of DAG lipase. Both *anandamide* and 2-AG have been shown to protect neurons in the cerebral cortex from ischaemic damage, and act as neuroprotectants after traumatic brain injury, as well as modulating the immune system, blood pressure, fever, pain, cognition and memory. Arachidonic acid may be released post-synaptically by NMDA-receptors, and it serves to increase neurotransmitter output of pre-synaptic neurons, strengthening their function. *Anandamide* and 2-AG are metabolised by fatty acid aminohydrolase, or FAAH [a.k.a. anandamide aminohydrolase, or oleamide hydrolase], and/or a monoacylglycerol-like enzyme. Two other endogenous fatty acid amides, oleamide and palmitoylethanolamide, have putative actions on the CB receptors. Oleamide is a hypnotic, soporific and analgesic, which interacts with CB1 and CB2 receptors to a small degree, 5-HT2a receptors and benzodiazepine-sensitive *GABA*a receptors to a higher degree. It mimics the behavioural and analgesic effects of *anandamide* in mice, despite its lack of significant CB-receptor binding. Palmitoylethanolamide mediates analgesic, antiinflammatory and antioxidant activities, which may also interfere with the metabolism of *anandamide*, and has binding activity at CB2 and putative CB receptors. Recently it has been shown that schizophrenic patients have higher levels of *anandamide* and palmitoylethanolamide in their CSF, as compared with non-schizophrenic controls.

The Purinergic system only recently came to be considered a NT-system – it is based on *adenosine*, a purine alkaloid which is released by neurons and received by its own receptors [the required criteria for a neurotransmitter]. When activated, they produce behavioural sedation, bronchospasm, and dilation of cerebral and coronary blood vessels, as well as regulating oxygen supply to cells, and decreasing the force of heart contractions. These receptors also cause inhibition of the release of *NE*, *DA*, *ACh*, *GABA* and *glutamine*. Purinergic receptors are classed as P1 [subdivided into A1, A2a, A2b, A3 and A4 types] or P2 [subdivided into P2x, P2y, P2z, P2t and P2u types]; the former react with *adenosine*, the latter with ATP-derivatives.

Other minor receptor types

Endothelin ETa, ETb and possibly ETc receptors

σ ***[Sigma], σ-1 and σ-2 receptors [once putative opioid receptors]*** – mediate some of the actions of PCP and ketamine [these are powerful dissociative-anaesthetics with some 'psychedelic' activities].

Somatostatin SSTR1, SSTR2, SSTR3, SSTR4 and SSTR5 receptors - see GHRIH below.

Tachykinin NK1, NK2 and NK3 receptors

Trace amine [TA] receptors - recently discovered in central and peripheral nervous systems, causes cAMP production and may mediate anxiolysis; ligands include many human trace amines including *tryptamine*, *DMT*, *tyramine* and *phenethylamine*, and the non-endogenous *amphetamine*, *methamphetamine*, MDMA and LSD.

Vanilloid VR1 receptors – ligands include capsaicin, N-vanillyloleamide [olvanil] and *anandamide*. Activation increases peptide release, modulates pain, causes vasodilation.

Vasopressin V1b receptors – ligand is *vasopressin* [see below]. Mice lacking these receptors were found to be less aggressive, though with deficits in social recognition, suggesting that antagonists of V1b receptors may also act as 'anti-aggression' agents.

Hormone substances and co-transmitters

The following are substances which are not thought to be true neurotransmitters, yet have neurotransmitter-like activities, or aid in the regulation of consciousness and physiological function. They are usually secreted into the blood or bodily fluids to be dispersed to other areas distant from the point of release.

Adrenocorticotropin [ACTH] stimulates the proliferation of the adrenal cortex, and activates release of hormones from the adrenal cortex. It is important in initiating and mediating complex behaviours, and improves learning, memory, and skill retention.

Androstenol or 5α-androstenol [5αandrost-16-en-3α-ol] is a pheromone made in the testes, and secreted by men in armpit sweat; it is also found in female urine. It may have some sexual arousal effects in humans.

Androstadienone is a male steroid hormone which may act as a pherom-

one; it appears to stimulate and improve mood in women, while acting as a sedative in men.

Angiotensin II is a brain peptide which controls peripheral blood pressure, and drinking behaviour. It stimulates *vasopressin*, *oxytocin*, *ACTH* and LHRH release [see below]. Angiotensin has receptors, divided into ATa and AT2 types; they are activated by angiotensin II and III.

Arginine vasotocin [AVT] is a peptide synthesised by the pineal. Its release into CSF is triggered by *melatonin*, and it seems to be responsible for some of *melatonin*'s effects on sleep [increasing REM sleep, and colour and intensity of dreams].

Bradykinin is a peptide which when injected into parts of the brain caused analgesia and raised blood pressure. It has B1 [BK1] and B2 [BK2] receptors.

CART [*cocaine* and *amphetamine* regulated transcript] peptides are forms of messenger RNA found in the brain and gut. CART 55-102 is a form which has been found to mediate [at least partially] locomotor and CNS effects of *cocaine* and *amphetamine*. It appears to act as an agonist at D2 *dopamine* receptors.

Cholecystolkinin [CCK 8] is a brain peptide that may aid in *DA*-regulation. It seems to be involved in improving learning and memory. CCK-8 sulfate ester is a sedative. There are cholecystokinin receptors – CCKA [CCK1] and CCKB [CCK2; gastrin receptor].

Cortisol is an adrenal steroid, secreted along with progesterone and *DHEA*. It is excitatory, but long-term stimulation causes depression and exhaustion. Its release is triggered by brain peptides, mediated by *ACTH* from the pituitary gland, as well as [indirectly] corticotropin-releasing factor [CRF] and *vasopressin* from the hypothalamus. CRF is anxiogenic and causes arousal; it may improve memory.

Dehydroepiandrosterone [DHEA] is the most abundant steroid in the blood, and is produced by the adrenal gland from cholesterol, which is converted to pregnenolone, then either to *DHEA* or progesterone and cortisol. Its secretion is stimulated by *ACTH*, and possibly prolactin, and it is released episodically throughout the day, along with cortisol. It also seems to be made in the brain, where it is excitatory and prevents degradation of neurons. Here it shares some properties with its precursor, pregnenolone, as they are both excitatory in areas of the brain that promote active sexual arousal; they inhibit *GABA* and BZ binding. Increase of *DHEA* production protects immune function, inhibits carcinogenic tumours, promotes bone growth, promotes weight loss, boosts energy utilisation, lowers conversion of energy to stored fat, lowers cholesterol, opposes the toxicity of glucocorticoid steroids, increases EEG theta wave amplitude, and reduces prolactin and *5-HT*. It is metabolised to estrogens, androgens, androsterone, and possibly pheromones in the skin. *DHEA* levels usually decrease after about age 30, and continue to decline.

Delta-sleep-inducing peptide has been found in the brainstems of sleeping and sleep-deprived mammals. Little is known about it, but obviously it is a peptide, and aids in inducing delta-wave sleep.

Diazepam-binding inhibitor [DBI; 'anxiety peptide'] is a brain peptide which binds to the benzodiazepine receptor in the *GABA*-system, blocking its effect and causing anxiety.

2-Dimethylaminoethanol [DMAE] is present in small amounts in the brain, and enhances the production of *ACh* [it is a precursor to phosphatidyl-*choline*]. It is a mild stimulant which elevates mood, increases intelligence, improves memory and learning, increases physical energy, and may help extend life-span, as well as improving sleep.

Estratetraene is a female steroid hormone which may act as a pheromone; although reputed to attract men, it appears to stimulate and improve mood in women, while acting as a sedative in men.

Estrogens [oestrogens] promote sex drive in females, by increasing desire, responsiveness and lubrication. The estrogen estradiol inhibits MAO; estrogens also facilitate the actions of *5-HT*, opioids, prolactin and *oxytocin*.

Growth hormone [GH] supports the growth of body tissue, as well as generating a calm and confident mood.

Growth hormone release inhibitory hormone [GHRIH; somatostatin (SOM)] prevents release of GH and *ACTH*, and inhibits TRH [see below]. It blocks the release of VIP [see below], insulin, glucagen, gastrin and renin in the gastro-intestinal system.

Luteinising hormone [LH] stimulates ovulation, progesterone synthesis in the ovaries, and testosterone synthesis in the male gonads. It appears to initiate sexual attraction and approach.

Luteinising hormone releasing hormone [LHRH] is a peptide released from the hypothalamus, which triggers release of LH from the pituitary. It has some effects on spatial orientation processes associated with learning.

Neurophysins I & II are proteins which are bound to *oxytocin* and *vasopressin*, respectively, and they are stored with them in the pituitary.

Nitric oxide [NO] is a gas which acts as an intra-cellular messenger, or neuromediator. It is formed from L-arginine by the enzyme nitric-oxide synthase [NOS], which produces L-citrulline and NO. NO is thought to be important in learning and memory, and it is formed mostly in areas of the brain important for these functions. Inhibition of NOS has been shown to impair learning and memory processes in primates. NO diffuses from nerve terminals, and forms covalent linkages with several potential targets. It activates the enzyme guanyl cyclase [this converts guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP), which work very similarly to ATP and cAMP, respectively], causing vessel-dilation; and regulates secretion of LHRH, prolactin, *oxytocin* and *vasopressin* [see below]. Carbon monoxide works as a neuromodulator in a similar way.

Oxytocin is secreted from the pituitary gland and has its own receptors, and is now regarded by some as a true neurotransmitter. It controls milk ejection, and speeds uterine contractions during labour; it is also a key substance known to be released in large amounts during orgasm, in short pulsatory bursts, followed by a rest period. Because it reaches its saturation levels rapidly, excessive or prolonged doses block its effects. It is involved in interpersonal bonding, and facilitates attraction and touch sensation. It may have a negative effect on memory retention. It increases circulation of *DA*, *Ep*, *5-HT*, prolactin, VIP, *vasopressin*, testosterone, estrogen, prostaglandin [see below] and LHRH, as well as increasing *glutamate*, α-1 adrenergic and cholinergic activity.

Pre-pro-opio-melanocortin [POMC] is a precursor to *ACTH* and the *endorphins*.

Progesterone is a sexual depressant, reducing sensation and neural excitation. It can cause depression and irritability, and lower testosterone levels. Its actions are facilitated by *5-HT*, and it facilitates opioid activity.

Prolactin is an inhibitory hormone secreted by the pituitary gland. It is involved in sperm production, and lowers sex drive.

Prostaglandins are fatty acids derived from arachidonic acid, catalysed primarily by cyclo-oxygenase enzymes [which are inhibited by aspirin and paracetamol]. They are synthesised and released as needed, and modulate *NE* release, as well as causing ANS stimulation. In the hypothalamus, they may be associated with producing fever caused by bacterial toxins. Also derived from arachidonic acid in this process are prostacyclin [very unstable; potently inhibits platelet aggregation; a potent vasodilator which can cause hypotension] and thromboxane A2 [very unstable; enhances platelet aggregation; released from tissues following injury]. Leucotrienes are metabolites of arachidonic acid, and are also released locally in response to injury, or antigen-antibody reaction.

Sleep-Promoting Substance A [SPS-A] is also known as uridine; it has been found in sleeping and sleep-deprived mammals, and enhances slow-wave sleep and dream-sleep.

Sleep-Promoting Substance B [SPS-B; GSSG] is oxidised glutathione, or γ-glutamyl-cysteine-*glycine* disulfide; see SPS-A above. This compound has also been shown to inhibit *glutamic acid*-binding.

Substance P is a neurokinin peptide found in the CNS and other parts of the body. It modulates the sensations of pleasure and pain, causing a pain reaction, inflammation, and some vasodilation; it also facilitates memory. It causes smooth-muscle contraction in the gut, and is the endogenous ligand for the neurokinin-1 [NK-1] receptor.

Taraxein is a protein complex which has been isolated from the blood serum of schizophrenics. Injected into 'normal' subjects, it produces many symptoms of schizophrenia; administered to a schizophrenic patient in remission, it caused a return of symptoms. It also renders *adrenolutin* active in smaller amounts than usual. Human subjects comparing it to LSD, *mescaline* and *psilocybin* all found taraxein to have the most unpleasant CNS and peripheral effects [for the record, most subjects reacted favourably to the other psychedelics]. This substance has, for some reason, received little further study, and I am not aware of the active principles ever being isolated.

Testosterone promotes sex drive, assertiveness and aggression. It inhibits MAO; facilitates the action of *DA*, *Ep* and *vasopressin*; and inhibits *5-HT*, opioids and prolactin.

Thyrotropin-releasing hormone [TRH] is a peptide which controls release of TSH [see below] from the pituitary gland. It stimulates release of prolactin, GH, *DA* and *NE*, causing central stimulation [along with excitation and hyperactivity]. Its release is calcium-dependent, and is caused by potassium or electrical stimulation.

Thyroid-stimulating hormone [TSH; thyrotropin] is released from the pituitary, and stimulates thyroid gland activity, such as thyroid-hormone secretion, essential for normal metabolic processes, and mental and physical development.

Vaso-intestinal polypeptide [VIP] is found in the alimentary canal, pancreas and gall bladder. It relaxes most smooth muscle, causing vasodilation, hypotension, bronchodilation and relaxed intestinal muscle. It induces the pancreas to release insulin, glucagen and GHRIH; and the adrenals to create steroids. It causes excitation in CNS neurons, where it stimulates release of prolactin, LH and GH from the pituitary; it also has *ACh*-potentiating activity at some muscarinic *ACh*-receptors, and increases *choline* acetyltransferase activity. In the pineal, it stimulates cAMP and N-acetyltransferase activity. VIP release is calcium-dependent.

Vasopressin [anti-diuretic hormone] is also released from the pituitary – it prevents water and salt depletion by inhibiting urination, stimulating thirst and stimulating water reabsorption in the kidney. It is excitatory, and facilitates sexual arousal in combination with testosterone; it also improves attention, concentration, memory retention and memory recall. In some parts of the brain, it may sensitise cholinergic and *glutamate* activity. It is facilitated by α-1 adrenergic receptors, and increased by *ACh*, *DA*, testosterone, estrogen, dynorphin, substance P, angiotensin II, *nicotine*, and *yohimbine*; it is decreased by *5-HT*, opiates, *endorphins*, *GABA*, α-2 adrenergic activity, progesterone and alcohol. In some neurons, it can enhance response to *glutamic acid*, though in others it inhibits the response. It also has some *ACTH*-releasing capacity. It potentiates both cAMP and *melatonin* production in the pineal induced by moderate *NE*-stimulation.

Zinc is a trace mineral nutrient discussed here as an exception – for other nutrients, see the next chapter. It is involved in sperm manufacture, and is excitatory, reducing *GABA* and opioid levels.

This chapter was compiled with the aid of the following references:

(Agoston 1988; Ameri & Simmet 2000; Arbo et al. 2008; Axelrod 1961; Axelrod et al. 1964; Baker 2000; Balemans 1981, 1985; Banerjee & Snyder 1973; Barchas & Usdin ed. 1973; Barker 1982; Barker et al. 1981; Baslow 2000; Bear et al. 1996; Beaton et al. 1975; Beck & Jonsson 1981; Bhattacharya et al. 1995; Biel & Bopp 1978; Binkley 1983; Binkley et al. 1979; Boger et al. 2000; Boulton & Juorio 1982; Bräuner-Osborne et al. 1997; Brenneman et al. 1993; Brossi 1993; Buckholtz & Boggan 1977; Callaway 1988; Callaway et al. 1995; Cardinale et al. 1987; Carpéné et al. 1995; Chahl 1991; Chowdhury et al. 1975; Christian et al. 1977; Claus et al. 1981; Coghlan 2002; Cohen et al. 1974; Collins 1983; Cottrell et al. 1977; Crenshaw & Goldberg 1996; Cryer 1992; Dean & Morgenthaler 1990; Deitrich & Erwin 1980; De Maio & Pasquariello 1964; De Rienzo et al. 1997; Devane & Axelrod 1994; Dickenson 1989; Di Marzo et al. 1996, 1999, 2000; Di Tomaso et al. 1996; Domino 1986; Dong-Ruyl et al. 1998; Dresser et al. 2000; Fagan 1997; Feenstra et al. 1983; Fillenz 1984; Finnin 1979; Franzen & Gross 1965; Fuhr et al. 1993; Garattini & Valzelli 1965; Garrett & Holtzman 1993; Gifford et al. 2000; Gillin et al. 1976; Glover 1998; Grady et al. 1992; Guchhait 1976; Haber et al. 1999; Hagen & Cohen 1966; Harborne & Baxter ed. 1993; Hartley & Smith 1973; Hattori et al. 1995; Haubrich et al. 1981; Hazum et al. 1981; Heath et al. 1957; Herz 1980; Hoffer & Osmond 1960; Holden 1999; Honegger & Honegger 1959; Houser et al. 2000; Hryhorczuk, L.M. et al. 1986; Hucklebridge et al. 1998b; Jacob & Presti 2005; Jansen 1990; Julien 1995; Kaplan & Sadock ed. 1989; Kapp 1958; Katzung & Trevor 1995; Kebadian & Neumeyer ed. 1994; Keller & Ferguson 1976a, 1976b; Kety 1961; Kimmel et al. 2000; Kolb & Whishaw 1995; Komoda et al. 1990; Kovacs & De Wied 1994; Krnjevic 1988; Kruk & Pycock 1983; Kveder & McIsaac 1961; Lambert & Di Marzo 1999; Lea 1955; Lee et al. 2005; Levi et al.1991; Leweke et al. 1999; Lewis & Clouatre 1996; Louw et al. 2000; Lyttle 1993; Madras 1984; Malitz ed. 1972; Mandell & Walker 1974; Mandell et al. 1969; Mantegazzini 1966; Mårtens et al. 1959; Martin ed. 1996; Martin & Sloan 1970, 1986; Marx 1985; Maslinski & Fogel 1991; Matsubara et al. 1992, 1998; McCormick & Tunnicliff 1998; McIntyre & Norman 1990; McIsaac et al. 1961; McKenna et al. 1990; Medina et al. 1989; Medvedev 1996, 1999; Medvedev et al. 1995a, 1995b; Melander & Mårtens 1959; Mendelson & Basile 1999; Meschler et al. 2000; Mess et al. ed. 1985; Minami et al. 1999; Mindell 1982; Mitchell 1999; Moore 1978; Moore & Klein 1974; Moore-Ede et al. ed. 1992; Moret & Briley 1988; Müller 1987; Murphree et al. 1960; Musalek et al. 1989; Nakazi et al. 2000; Nathan 1998; Neale et al. 2000; Nyham 1987; Oon et al. 1977; Osvaldo 1974; Panikashvili et al. 2001; Parthasarathy 1999; Pavel et al. 1980; Peroutka 1993; Pevet 1983, 1985; Pfeiffer et al. 1957; Phillips 2000; Phillis et al. 1986; Piomelli et al. 2000; Prendergast et al. 1997; Rabin et al. 1997; Rakhshan et al. 2000; Relkin 1983a, 1983b; Rodnight 1983; Romijn 1978; Rosengarten & Friedhoff 1976; Rothwell 1996; Runkel et al. 1997; Saavedra 1989; Saavedra & Axelrod 1973; Sabelli & Giardina 1972; Sabelli et al. 1978; Sánchez-Blázquez et al. 1999; Sanger et al. 1999; Schwartz et al. 1991; Seiden & Dykstra 1977; Shulgin & Shulgin 1991, 1997; Silva et al. 1960; Sinor et al. 2000; Skup et al. 1983; Smith & Prockop 1962; Smith & Lane ed. 1983; Smythies et al. 1979; Song et al. 1996; Sprince 1970; Squires 1978; Stella et al. 1997; Stone 1993; Strassman 1990, 2001; Szara 1961a, 1961b; Szekeley et al. 1980; Szekeley & Ronai 1982; Szolcsányi 2000; Takeda et al. 1995; Tanimukai et al. 1970; Tasaka 1991; Tucek 1988; Tunnicliff 1992, 1998; Unseld et al. 1989; Vanderwolf 2000; Vayda 1992; Wachtler 1988; Watanabe et al. 1991; Webster & Jordan ed. 1989; Welch & Eads 1999; Wildmann et al. 1987, 1988; Wiley 1999; Winter et al. 1999a, 1999b; Wurtman 1987a, 1987b; Wyatt 1972; Wyatt et al. 1973; Yamatodani et al. 1991; Yatri 1988; Young 1983; Yu et al. 2003; Yuwiler 1983, 1990).

INFLUENCING ENDOGENOUS CHEMISTRY

Apart from the obvious techniques of drug consumption, our neurochemistry may be altered in a number of ways. For greater detail on some of the procedures discussed below, see also the enjoyable and accessible work of Wells and Rushkoff (1995). The practices outlined here are often used together in combination, and are usually more effective that way (Prince 1980; pers. obs.). They are also often used in combination with ingestion of sacred plants. Due to the often great synergy resulting from such combinations, minimal dosages of psychedelic sacraments are often suggested as being preferable, allowing one to focus whilst still reaching great depth. The reader is encouraged to find out more about the practices outlined here, as this can only be a summarisation, particularly in fields related to yoga and meditational practices. Yoga and Tai-Ch'i, in particular, are easiest to learn in a group situation with a teacher that you like.

Dietary influences

The diet is crucial to any CNS activity taking place, for without foods our vital organs, including the brain, would not function [possibly with adept 'Breatharians' excluded!]. Vitamins and mineral nutrients can have subtle influences on consciousness, as well as being important in physiological functions, some of which are involved in the regulation of neurochemistry. Some are vital as co-factors in the manufacture of neurotransmitters, while some aid in other processes necessary for consciousness, such as maintaining proper circulation [distributing, amongst other things, oxygen, which is essential for cells and neuronal function]. Nutrients are best absorbed in the form of food, rather than as supplements. Supplemental nutrient mega-dosing may sometimes do more harm than good, and should not be employed for extended periods. Here is a run-down of nutrients and their potential roles in CNS function, bearing in mind that these summaries are not complete:

Vitamin A [β-carotene; retinol] aids vision, builds resistance to respiratory infections, shortens duration of diseases and promotes healthy growth. Good sources are carrots, green & yellow veges, eggs, dairy products, yellow fruits, meats and fish liver oils.

Vitamin B1 [thiamine] keeps nervous system, muscles and heart functioning normally, and positively affects mental attitude. Needed most in stressful situations. It is also a powerful antioxidant. Good sources are dried yeast, rice husks, whole wheat, oatmeal, peanuts, bran, milk, seafood and most veges.

Vitamin B2 [riboflavin] is also needed in stressful situations, and benefits the vision, as well as inhibiting AChE. It has an important role in metabolism [particularly for that of B6], as well as aiding growth and reproduction. Good sources are milk, yeast, cheese, leafy greens, eggs and meats.

Vitamin B3 [niacin, or nicotinic acid; and another form of B3, niacinamide, or nicotinamide] can be made in the body from *tryptophan* by the enzyme tryptophan oxidase, requiring also B1, B2 and B6; it is also essential for the synthesis of cortisone, insulin and sex hormones. It is necessary for a healthy nervous system; a lack of it can bring about negative personality changes. Niacin can enhance memory, and nicotinamide has benzodiazepine-like activity [sedative, hypnotic, anticonvulsant in large doses; see *diazepam*]. Large doses [in the gram-range] should only be used under medical supervision, as they can cause liver damage, diabetes and other health problems. Good sources of B3 are whole wheat, brewer's yeast, eggs, roasted peanuts, avocados, dates, figs, prunes, fish and lean meats including poultry.

Vitamin B5 [pantothenic acid; pantothenol; panthenol] is vital for proper adrenal function, and helps in cell building and CNS development. It is needed in the conversion of *choline* to *acetylcholine*, and conversion of fats to energy, as well as antibody synthesis. Also a powerful antioxidant. Good sources are whole grains, wheat germ, bran, green veges, brewer's yeast, nuts and crude molasses.

Vitamin B6 [pyroxidine] is needed for proper absorption of B12, protein and fat. Helps convert *tryptophan* to niacin. Helps prevent nervous disorders, though too much [2-10g a day] can cause them [ie. mental overactivity]. It alleviates nausea, and promotes proper synthesis of anti-ageing nucleic acids. Can enhance dream-recall. Good sources are brewer's yeast, wheat bran and germ, cantaloupe, cabbage, milk, eggs, crude molasses and meats.

Vitamin B12 [cobalamin] needs calcium and a properly functioning thyroid to aid absorption. It increases energy and maintains a healthy nervous sytem – it can relieve irritability, as well as improving concentration, memory and balance. A deficiency, in time, can cause brain damage. Reported anecdotally to intensify dream colouration [in 1mg doses]; 3mg a day increases sensitivity to bright-light induced *melatonin* suppression. Good sources are fermented yeast, eggs, milk, cheese, mushrooms, fish, beef, pork and organ meats such as kidney and liver.

Vitamin B15 [pangamic acid] is an antioxidant, working best with vitamins A and E. It can speed recovery from fatigue, aid protein synthesis, protect against toxins and stimulate the immune system. Good sources are brewer's yeast, whole brown rice, whole grains, pumpkin seeds and sesame seeds.

Vitamin C [ascorbic acid] is important in growth and repair of cell tissue, and helps iron absorption, as well as being an antioxidant. It is used up rapidly during stress periods, and aids in preventing infections and allergies. It acts as a *dopamine*-receptor blocker. Good sources are citrus fruits, berries, green leafy veges, capsicum, tomatoes, cauliflower, potatoes, sweet potatoes, and rosehips.

Vitamin D [ergosterol; calciferol] may be produced in the skin with sunlight, or may be obtained from the diet. It aids in assimilation of vitamin A, calcium and phosphorous. Good sources are fatty fish, liver, egg yolks and dairy products.

Vitamin E [tocopherol] is an antioxidant stored in the adrenals, pituitary, testes, heart, blood, liver, muscles, uterus and fatty tissues. It is a vasodilator and anticoagulant which enhances the activity of vitamin A. Good sources are wheat germ, whole wheat, soya beans, vegetable oils, broccoli, Brussels sprouts, leafy greens, whole grain cereals and eggs.

Biotin [Coenzyme R; vitamin H] is essential for fat and protein metabolism. Deficiency causes extreme exhaustion. Good sources are nuts, fruit, brewer's yeast, egg yolk [without egg white, which prevents absorption], milk, unpolished rice and organ meats.

Calcium [Ca] maintains strong bones and teeth, and aids in iron metabolism. It aids impulse transmission in the nervous system, and can help alleviate insomnia. Good sources are dairy products, soy beans, peanuts, walnuts, sunflower seeds, dried beans, leafy green veges and salmon.

Folic acid is important for RNA and DNA production. It can ward off anaemia, and act as an analgesic. Good sources are dark-green leafy veges, carrots, tortula yeast, egg yolk, melons, apricots, pumpkins, avocados, beans, whole wheat, dark rye flour and liver.

Iodine [I; iodide] is mostly stored in the thyroid; it can improve energy and mental reaction times, as well as help in burning excess fat. Good sources are onions, seafood and kelp.

Iron [Fe] is needed for proper metabolism of B vitamins, as well as production of haemoglobin and some enzymes. It can prevent fatigue, and promote resistance to disease. Good sources are meats, fish, soybean hulls, dried peaches, egg yolks, nuts, beans, asparagus, spinach, molasses and oatmeal.

Magnesium [Mg] can reduce stress and depression, and is essential for nerve and muscle function. It is also needed in converting blood sugar to energy, and in metabolism of vitamin C, calcium, phosphorous, sodium and potassium. Good sources are figs, lemons, grapefruit, corn, almonds and other nuts, seeds, apples, dark-green veges, dairy products, meats and fish.

Phosphorous [P] requires vitamin D and calcium for proper utilisation. It is needed for the transference of nerve impulses, and is involved in virtually all physiological reactions. Good sources are whole grains, nuts, seeds, eggs and dairy products.

Potassium [K] works with sodium, and regulates water balance and heart rhythms. It is decreased by stress; deficiency of potassium and sodium together diminishes proper functions of nerves and muscles. It can aid in oxygenating the brain. Good sources are watercress, citrus, sunflower seeds, bananas, potatoes, green leafy veges and mint leaves.

Sodium [Na] helps with proper nerve and muscle function, and helps keep other mineral nutrients soluble for use. High intakes deplete potassium levels. Good sources are salt, carrots, beetroot and artichokes.

Zinc [Zn] can promote growth and mental alertness, and may be vital in DNA synthesis. It ensures efficient metabolism [especially of vitamin A], and maintenance of cells and enzymes. It is depleted by corticosteroids, and renders cells more resistant to toxins and oxidation. Good sources are wheat germ, brewer's yeast, pumpkin seeds, eggs, ground mustard, meats and seafoods.

Besides nutrients, the food we eat also contains trace amounts of other compounds which are either psychoactive, potential precursors, neurotransmitters or of interest due to their relation to chemicals in these criteria. However, many of these substances are weakly active at best, and do not easily cross the blood-brain barrier – also, they are concentrated in foods at relatively low levels. Thus, this information is presented primarily to illustrate the widespread nature of these chemicals. To be used practically, they would [in most cases] need to be extracted under laboratory conditions. In many of these plants, this would not be practical. Some of the hidden secrets in common foods are broadly summarised below. Bananas [see **Musa**], **Citrus**, passionfruit [see **Passiflora**], plums [see **Prunus**], eggplant and potatoes [see **Solanum**] will be discussed under

their own entries in the second part of this book.

Apple [Malus domestica] – *melatonin* [47.6 pg/g], AChEI's, *narcotine*; *phenethylamine* in leaves of an unidentified Malus sp.

Asparagus [Asparagus officinalis] – *melatonin* [9.5 pg/g]; shoots are regarded as aphrodisiac (Rätsch 1990) [see also *Endnotes*]

Avocado [Persea americana] – *serotonin* [5-HT] [10 µg/kg], *tyramine* [23 µg/kg], *dopamine* [DA] [4-5 µg/kg] [see also *Endnotes*]

Barley [Hordeum vulgare] – *melatonin* [378.1 pg/g], *gramine* [535 mg/kg fresh 14-day old plant shoots (var. Champlain)], *tryptamine* [2.18 mg/kg from same plant], *tryptophan* [46 mg/kg from same plant], 3-aminomethylindole, N-methyl-aminomethylindole, *5-HT* [in barley malt, along with N-methyl-*5-HT*, indole-3-acetic acid, 3-aminomethylindole, *gramine*], *tyramine*, N-methyl-*tyramine*, *hordenine*

Beetroot [Beta vulgaris var. cruenta] – *tyramine* [160 mg/kg], *DA*, AChEI's

Brewer's yeast [Saccharomyces cerevisiae] – indole-di-β-indolylmethyleneindolenine

Broad bean [Vicia faba] – *L-DOPA* [up to 0.25%, either in free-form or as a β-glycoside], epinine

Cabbage [Brassica oleracea] – *melatonin* [107.4 pg/g], *tyramine* [440-800 mg/kg], *narcotine* [0.00004%] [see also **Brassica**]

Carrot [Daucus carota] – *melatonin* [55.3 pg/g], *tyramine* [0-230 mg/kg] [see also **Daucus**]

Cucumber [Cucumis sativus] – *melatonin* [24.6 pg/g], *tyramine* [250 mg/kg] [see also *Methods of Ingestion*, *Endnotes*]

Ginger [Zingiber officinale] – *melatonin* [583.7 pg/g], acetone, benzaldehyde, *GABA*, *aspartic acid*, *borneol*, *camphor*, 6-gingerol [sedative and anti-*5-HT*], glucose [acetylcholinergic, memory enhancer], *glutamic acid*, *glycine*, histidine, iso-*eugenol*-methyl-ether, lecithin [source of phosphatidyl-*choline*], *methionine*, niacin, thiamine, *phenylalanine*, tyrosine, 6-shogaol [sedative, anti-*5-HT*], β-*thujone* [and many more] [see also *Endnotes*]

Grape [Vitis vinifera] – *tyramine* [24-1400 mg/kg], trans-1,2,3,4,5-pentahydroxypentyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [0.43-0.85 mg/L in juice], and the cis-isomer [1.5-3 mg/L in juice]

Indian spinach [Basella alba] – *melatonin* [38.7 pg/g]

Japanese butterburr [Patasites japonicus] – *melatonin* [49.5 pg/g]

Japanese radish or ***Chinese cabbage*** [Brassica campestris] – *melatonin* [657.2 pg/g], *tryptophan*-indoleacetamide, *tryptophan*-1-MeO-indoleacetonitrile, *tryptophan*-4-MeO-indoleacetonitrile [see also **Brassica**]

Kiwi fruit [Actinidia chinensis] – *melatonin* [24.4 pg/g] [see also **Actinidia**]

Lentils, brown [Lens esculenta] – desmethyl-*diazepam* [0.008-0.02 ng/g]

Mushroom, edible [Agaricus psalliota brunnescens] – *diazepam* [0.002-0.003 ng/g]

Oats [Avena sativa] – *melatonin* [1796.1 pg/g], *tryptamine* [0.03 mg/kg fresh] [see also *Endnotes*]

Onion [Allium cepa] – *melatonin* [31.5 pg/g]

Pea [Pisum sativum] – *5-HT* [0.0001% in stems, 0.00009% in tendrils], *tyramine*, *norepinephrine* [NE] [14 day-old plants – 0.00008% in stems, 0.00018% in tendrils, 0.0001% in leaf]

Pineapple [Ananus comosus] – *melatonin* [36.2 pg/g], *serotonin* [in juice], trans-1,2,3,4,5-pentahydroxypentyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [0-0.48 mg/L in juice, 0.0000089% in jam], and the cis-isomer [0.036-1.7 mg/L in juice, 0.000019% in jam]; eaten with 'chili' [see **Capsicum**] or taken in rum with honey, it is regarded as an aphrodisiac (Rätsch 1990)

Purslane [Portulaca oleracea] – *DA*, *NE*

Radish [Raphanus sativus] – *tyramine* [200 mg/kg], *melatonin* [112.5 pg/g]

Rice [Oryza sativa japonica] – *melatonin* [1006 pg/g], *diazepam* [0.006-0.05 ng/g], desmethyl-*diazepam* [0.003-0.004 ng/g], peptide opioid ligands in albumin

Soy beans, yellow [Glycine max] – *diazepam* [0.006-0.05 ng/g], desmethyl-*diazepam* [0.004-0.006 ng/g]

Spinach [Spinacia oleracea] – *tyramine* [up to 680 mg/kg], *DA*, rubiscolin-5 and rubiscolin-6 [opioid peptides derived from the common plant enzyme Rubisco (d-ribulose-1,5-biphosphate carboxylase/oxygenase); rubiscolin-6 has shown learning improvement and anxiolytic activity in mice, and appears to be an agonist at D1, sigma-1 and delta opioid receptors]

Strawberry [Fragaria magna] – *melatonin* [12.4 pg/g], trans-1,2,3,4,5-pentahydroxypentyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [c.0.000008% in jam], and the cis-isomer [c.0.000031% in jam] [see also *Endnotes*]

Sweet corn [Zea mays] – *melatonin* [1366.1 pg/g], *tryptamine* [0.05 mg/kg fresh], N-(p-coumaryl)-*tryptamine* [140 µg/kg], N-ferulyl-*tryptamine* [40 µg/kg], *tyramine*, desmethyl-*diazepam* [0.005-0.015 ng/g] [see also *Endnotes*]

Taro [Colocasia esculenta] – *melatonin* [54.6 pg/g] [see also *Endnotes*]

Tomato [Lycopersicon esculentum] – *tryptophan* [12 mg/kg from fresh 6-week old plant shoots], *tryptamine* [4 µg/g], *5-HT* [12 µg/g], *melatonin* [32.2 pg/g], *tyramine* [4-51 µg/g, leaves], 3-formylindole, indole-3-acetic acid, *narcotine*, traces of *nicotine*, AChEI's in leaves, trans-1,2,3,4,5-pentahydroxypentyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [0.06-0.43 mg/L in juice, c.0.000035% in ketchup, 0.000129% in tomato concentrate], and the cis-isomer [0.27-1.89 mg/L in juice, c.0.000121% in ketchup, 0.000519% in tomato concentrate]

Walnuts [Juglans regia] – *5-HT* [170-340 g/kg], *tyramine* [0.0095% in leaf]

Watermelon [Citrullus vulgaris] – *tyramine* [460 mg/kg]

Welsh onion [Allium fistulosum] – *melatonin* [85.7 pg/g]

Wheat [Triticum vulgare] – *tryptamine* [0.2 mg/kg fresh], *hordenine*, *diazepam*, N-desmethyl-*diazepam*, deschloro-*diazepam*, 2-chloro-*diazepam*, 7-deschloro-2'-chloro-*diazepam*, delorazepam, lormetazepam, exorphins A4, A5, B4, B5 and C [opioid peptides in gluten; A5 has improved learning in mice]

(Applewhite 1973; Bell 1973; Culvenor 1970; Ehmann 1974; Hanson 1966; Hartmann et al. 1972; Hattori et al. 1995; Herraiz & Galisteo 2002; Hirata et al. 2007; Husson 1985; Lovenberg 1973; Lundstrom 1989; Rimpler 1965; Schneider et al. 1972; Schulick 1996; Smith 1975; Teschemacher 2003; Udenfriend et al. 1959; Usneld et al. 1989; Wheaton & Stewart 1970; Whitaker & Feeney 1973; Wildmann et al. 1988; Yang et al. 2001; Yoshikawa et al. 2003).

Overindulging in cheese has long been said to result in nightmares, though whilst a recent study found a variety of cheeses to improve sleep and apparently increase and influence dream activity and content, nightmares were not reported. Interestingly, different types of cheese seemed to produce different kinds of dreams in the majority of test subjects. The pharmacology behind this is unknown, but often attributed to *tryptophan* for want of a better explanation (British Cheese Board 2005). Some cheeses use potentially psychoactive mould fungi in their manufacture [eg. see **Penicillium**], which might play a role in the phenomenon (pers. obs.). Also worth noting is the presence of traces of *morphine* in human and cow milk (Hazum et al. 1981; Teschemacher & Koch 1991), which would presumably also be present in cheese. Likewise, proteins present in milk may fragment to yield opioid peptides such as casoxin D or α-casein exorphins [from α-casein], β-casomorphins or β-casorphins [from β-casein], casoxins A. B & C [from κ-casein], α-lactorphins [from α-lactalbumin], β-lactorphin [from β-lactoglobulin] and lactoferroxins [from lactoferrin]. These act as opioid agonists, except the casoxins and lactoferroxins which act as antagonists (Teschemacher & Koch 1991; Teschemacher et al. 1997).

Morphine has also been found in hay and lettuce [2-10 ng/g] [see **Lactuca**] (Hazum et al. 1981). Peptides with opioid activity have been found in bovine serum albumin and hemoglobin, which may be present in meat (Teschemacher 2003). *Histamine* is found in large amounts in poorly stored fish [up to several g/kg], some ripened cheeses [up to 400 mg/kg], wine [generally below 10 mg/L], dry fermented sausages [400 mg/kg], soy sauce [220 mg/kg] and tamari [2393 mg/kg]. Oral ingestion of large quantities of *histamine* can cause typical symptoms of allergic-reaction, such as flushing, intense headache, nausea, vasodilation, constriction of chest, etc. (Slorach 1991). It may be that the "Chinese Restaurant Syndrome" that has been sensationalised by the media in the past, is due not only to MSG [monosodium-glutamate, a form of *glutamic acid*; flavour-enhancer 621], but also to *histamine* (pers. obs.). Soy sauce and sake [rice wine] also contain β-carbolines [THβC-3-carboxylic acid, 1-methyl-THβC-3-carboxylic acid, *harman* and β-carboline (*norharman*)] (Shulgin & Shulgin 1997); some of these [as well as *tetrahydroharman*] are also found in red wine (Allen & Holmstedt 1980; Shulgin & Shulgin 1997), as well as *anandamide* (Rätsch 1999b). Red wine, but not white wine, was shown to inibit cytochrome P450 3A4, but with only 16% of the efficiency of grapefruit juice in this regard [see **Citrus**] (Chan et al. 1998). Beer contains traces of 6-OH-THβC (Shulgin & Shulgin 1997), amongst other things [see also **Humulus**]. The β-carbolines can be formed from *tryptophan* by pyrolysis, as has been demonstrated in charred egg yolk [*harman*, *norharman*, 1-isopentyl-β-carboline and 1-(1-methyl-butyl)-β-carboline] (Tsugi et al. 1973) and roasted chicory root [Cichorium intybus] [*harman* and *norharman*] (Proliac & Blanc 1976), the latter of which also contains *lactucin*, lactucopicrin [see **Lactuca**], and related compounds [in both leaf and root, though some studies found no *lactucin* in roots], and has a sedative action antagonistic to *caffeine* (Balbaa et al. 1973; Kisiel & Zielinska 2001; Sessa et al. 2000). Chicory, incidentally, is said to be narcotic in India (Nadkarni 1976). The β-carbolines can also be formed under conditions that may occur during food processing, resulting from *tryptophan* reacting with glucose or other reducing sugars. These include 1-acetyl-β-carboline and (1R,3S)-1-(D-gluco-1,2,3,4,5-pentahydroxypentyl)-THβC [which may be transformed into 1-(D-gluco-1,2,3,4,5-pentahydroxypentyl)-β-carboline with oxidation] (Rönner et al. 2000). Processing is thought to be behind the formation of β-carbolines [*harman* and *norharman*] found in reasonably high levels in cooked fish and meat [especially when well-done], sauces such as soy sauce and Tabasco, fermented alcoholic bev-

erages, toasted bread and coffee [see **Coffea**]. Raw fish also contained THβC-3-carboxylic acid, with levels it and of 1-methyl-THβC-3-carboxylic acid increasing in cooked or smoked fish and meat; both act as precursors to *harman* and *norharman* (Herraiz 2000b, 2004). See also *Endnotes*.

Recent research has found that foods rich in fats and sugars [such as most 'fast food' and 'junk food'], despite being unhealthy, are mildly psychoactive and probably addictive, triggering release of brain *endorphin*s and *enkephalin*s which in turn induce *dopamine* release. This is a path of action shared by strongly habituating drugs such as heroin and *cocaine*, though of a lower magnitude than such drugs (Martindale 2003).

Alcohol and *caffeine*, which many people regularly consume with their meals, interfere with absorption of some of the vital nutrients, and should preferably be avoided or consumed at least 1-2 hours apart from meals. Alcohol was long thought to destroy brain cells by causing the withdrawal of necessary water from them (Dean & Morgenthaler 1990; Lewis & Clouatre 1996; Mindell 1982; Vayda 1992). Although it now appears that alcohol consumption does not markedly destroy neurons, it can still destroy white matter and cause other kinds of reversible brain damage in alcoholics (Tyas 2001). To avoid the majority of negative after-effects from alcohol, consuming an equal amount of water between drinks is recommended - although moderation is still best.

Alcohol [or ethanol] consumption may also result in endogenous formation of tetrahydroisoquinoline and β-carboline alkaloids, from the condensation of endogenous *phenethylamine*s or indoles with acetaldehyde, a metabolite of ethanol [see above for discussion of similar reactions in food processing, and substances found in alcoholic beverages]. Such alkaloids include *salsolinol*, O-methylsalsolinol, *harmalan*, 6-OH-*tetrahydroharman*, *harman*, and possibly 1-methyl-β-carboline and *pinoline*. However, similar reactions and metabolites may be observed without alcohol consumption (Collins 1983; Deitrich & Erwin 1980; Shulgin & Shulgin 1997).

The foods we eat also supply most of our essential amino acids [see *Neurochemistry*], either in free form or bound in proteins. After consumption, a portion is transported into the brain and metabolised to produce neurotransmitters, or otherwise influence physiological functions. The 'abnormal' metabolites of some of these neurotransmitters [especially of *dopamine*, *epinephrine*, *norepinephrine* and *serotonin*] have been proposed in the past to contribute to types of schizophrenia, in the case of genetic enzymatic defects causing excessive production of some of these metabolites (eg. see Rodnight 1983; Rosengarten & Friedhoff 1976; Wyatt & Murphy 1976). Although no conclusive evidence has yet been found to support the validity of any of these assumptions, in connection to mental illness, it would not seem unlikely if such metabolites were involved in some way in the symptoms of some people. Given the effects of some of these powerful substances [such as *DMT*], imagine the reaction of a person feeling such effects, who had not taken any drug, nor had access to any logical explanation for this potentially terrifying state of mind. Continuing negative reactions, manifesting in a psychosis or other aberrations, would be expected. This is contrasted with the usually positive experiences of those who consciously choose to ingest such substances, with a good set and setting, or of those who deliberately awaken such endogenous biochemical changes through other means. To the informed psychonaut, who is attempting to induce such a state intentionally, and is not making any permanent metabolic alterations in order to do so, a somewhat more brief and positive outcome could be hoped for.

[Also, as mentioned in *Neurochemistry*, the protein substance taraxein has been implicated in schizophrenia, apparently with a stronger correlation than has been reported for any of the abnormal metabolites mentioned above, and is chemically unrelated to them. It is unclear why taraxein has been the focus of so little scientific enquiry.

Part of the confusion in this issue no doubt also arises from the fact that many scientists have persisted in viewing schizophrenia as effectively a unified, defined disease, which it is not – rather, it serves as a label given to a loose assemblage of symptoms, most of which may or may not apply in any given case. To establish a single endogenous metabolite as being responsible for all of the symptoms of 'schizophrenia' seems a goal destined to failure.]

Amino acids compete with each other to varying degrees, and for any one amino acid to gain prominence in the metabolism, its concentrations must be raised above those of competing amino acids. One way this can be approached is by obtaining preference over either indoles or catecholamines through regulating carbohydrate and protein intake. As *tryptophan* is usually the least-prevalent amino acid in proteins, consumption of a high-protein meal will not favour *tryptophan* crossing the blood-brain barrier in preference to tyrosine; however, consumption of a high-carbohydrate meal induces insulin secretion, which lowers the levels of other amino acids, boosting the relative levels of *tryptophan* available to the brain (Fernstrom & Wurtman 1973; Lieberman 1987).

Another approach, which allows for a broader range of amino acids to manipulate, is known as precursor-loading. It involves oral ingestion of either foods particularly rich in a particular amino acid, or the amino acid in pure form, as well as vitamins and minerals crucial for the required biosynthesis. Relatively large amounts usually must be consumed, to allow for the fact that only a small portion will reach the brain; also, effects may be rather delayed in onset. This then either allows the amino acid as it is to elicit effects, or for it to be affected by enzymes and converted to its related neurotransmitters. It should still be borne in mind that feeding precursors in one end and hoping the desired reaction results [see below] is still somewhat of a 'crap-shoot', and the potential explorer should, as always, be very careful! Cyclic and/or chaotic changes in the metabolism and biochemistry of an individual can make the results highly unpredictable.

It is known that preloading with *methionine* can increase the production of N-methylated derivatives; for example, if given with *tryptophan*, then *DMT*, *bufotenine* and/or *5-methoxy-DMT* may potentially be produced, resulting in a state characteristic of those chemicals in the CNS. This process is greatly exacerbated with the co-administration of an MAO-inhibitor [MAOI], which prevents immediate degradation of these metabolites (Beaton et al. 1975; Cohen et al. 1974; Kety 1961; Sprince 1970). Inhibition of both MAO-A and MAO-B is required for full elicitation of the 'psychedelic indole syndrome', when *tryptophan* is given, though MAO-A inhibition is most crucial (Kruk & Pycock 1983; Squires 1978); this is also reportedly a requirement for the full development of '*serotonin* syndrome' [see below] (Sternbach 1991).

One underground publication described a theoretical method to boost endogenous production of *5-methoxy-DMT*, by consuming chocolate bars [to boost carbohydrate levels] along with a large oral dose of L-*tryptophan* and an MAOI (Most 1986). However, Most did not note whether he had actually tried this method himself [I believe he probably had not], or if he knew of anyone who had. Care should be taken when combining large amounts of *serotonin* precursors with an MAOI, as excessive central levels of this neurotransmitter can cause a potentially dangerous disorder known as '*serotonin* syndrome' [see below].

MAOIs can also be used to increase and modify the effects of some other drugs [such as **Psilocybe** mushrooms, *5-hydroxytryptophan* and LSD] (Kent 1995/96; Squires 1978; pers. comms.). An MAOI given with *reserpine* results in an excited state reminiscent of LSD in animals, and MAOIs also potentiate *amphetamine* and *ephedrine* (Squires 1978). MAOIs, particularly inhibitors of MAO-A, allow for *DMT* [which would normally be metabolised before reaching the brain] to express oral activity (McKenna et al. 1984a; Ott 1994; Sai-Halasz 1963). This is the basis of what is known as the 'ayahuasca effect' [see *Methods of Ingestion*, **Banisteriopsis**].

Some MAOIs have been shown to induce pineal N-acetyl transferase activity (Finnin 1979); and MAO-A inhibitors also increase pineal levels of N-acetyl-*serotonin* and *melatonin*, an effect which was negated by coadministration of propranolol, a β-adrenergic antagonist. High doses [or chronic administration of low doses] of MAO-B inhibitors also inhibit MAO-A (King et al. 1982; Nathan 1998; Oxenkrug 1999). Inhibition of MAO-B results in a rise in catecholamine concentrations, including *phenethylamine* [PEA] and *tyramine*. *PEA* is largely inactive if MAO-B is not inhibited (Sabelli et al. 1978).

Strong or 'irreversible' MAO-B inhibition [or non-selective MAOIs] can be a problem, particularly with foods high in *tyramine* or tyrosine [such as banana peel or essence (see **Musa**), aged products such as meats or cheeses, yeast products, and fermented foods – consult your physician for a full list] as a hypertensive crisis can result, in which there is a massive rise in blood pressure which can cause cranial haemorrhage and even death. This is mostly only a concern with 'irreversible' MAOIs, which are synthetic pharmaceuticals, and generally non-selective as to MAO-type. Caution should still be exercised with short-term MAOIs, as such foods can still initiate a hypertensive crisis if eaten in quantity on the same day as taking a short-term MAOI (Julien 1995; Mashford et al. 1993; Ott 1994, 1996).

In a similar vein, combination of an MAOI with a selective-*serotonin*-reuptake-inhibitor [SSRI], such as Prozac™ [fluoxetine] or other serotonergic drugs, can result in what is known as '*serotonin* syndrome', due to an over-abundance of synaptic *serotonin* [increased extracellular levels do not necessarily result in this syndrome], causing over-stimulation of central 5-HT1a receptors. The reaction can also occur when combining an MAOI with MDMA [3,4-methylenedioxy-*methamphetamine*; 'ecstasy'], dextromethorphan [DXM], or large doses of *serotonin* precursors, such as *tryptophan* and *5-hydroxytryptophan*. The syndrome seems to be a result of non-specific *serotonin*-receptor blockade, though 5-HT1a subtypes are most important. Symptoms include drowsiness, rigidity, shivering, agitation, restlessness, hyperreflexia, clumsiness, nausea, flushing, diarrhoea, sweating, euphoria, mental confusion, feeling of inebriation, fever, and rarely coma and death. If the responsible chemicals are eliminated from the diet, symptoms usually subside within 24hrs. However, in cases including delirium, symptoms have been observed to last up to 4 days. Combining *L-DOPA* with an MAOI can result in behavioural symptoms similar to those seen with *tryptophan* and an MAOI (Bodner et al. 1995; Gillman 1998; Sternbach 1991).

SSRI's can interfere with the activity of serotonergic psychedelics, though the nature of the interference seems to depend on both the type

of SSRI used, and the psychedelic used (pers. comms.). This is based on both subjective observations in humans [usually spread anecdotally], and observations on experimental animals treated with such drugs. For example, the SSRI (+)-fluoxetine has been observed to potentiate some effects of LSD in both rats and humans [contradicted by most other human experience – see below]. Some people have experienced 'LSD flashbacks' when using SSRI's such as fluoxetine, paroxetine [Paxil™] or sertraline [Zoloft™]. Potentiation between various SSRI's and DOM [2,5-dimethoxy-4-methyl-*amphetamine*; 'STP'] or *ibogaine* has also been observed in rats, though not with *5-methoxy-DMT* [except at high doses, with fluoxetine] (Winter et al. 1999a). However, psychonauts also report that SSRI's can block the effects of many psychedelics. A recent overview of psychonautic reports indicated that fluoxetine decreases the effects of LSD, MDMA and ketamine, without altering response to *psilocybin*, although a friend of mine has found that for her, fluoxetine decreases the effects of **Psilocybe** mushrooms. Sertraline decreased the effects of LSD and MDMA only at high doses [of the former], whilst normal doses did not affect the response to LSD or *psilocybin*. Paroxetine and trazodone [Desyrel™] decreased the effects of LSD. Conversely, tricyclic antidepressants such as imipramine [Tofranil™], desipramine [Norpramine™] and clomipramine [Anafranil™] increased the effects of LSD, and lithium increased the effects of LSD and *psilocybin* (Bonson 2002).

Some people have a mutation in the structural gene for MAO-A; the resultant permanent neurochemical imbalance has been observed to manifest, in those males studied, as aggressive and antisocial behaviour, as well as 'borderline mental retardation' (Brunner et al. 1993). Chronic, but not acute, schizophrenics have been observed to have low platelet MAO levels, but brain levels were normal. MAO abnormalities appear to be at least partly due to genetic inheritance (Rodnight 1983; Wyatt & Murphy 1976).

Consumption of an AChE-inhibitor [AChEI] such as physostigmine can increase *acetylcholine* [ACh] levels (Seiden & Dykstra 1977); see also *huperzine A* and *galanthamine*. AChE-inhibitors can cause sedation, subjective internal agitation or jitteriness, confusion, impaired concentration and short-term memory, and sometimes nausea and vomiting. Central effects are often more predominant in those who get little in the way of nausea or vomiting. Nightmares may be more frequent in the first sleep after other symptoms have subsided (Bowers et al. 1964). AChE-inhibitors can be hazardous in overdose, acting as convulsants and causing symptoms associated with cholinergic receptor stimulation; death may result from respiratory paralysis. Many pesticides and nerve poisons are AChE-inhibitors; these are much more dangerous because their activity is highly potent and 'quasi-irreversible' rather than moderate and short-term. *Atropine* and similar anticholinergic drugs are used as emergency antidotes to AChEI poisoning (Katzung & Trevor 1995).

It should be mentioned briefly that overeating or poor digestion, combined with a diet high in animal protein and fat, can cause [besides bowel cancer] a build-up of bowel toxins [such as indole, indican, skatole, guanidine, phenol, *histamine* and clostridium perfringen enterotoxin] from overgrowth of putrefactive bacteria in the intestines. This is called intestinal toxaemia, and symptoms can include mental disturbances [hallucinations, delirium, loss of mental co-ordination, etc.], mood disorders, fatigue and other physical problems (Cousens 1996).

Many of the following procedures or conditions may fall into the collective category of 'asceticism', mostly known to us from the practices of Hindu saddhus in India, where lengthy and sometimes painful ordeals are pursued as a route to enlightenment.

Fasting

Fasting, of course, involves not eating for any extended period of time, and fluids such as water may or may not also be excluded from the diet. So, here we are dealing with the withdrawal of dietary influences. Fasting eventually depletes the body of energy and nutrients, causing psychological and physiological disturbances. Fasting for short periods, however, is not as drastic a procedure, and if done in moderation can actually be good for clearing accumulated toxins from the system. Here, also, psychological symptoms may manifest when stored toxins resurface to be excreted.

Starvation is accompanied by an increase in the brain of *tryptophan*, and 5-hydroxy indoles (Young 1983). With prolonged starvation, activity of the enzyme glutamic acid dehydrogenase is decreased, and blood-brain barrier permeability is increased to some chemicals [such as *cocaine*] (Yuwiler 1971). This practice [inducing malnutrition] may also cause abnormal metabolism of nutrients and neurotransmitters (Cousens 1996), which could have rather unpredictable effects. Oxidised catecholamine products, such as *adrenochrome*, may be produced in greater amounts than usual as a result of anti-oxidants being excluded from the diet, including vitamin C depletion. Fasting can also increase the effects of other drugs, due to more rapid absorption and lack of competing substances [and, perhaps, reduced efficiency of toxin-clearing functions in the long term]. This is partially the rationale for most shamans fasting for at least one day before ingesting a sacred plant.

Stress

This is a fairly broad heading, as many things [such as fasting and sleep deprivation, covered above and below, respectively] can be interpreted as causing stress. This may refer to getting angry and upset from an argument, running a marathon, being shot at, or ascetic practices such as exposure to the elements. Many readers may recall the Biblical accounts of Jesus going alone without food into the desert for 40 days, and being besieged by visions of temptation [Matthew 4:1-11; Mark 1:9-13; Luke 4:1-13]. This is an example of fasting combined with isolation and exposure to the elements.

Long-term stress produces more drastic side-effects than a brief moment of stress. A primary function in stressful situations is activation of the adrenal glands, with a subsequent rise in blood-sugar [caused by release of glucocorticoids] to provide extra energy, and excretion of *epinephrine* and other adrenal hormones (Vayda 1992). Vitamin C levels drop greatly during stress, and thus formation of *adrenochrome* and related products could be expected, however, the adrenal cortex contains the highest concentrations of vitamin C in the body [except for the brain] – also, *adrenochrome* levels in plasma drop more rapidly in people with nervous tension (Hoffer & Osmond 1960). Plasma levels of β-*endorphin* are elevated during acute emotional or physical stress; the concentrations are highest in people who can withstand such stressful periods without disturbed function of the peripheral organs (Teschemacher et al. 1980). *Endorphin*s are released during stress from the pituitary gland along with *adrenocorticotropin* [ACTH], as well as from the adrenals with the catecholamines (Kruk & Pycock 1983). Stress can also increase the turnover of *dopamine*, reduce concentrations of p-*tyramine*, increase concentrations of m-*tyramine* (Boulton & Juorio 1982), deplete *norepinephrine* (Hellriegel & D'Mello 1997), and increase levels and turnover of *tribulin* (Doyle et al. 1996; Glover 1998; Glover et al. 1987; Medvedev 1996). Levels of endogenous *DMT* are also increased by stress (Barker et al. 1981), as is the activity of the enzyme N-acetyl transferase in the pineal (Finnin 1979). Rats subjected to acute psychic stress [my regrets to the rodents involved] used up more *tryptophan*, and in another experiment with rats stress increased the synthesis and release of *melatonin*, which as well as properties already mentioned, has antistress and immune-stimulating functions (Maestroni et al. 1989; Relkin 1983a). Psychic stress such as is experienced in an emergency or crisis, or in cases of life-threatening illness, has been known to induce 'hallucinations' (Dronfield 1995). Physical stress increases *vasopressin* levels, though emotional stress produced by fearful conditioning suppresses its secretion. Stress also lowers *dehydroepiandrosterone* levels (Crenshaw & Goldberg 1996).

Exposure to cold reduces the release rate of *norepinephrine* (Fillenz 1984), stimulates pineal *melatonin* synthesis, and increases *tribulin* production (Oxenkrug & Requintina 1998). Acute cold exposure [in adult rodents] raises the levels of peripheral cortico-steroids, adrenal cortico-steroids and pituitary *ACTH*, as well as decreasing adrenal vitamin C and adrenal cholesterol. In humans, if the temperature is lowered gradually, there is no change in cortico-steroids. Also [again with acute cold-exposure] the autonomous nervous system [ANS] immediately releases catecholamines, and the brain activity of MAO, and levels of *glutamic acid*, are decreased (Yuwiler 1971). Excessive exposure to heat [also when coupled with complete fasting] depletes the organism of water and sodium, which decreases the efficiency of waste removal [leading to build-up of potenially psychoactive toxins], and decreases efficient nerve function (Mindell 1982), which can cause a delirious state. Taken further, the risk of heat stroke and consequent organ failure and death is present. However, the sweating that occurs before waste removal is hindered is itself a form of heightened waste removal, so under controlled conditions [such as sweat lodges led by an experienced practitioner] heat exposure can be beneficial. The intense moist heat encountered in native American sweat-lodges, which are carried out ritually for both health and shamanic purposes, can produce an altered state that some people experience as psychedelic. This may be aided by *endorphin* production, flushing of psychoactive toxins from the body, ritual intent, social isolation and darkness [see below] within the tent or lodge, rhythmic chanting [see below], and fumes from psychoactive plants which are sometimes burned and/or smoked inside the lodge. Although unquestionably an ordeal for most people, this turns to feelings of euphoria and profound well-being once the ceremony comes to a close and participants leave the lodge, naked or semi-clad, to the cool outdoors (Weil 1976b; pers. obs.). Quick alternation between exposure to extreme temperatures, such as very hot and very cold water, can also produce some interesting alterations in consciousness, but may be contraindicated in some medical conditions (Wells & Rushkoff 1995).

Stressful anxiety resulting from drug withdrawal [*morphine*, *nicotine*, ethanol and lorazepam, but not **Cannabis**] increased *tribulin* levels (Bhattacharya et al. 1995). Sufferers of migraine headaches sometimes experience visual disturbances, and even hallucinations (Dronfield 1995).

Procedures for causing pain and letting blood have also been practiced by some traditional cultures, either simply to show spiritual devotion, or also to create an altered state. The Mayans practiced ritual bloodletting, often by drawing strings of sharp objects [eg. see **Urolophus**] through the

tongue, genitals or other body parts, in order to experience visions from the 'vision serpent'. This is probably mediated by release of *endorphins* and other neurochemicals in response to pain and blood loss (Schele & Miller 1986). Levels of endogenous *anandamide* also rise in suppressive response to pain (Boger et al. 2000).

Sleep and dreaming

The state of dreaming is a powerful, vivid and meaningful realm of consciousness, accessible nightly to almost anyone. While it may provide us with a greater understanding of ourselves, its function and neurological mechanisms are still barely understood. Dreaming generally occurs in periods of rapid-eye-movement [REM] sleep, which occur in a beta-wave brain state; non-REM sleep is characterised by theta- and delta-rhythms, slowing to 2Hz or less (Bear et al. 1996). There are few concrete theories regarding the neurochemical origin of dreams, but one with some credibility suggests that *5-methoxy-DMT* and 6-MeO-β-carbolines [such as *pinoline*] may be integrally involved (Callaway 1988). The 'twilight zone' just before falling asleep is also often characterised by symptoms of an altered state of consciousness [apart from drowsiness], as well as muscular relaxation. Imagery ['hypnagogic hallucinations'] is often experienced, of a disjointed nature; the intensity and complexity increase as the subject enters the deeper theta wave states, when approaching sleep. Similar experiences also occur when awakening from sleep, termed 'hypnopompic hallucinations'. These are both also reported to be induced by the use of 'khat' [see **Catha**] and 'hashish' [see **Cannabis**] (Ohayon et al. 1996; Richardson & McAndrew 1990; Stoyva 1973). Lucid dreaming, the phenomenon of becoming aware in dreams and being able to influence them, also offers interesting possibilities for exploring altered states of consciousness (eg. see Wells & Rushkoff 1995). Brain levels of *acetylcholine*, *melatonin* and *serotonin* are highest during sleep. Brain levels of the catecholamines are highest during waking hours, beginning just before waking, and subsiding again to a minimum at the end of the day. Salivary *tribulin* levels are highest at waking, and rapidly decrease, followed by a rise in cortisol (Balemans 1981; Hoffer & Osmond 1960; Hucklebridge et al. 1998a; Lewis & Clouatre 1996; Mandell et al. 1969; Wyatt 1972).

Sleep deprivation

Forcing one's self to remain awake for more than a couple of days at a time can result in peculiar mental changes. Such a practice is known to produce 'schizophrenic-like' symptoms, or aggravate existing schizophrenia, and can sensitise the individual to the effects of other drugs, such as LSD [which under these conditions is active in doses normally considered 'non-hallucinogenic']. After 2-3 days of no sleep, there is usually a turning-point, as visual and auditory alterations and hallucinations first manifest. For some people, this turning point may not eventuate until the 5th or 6th day of sleep-deprivation, which for most people would mark a second turning-point, after which symptoms become much more pronounced. Other common symptoms include irritability, emotional instability, disorientation, feelings of being in two places at the same time, motor incoordination, paraesthesia, time distortion, delusional thinking patterns, depersonalisation, sensations of a band of pressure around the head, and eye strain. When called upon to perform important duties for brief periods, subjects often show no sign of mental fatigue and perform to some semblance of normality, though at other times disorganisation and fragmentation of thoughts may be observed. Strange behaviour and hallucinations may occur in 90-120 minute cycles, as though dream-sleep was trying to re-assert itself in the enforced waking state. There is usually complete recovery after 8-15 hours of sleep, though sometimes it may be difficult to initiate sleep at first. This first sleep is often highly enriched in its dream content. For some people, up to a week or more may be required to recover fully (Bliss et al. 1959; Hoffer & Osmond 1960; Katz & Landis 1935; Luby et al. 1960, 1961; Mauriz 1990; Morris et al. 1960; Safer 1970; Vogel 1975; West et al. 1961). A friend of mine and his brother once deprived themselves of sleep for 5 days, and experienced "sinister shadow-like hallucinations", and bizarre and vivid auditory hallucinations of voices and sounds. No drugs other than small amounts of food were consumed (pers. comm.).

Sleep deprivation causes levels of endogenous oleamide [see *Neurochemistry*] to accumulate in cerebro-spinal fluid [CSF], in animals (Boger et al. 2000). In rats, there was an intial increase in brain MAO activity, followed by a decrease (Thakkar & Mallick 1993). In humans, there was an initial rise in ATP activity in red blood cells [see *Neurochemistry*], after which there was a large decrease, coinciding with a decrease in sympathetic nervous system response. EEG readings generally show a decline in alpha-wave activity (Luby et al. 1960, 1961).

Near-death experience

There are many examples of 'near-death experiences', or 're-emergence phenomena', recorded in the medical literature. The person in such a state often later reports having had 'transcendental' experiences, featuring elements such as out-of-body-experience [OBE], time-distortion, accelerated thoughts, review of life events, sudden profound realisations, feelings of joy and cosmic unity, precognition, encountering spirits or entities and 'unearthly realms', and encountering a barrier or brilliant all-pervading white light (Greyson 1985). Those who return to tell the tale often speak of moving towards this light, but being pulled away again before returning to life. Presumably, full death entails actually merging with this light, and to whatever is beyond. It has been suggested that the near-death experience is mediated by the NMDA and sigma receptor sites, in reference to similar effects induced by ketamine (Jansen 1990). Others consider the described experiences may be more similar to those potentially induced by *DMT* (Strassman 1997) or *5-methoxy-DMT* (pers. obs.).

Isolation and sensory deprivation

Isolation from others has long been used to initiate visions or other psychic alterations, most notably in native North American vision quests. Such vision quests combine isolation in the wilderness [preferably in a spot felt to be particularly endowed with natural energy] with fasting and exposure to the elements, and sometimes ingestion of sacred plants. Isolation from the community is also used in initiation procedures in many tribal groups around the world, to aid in the undisturbed re-arranging of the senses that is considered necessary for transition into fully-aware adulthood. In rats, social isolation has been found to induce enlargement of the pineal gland (Relkin 1983b).

Isolation by sensory deprivation is a well-known means of inducing altered states of consciousness, sometimes with 'hallucinations' (eg. Ziskind & Augsburg 1962). Subterranean constructions of religious importance, such as have been found in parts of Britain, were likely used in sacred rites in part due to the sensory deprivation which would be experienced within (see also Dronfield 1995). Ancient Taoists and other mystics have also been known to isolate themselves in caves for varying periods of time, as an aid to developing spiritual awareness (pers. comms.). In Tibet, seclusion in caves is a relatively common form of spiritual practice, known as 'muntri' or 'dark retreat'. Amongst the Bonpo and Nyingmapa, this seclusion may last for 3 years or more. In the words of Lopon Tenzing Namdak, "If we remain in darkness, we will discover the radiance of the natural state. If we take that as the basis of practice, we will quickly attain Buddhahood... The wisdom eye opens and we will be able to see everything in the three worlds. This is the purpose of dark retreats" (Dunham et al. 1993). Darkness as a crucial element is further discussed below.

Also, much work has been done on sensory-isolation in flotation-tanks, most notably by Dr John Lilly, inducing dissociative-visionary experiences both with or without the co-administration of psychedelic substances (Stafford 1992). A well-known 'science'-fiction film, 'Altered States', was very loosely based on this work. People often come out of the tanks feeling refreshed, positive and vibrant, and notice enhancement of sensory perceptions, including heightened awareness of colour, and mild psychedelic symptoms. Flotation tank experiences can increase alpha- and theta-waves in brain EEG activity; synchronise activity between the hemispheres of the brain; reduce secretion of catecholamines, *adrenocorticotropin* and cortisol; increase secretion of *endorphins*; decrease blood pressure, heart rate, oxygen consumption and muscular tension; and increase circulation to the extremities and gastro-intestinal system (Brain Mind Bulletin 1984; Deikman 1963; Hutchison 1984, 1994).

Day and night fluctuation

It has already been mentioned that darkness increases *melatonin* production in the pineal gland and other neurons. Alteration of natural light periods, either through artificial lighting, abnormal sleeping patterns, or jet lag, can hinder normal *melatonin* synthesis, giving rise to symptoms described under sleep deprivation. However, the intensity of artificial light is usually not sufficient to have a major contribution (Lewy 1983), though individual sensitivity varies greatly and some people are affected by some spectrums of artificial light (Nathan 1998). Problems generally may arise when one has little or no exposure to natural light during the day, but is instead exposed only to artificial light not bright enough to effectively influence pineal rhythms (Lewis & Clouatre 1996). Strong artificial light has also been shown to cause a stress-related rise in *adrenocorticotropin* and cortisol levels (Mahnke & Mahnke undated). Light of shorter wavelengths [blue (470nm) to green (525nm)] was most effective in suppressing *melatonin* production (Wright & Lack 2001). Pineal N-acetyl transferase is also influenced by diurnal rhythms, its activity rising at night (Binkley et al. 1979). Continuous light pulses of up to 10hr duration have been shown to suppress night-time N-acetyltransferase activity; such light pulses can also be used to rest the diurnal rhythm of this enzyme. The rhythm has been shown to persist as normal after 24hrs in constant darkness (Binkley 1983). Use of extended darkness-periods can boost *melatonin* production, leading to a greater concentrated supply of precursor material for *5-methoxy-DMT*, if combined with other appropriate manipulations. In rats, constant darkness is known to reduce MAO activity in the pituitary, and to a slightly lesser degree in the rest of the hypothalamus (Relkin 1983a) as well as increasing HIOMT activity (Finnin 1979).

Sympathetic neurons increase their firing rate at the onset of night-darkness, and the levels and turnover rate of *norepinephrine* increase in the

pineal. Pineal *norepinephrine* is taken up by pineal β-adrenergic receptors, which stimulate N-acetyl transferase activity [increasing it by at least 20-fold at night; HIOMT increases 2-fold at night] (Lewy 1983).

Intermittent light stimuli

Intermittent light stimuli [ie. flickering fire, strobe lights, and 'mind machines' (opaque goggles with a light/LED facing each closed eye, flashing at varying frequencies)] have been shown to cause behavioural changes, including psychotic reactions, as well as epileptic seizures or convulsions in individuals susceptible to epilepsy. It should be noted that epileptics commonly experience altered states of consciousness during their seizures. More often, in 'normal' individuals such stimulus produces positive effects [visual alterations and enhancements, 'hallucinations' which are often dream-like, sensations of movement, tingling on the skin, disturbed sense of time, emotional and mental involvement] which can translate into improved day-to-day functioning, and other benefits that meditation and trance can bring [see below]. Intermittent light stimuli are thought to work by entraining the EEG rhythms of the brain to the rhythm or frequency of the stimulus. Darkness enhances these effects. One experiment using two light sources with independent flash frequencies produced particularly vivid 'hallucinations' [see 'binaural beats', below under Rhythm and Percussion]. A rapid variation of flash frequency between 10 and 15Hz caused "unpleasant 'swimming' sensations". Blue light produced more effective entrainment than red light, and monochromatic light was more effective than neutral light of equivalent intensity. The visual component of these effects is more prevalent at frequencies of 6-10Hz and lower, particularly in theta frequencies (Dronfield 1995; Halstead et al. 1942a, 1942b; Hutchison 1994; Knoll & Kugler 1959; Richardson & McAndrew 1990; Rouget 1980; Ulett 1953; Walter & Walter 1949; Walter et al. 1946; Wells & Rushkoff 1995), and this effect can be exacerbated by drugs, such as LSD. Intermittent light stimulus in the alpha-range was shown to induce "striking subjective visual effects" with eyes closed, in people who had taken a sub-threshold dose of *mescaline* (Wheatley & Schueler 1950). In other tests, intermittent light stimulus in the range of 4-24Hz was shown to enhance the activity of LSD, as well as to encourage its effects in individuals normally insensitive to LSD (Fischer et al. 1961).

As a word of caution, there is plausible suggestion from a one-time friend of the infamous and legendary guitarist Syd Barrett [of the original Pink Floyd] that strobe lighting, combined with a large dose of LSD [given apparently without his knowledge, on top of a previously-consumed large dose], appeared to have triggered the beginning of the 'negative' personality changes that Syd is, unfortunately, now better known for (John 'Twink' Alder, in Watkinson & Anderson 1991). This may be more an observation of coincidence or individual differences in reaction than any concrete analysis of the matter, but should perhaps be borne in mind, nonetheless.

Colour

Experiments with humans comparing a grey, 'sterile' room and a colourful, 'diversified' room, showed that the colourful environment produced less alpha-wave EEG activity, and lower heart rate, than the grey room, in which subjects became restless and agitated. Subjects in the colourful room felt 'silent and subdued'. Red is regarded as stimulating, and red objects or images give the impression of being closer than they really are. Green and blue are relaxing; green is the most comfortable colour for the eyes, as green wavelengths focus exactly on the retina. Purple is regarded as 'subduing', and yellow as positive and 'cheering'. Strong hues of a single colour, however, usually do not produce a sustained effect, once the nervous system becomes accustomed to it [or irritated by it]. Visible light received through the eyes is known to stimulate the pineal and pituitary glands (Mahnke & Mahnke undated). Green light is the most effective wavelength in suppressing retinal HIOMT (Finnin 1979). Some experiments stimulated the pineal gland with blue-green light at 509nm (Lyttle 1993), and as noted above, wavelengths in this part of the spectrum are more effective in suppressing *melatonin* production (Wright & Lack 2001). It has even been shown experimentally that exposure to different colours can greatly enhance production of *serotonin*, *norepinephrine*, β-*endorphin*, *melatonin*, AChE, *oxytocin*, growth hormone, luteinising hormone and others, as well as increasing the effectiveness of some enzymes by up to 500%. Varying frequencies of light projection can also alter these effects. Beneficial combinations [for general cognition and feeling of well-being] include violet, green, or red at 7.8Hz and 31.2Hz, and varying shades of yellow, orange, and red at 12-15Hz or higher. 'White' light can also be used beneficially by constructing a simple goggle device, consisting of two ping-pong ball halves, fitted over the eyes [it is important to get a comfortable fit that completely blocks out sidestream-light] – when fitted, the subject gazes at a bright beam of light directed at the goggles. The desired effect initially is the perception of a white, homogenous, empty field, progressing into deeper states of consciousness [this is a form of sensory-deprivation – see Isolation, above]. However, ping-pong balls can be imperfect in that bright spots may be perceived, instead of a uniform light, though experimentation with different semi-opaque materials would smooth out such problems. This simple technology has been known and used for some time now, with developments mainly in the commercial field (Hutchison 1994).

Art and art appreciation

'Art' can be construed to mean many things, depending on who is talking about it. In this discussion, art is defined as any form of creative expression. This definition first leads to the obvious appreciation of the intricate and mind-boggling art of nature. In the natural world, everywhere we look we find evidence of inherent creative expression, whether or not one believes in a greater creative force. Contemplation of nature, its inherent beauty, its order and form within seeming chaos (or chaos within seeming order and form), and the observation of the wild patterns and connections underlying these perceptions, may be seen as one ancient route towards the expansion of consciousness in subtle, yet penetrating ways. This contemplation is vastly potentiated when the observer is already in an altered state of consciousness, eg. having consumed *mescaline* or *psilocybin*.

Our other major point of consideration is that of art created deliberately by humans. The actual creation of art – from initial conception of the piece, through to its completion and appreciation by self and others – can be a deep learning experience in itself, when the artist is committed to the integrity of the work. In such a case, the entire process may be one of prolonged meditation, as the artist opens up to their creative energies and the art becomes manifest. Alex Grey (1998) has written extensively on the sacredness of great art, and calls for us to consider the truest potential of art – that is, as a reflection and communication of higher consciousness or mystic revelations perceived through the artist. Many great artists throughout history have been inspired mystics – those who experienced visions of other realms, and tried to capture them in their art, so that they could be shared with the world. This is the end reward of great art – it gives a vision back to the world, so that it may heal and inspire those who are exposed to it. This is also where the artist has the greatest responsibility – to go beyond commercial or egotistical concerns, and use their given talents to create a reflection of ultimate reality. Having realised profound states of being, it is only natural for the visionary artist to channel this glimpse of the divine into form, and the creation of art is a very appropriate funnel for such noble aspirations. Apart from the impact the resulting work will have on its audience, the act of creation is also a transformative process for the artist. Even dark art has its place here, when the art seeks to explore the realms of the soul we may rather not contemplate. It is essential to know darkness in order to truly know light. Both constitute the unidifferentiated whole that is the paradox of life. For those particularly interested in these avenues of artistic endeavour, it is highly suggested that you read Grey's books and witness his art.

Art as created by humans takes many forms, and has become increasingly diverse over the last few decades. As technology has grown, art has grown with it, seizing every new opportunity for greater avenues of expression. The mixing of different forms of art has evolved to create true multimedia spectacles. Painting, sculpture, dance [see below], performance and installation art, poetry, film, computer animation, and many other art forms have been combined effectively with music [another potent art, when used well – see below for more] to produce a greater impact. As mentioned with nature above, the appreciation of human-made art whilst already in an altered state of consciousness can greatly increase the profundity of the experience.

Below is a selection of some 20th century visionary artists who have produced visual works which attempt [with success] to express aspects of the ineffable. Seeking out their works will hopefully be of value to the interested reader. It should be pointed out that many of these artists have produced works of greatly differing style and intent throughout their careers, and not all of the work by a listed artist will necessarily be of relevance here.

As well as 'modern art', much contemplative satisfaction may be found in ancient arts from around the world. Noteworthy examples are south-east Asian mandalas, Australian aboriginal 'dot' paintings, South American indigenous art inspired by the visionary experience ['San Pedro' (see **Trichocereus**), ayahuasca-related art (see **Banisteriopsis**), as well as snuff-tray designs – see **Virola** and **Anadenanthera**], Huichol yarn paintings and bead masks [see **Lophophora**], art of the Aztec, Maya, and Inca cultures, carvings and statuettes by native North Americans ranging from Alaska and Greenland to northern US, Japanese 'Zen paintings', Celtic rock carvings and metalwork, and north African cave art. This, of course, is only a small selection from some diverse world cultures past and present.

Massage, acupuncture and acupressure

It is known that stimulation of certain points on the body can induce *endorphin* release, whether this be from manual stimulation, electrical stimulation, or application of needles in acupuncture. These points are located all over the body, and a few can be easily located without more detailed instruction:

- draw your thumb in towards your hand, and locate the point at the summit of the skin folds that crease together between thumb and index finger on the top of the hand [but massage the point with the hand relaxed]
- point where the lines on the palm converge, under the base of the index finger
- point near the corner of the eye, just above the tearduct [stressed or tired people often instinctively rub these points]
- point on the neck just behind the earlobe [behind the jawbone]
- point in the hollow shell of the ear

This last region directly stimulates the peripheral nervous system via the vagus nerve. Stimulation here generally produces a tranquil feeling. Apparently Roman slaves used to stand behind their masters to manually stimulate their inner ears with warm water while they ate.

Electroacupuncture stimulation increases *endorphin* levels in the cerebrospinal fluid, related to the frequency of electrical current used. A frequency of 2Hz increased *endorphin*s; 15Hz increased *endorphin*s and *enkephalin*s; whilst 100Hz increased dynorphins (Abbate et al. 1980; Kruk & Pycock 1983; Pomeranz 1977; Ulett & Nichols 1996; Wells & Rushkoff 1995).

Massage of the feet and hands in specific areas is said by reflexologists to influence different parts or organs of the body. For instance, the toes stimulate the head, brain and sinus area, and the underside of the big toe stimulates the pituitary.

Magnetic fields

It has been known for a few decades that magnetic fields can produce altered states of consciousness. This can occur naturally, due to changes in geomagnetic activity. Geomagnetic storms, periods of deviation from the normal, stable magnetic field of the earth, can sometimes last for weeks at a time, and have been observed to affect insect behaviour, disrupt the homing skills of homing pigeons, and reduce *morphine*-induced analgesia in animals at night. Geomagnetic storms seem to be linked with solar activity, and have their highest activity from January to February, and June to July [lowest in March to April, and October to November]. 'Geomagnetic variation anomalies' usually act over less extended periods, and are often associated with underground basins, channels and deposits that affect conductivity. Sometimes geomagnetic variation anomalies are induced by changes brought about by geomagnetic storms. Extremely low frequency [ELF – 300Hz and below] electromagnetic fields propagating between the earth's surface and the ionosphere appear to be able to affect mood in humans by entrainment with brain EEG patterns [see Intermittent light stimuli, above]. The diurnal variations of these ELF fields are also suspected of being related to the control of human circadian rhythms, the disruption of which can result in behavioural and physiological anomalies (Persinger 1987). ELF fields associated with electric power generation and transmission have been shown to negatively influence pineal *melatonin* production, as well as decreasing immune and sexual function, causing emotional depression [all changes probably due to disruption of *melatonin*], increasing cancer risk and changing brain morphology in animals (Adey 1975; Moore-Ede et al. ed. 1992).

Geomagnetic storms have been associated with reduction of the convulsive threshold in susceptible humans [also observed from a geomagnetic variation associated with a solar eclipse] (Persinger 1987), and increases in reported poltergeist activity (Gearhart & Persinger 1986). Sensations of fear and perceived paranormal phenomena have been experienced by some people in a house with poor electrical grounding, particularly in an area dense with 60Hz magnetic fields varying irregularly in amplitude between 1-5 microT (Persinger et al. 2001). Geomagnetic variation anomalies in the weeks or even months leading up to major seismic activity have also been linked to odd behaviour, possible hallucinations and forms of mass hysteria. Some studies suggest that people [particularly females] born at the time of high geomagnetic activity are more likely to suffer from high anxiety. Very small variations in electromagnetic fields can affect DNA synthesis and bring about morphological changes in unborn children.

Humans are able to detect some degree of change in geomagnetic fields [with some individuals more sensitive than others], and it is suspected that the same applies for animals in general. This may be due at least partly to the responsiveness of magnetite [bio-organic iron] complexes in the body. Small changes in the geomagnetic field can significantly affect electrical activity in rat and pigeon pineal glands (Persinger 1987).

Spiritual experiences, fear, the sense of a 'presence' in the left peripheral visual field, and other altered states of consciousness have been reported from many human experiments involving weak [1 microT] complex pulsed magnetic fields applied to the temporal lobes of the brain, particularly when applied to the right hemisphere, or equally to both hemispheres. Opaque goggles were sometimes also used. Results were obtained with sine-wave magnetic fields applied in various ways at frequencies of 5, 7 and 40Hz, with the 40Hz treatments being most pleasurable, and 5Hz treatments being more visual in subjective effect. 5Hz treatments, and 40Hz treatments phase-modulated at 5Hz, also increased alpha-wave activity n the temporal lobes. These psychic effects have been hypothesised to be related to low-level endogenous *DMT* production and secretion, although this remains to be demonstrated (Booth et al. 2003; Cook & Persinger 1997; Hill & Persinger 2003; Persinger & Healey 2002; Sculthorpe & Persinger 2003).

Movement, exercise and dance; music and rhythm

Many of us will remember practices we utilised as children to produce altered states through movement aimed at producing dizziness, such as twirling, or rolling down slopes, a simple way of altering our perceptions momentarily (McKim 1977; Weil 1972). The simple act of sitting up in bed increases secretion of catecholamines such as *epinephrine* (Hoffer & Osmond 1960); changing from a lying to a standing posture increases the plasma levels of *melatonin*, cortisol, prolactin, aldosterone, *ACTH*, *norepinephrine* and β-*endorphin* (Nathan 1998).

Exercise also affects neurochemistry, as any athlete will know. Vigorous exercise raises levels of *dehydroepiandrosterone* [DHEA] (Crenshaw & Goldberg 1996) and *tribulin* (Glover et al. 1987), as well as those of catecholamines [*epinephrine*, *norepinephrine* and *dopamine*], which also increase with static exercise, such as Tai-Ch'i. Increasing the intensity of exercise elevates *norepinephrine* levels above those of *epinephrine*, and its plasma concentration remains raised for at least 30 minutes after exercise has ceased. Levels of *endorphin*s and *enkephalin*s are also raised with vigorous exercise (Jin 1992; Kruk & Pycock 1983). Another interesting effect noted with long-term exercise in rats was increased sensitivity of 5-HT2 receptors (Dey 1994).

Dance can awaken expressive and creative energies within the dancer, probably linked at least in part to those changes just mentioned. Ritual

rhythmic dancing is an integral part of group spiritual practices in many traditional tribal groups world-wide, usually closely linked with music, involving percussion instruments, 'wailing' and/or 'droning' reed or wind instruments [such as shahnai, horns, flutes, bagpipes], and/or stringed instruments [such as the sitar], and often also the human voice, released spontaneously in non-verbal rhythmic and tonal expression, or as repetition of mantras. Music played for such intent has been claimed to operate by distracting or overloading the nervous system in such a way as to cause dissociation or trance. This may be a contributing factor, with some kinds of music, but the whole phenomenon is much more complex, and still little-understood. It is usually the dancers, however, not the musicians, who enter the deeper trance-states [though the shaman is often capable of reaching trance whilst playing a drum at the same time]. This is probably largely due to the dancers not being constrained by the necessity of maintaining control over a musical instrument (Kovach 1985; Rouget 1980; Wells & Rushkoff 1995; pers. obs.). An interesting example of trance-dancing is the spinning 'whirling dervish' dance of the Sufis.

These rhythmic practices are used in some tribal groups to awaken the 'kundalini' energy [discussed below], particularly amongst the Kung Bushmen of the Kalahari, who do so to 'heat up' the 'n/um' or 'ntum', the 'spiritual potency' or kundalini energy. They say this energy resides in the pit of the stomach, and rises up the spine and into the head, where it causes them to 'lose their senses', being so overwhelmed by the energy that they often collapse, helped to the ground and comforted by the others for the duration of the trance. Older, more experienced 'ntum masters' often do not go into this semi-comatose state, as they have learnt to control the energy to some greater degree, and better utilise it for channelling into healing purposes. The quality of ntum is also attributed to shamans, as well as other things of importance, such as the sun, falling stars, rain, bees and honey, blood, sacred fires, 'medicine songs' and certain plants and fruits. The purpose of kindling ntum is to attain the '!kia' state, the state of transcendence, where one can 'see' all and heal.

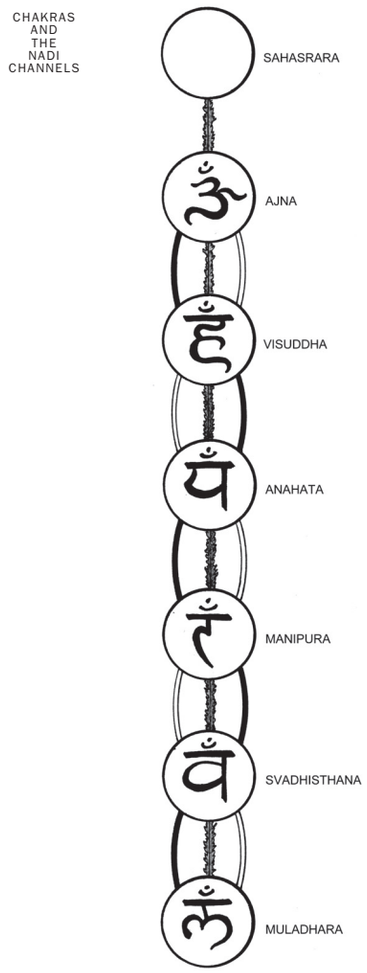
Ntum ceremonies may take place 3-4 times a month, and begin spontaneously when a group of women light a fire, sit tightly around it, and begin singing and clapping rhythmically. The men gather around in a line and begin dancing in a vertical, pogo-like motion; rattling ankle-bracelets stress the beat, as do the heavy footfalls. The rhythms are in complex 5- and 7-beat phrases; the arms are held close to the side, slightly flexed, and the body slightly hunched forward; they stare at their feet, or straight ahead, to avoid distractions. As the dance continues, the body becomes tense and rigid, with a heaving chest, profuse sweating, and prominent veins in the neck and forehead. If the dancer feels ntum rising too soon to be useful, he may stop dancing for a while and is refreshed by water from the women. The women, it should be noted, also control the ntum by their control over the pace of the dancing; thus, the ritual is in a sense a complementary one between both sexes. Some dancers may come dangerously close to the fire to help the heating up of ntum [exposure to the elements; see above]. Ntum may rise gradually, or suddenly – they say "their spirits fly along threads of spider silk to the sky", where they interact with normally invisible forces, before returning to the body. The ntum-masters blow a powder in the face of the trancer to revive him – it is said that if this is not done, death can result (Campbell 1984; De Rios 1986; Rouget 1980; Sannella 1977).

As mentioned, rhythm can play a vital role in aiding trance induction. In cultures who have been using such methods for thousands of years, there are several factors that may be aimed for in trance-rhythms: 1) monotony or repetition, 2) predominance of bass frequencies, which can deliver more energy to the brain via the ears without causing hearing damage, and 3) spontaneous and complex changes of rhythm [which aids in disorientating the system, shifting it to new levels of consciousness]. Rhythms are often relatively fast, with a rapid and pronounced beat, usually around 8-9 beats per second. In my experience, slower rhythms, around 1-4 beats per second [or slower, to a point], may be conducive to achieving a more relaxed trance state, though care should be taken not to fall asleep! Shamans of some cultures often use a drum, to which they attribute great spiritual power, to help reach the healing trance-state. Rhythmic beats in repetition seem to act on the brain through synchronising EEG rhythms [as with intermittent light-stimuli] with the rhythm of the drum-beat and/or chanting and other music, altering them to a frequency conducive to trance. This process is called entrainment, where an external frequency is maintained to induce brain frequency to harmonise with it. [Bio-feedback is a process in which people train themselves to alter their own dominant brain-wave frequencies, via connection with a monitoring device which alerts the subject, via a beep or other cue, when their EEG rhythm is synchronised with the chosen frequency.] Also of interest is the phenomenon whereby frequencies of small amplitude, applied steadily, will gradually 'build' to create harmonic overtones of far greater intensity. Music as a whole, if geared to such a purpose, can act as a focus [such as used in meditational states] to entrance the mind and aid the shift to an altered state. The topic of sound frequency also brings us to discuss binaural beats – this phenomenon rests on the output of two or more frequencies, fed into different ears, which have a small difference [eg. 200Hz and 206Hz] – when this occurs, the brain detects mainly the difference in frequency, and synchronises with it [the beat frequency – 6Hz, following our example]. This often brings about entrainment much more readily than when using single frequencies. Knowledge of this can be used to construct complex frequency-overlays, aimed at inducing an altered state of consciousness (Bear et al. 1996; Bentov 1977; Hutchison 1994; Neher 1961, 1962; Prince 1980; Rouget 1980; Wells & Rushkoff 1995).

Many examples of modern music should not be ignored for their ability to alter consciousness, especially in conjunction with consumption of psychoactive plants and/or other practices as outlined here. Whatever your tastes, there is plenty to choose from, particularly if you avoid major commercial music stores. One should choose with care, however, as music can potently affect the mood and content of an experience. This is something that Amazonian 'ayahuasqueros' have evolved to a fine art, with their skilled use of the voice to alter and direct consciousness [see below].

Perhaps the ultimate way of appreciating music and sound in connection with consciousness exploration is the ancient observation that everything is sound – although it can require a lot of quiet attention to actually realise this.

Breathwork and chanting



The breath supplies oxygen to the body, without which we have no life. The Hindus consider the breath to be a primary source of 'prana', or vital life energy [see ch'i in *Glossary*], and the practice of breath control is called 'pranayama'. Control of the breath is very important for effective meditation, and inducing trance states in general. In the 'etheric body', prana is said to flow along the 'nadis', the nerve-channels that, when in harmony, can liberate the kundalini energy [which we will discuss below, along with the 'chakras']. According to this model there are three main nadi currents, which can be visually conceptualised in relation to the physical body. With the spine as a central axis, the 'ida nadi' extends from the base of the spine to end in the left nostril; the 'pingala nadi' extends up to the right nostril; and the 'sushumna nadi' is the central nerve-channel of the spinal cord, culminating at the pineal and pituitary axis, merging into an up- and out-ward energy flow from the top of the head, called the 'sutratma'. There are seven major chakras [the exact number may differ depending on how you look at it – see below] ascending the sushumna, and the other two nadis [ida and pingala] intertwine in an opposite fashion between them, like opposing sine-waves or a DNA double helix [see diagram]. [Also, if you take the Kabbalistic 'Tree of Life'

and condense it vertically (uniting each opposing 'sefiroth' as one) you see a practically identical 7 chakra system, complete with nadis.] These nadis can be strengthened by practicing exercises to control nasal breathing. It is now known that breath from either nostril leads to dominant activity in the opposite cerebral hemisphere; ie. if inhaled breath is strongest through the right nostril [only one nostril being dominant at any one time], then the left hemisphere of the brain will be the most active at that time. Alternating nasal air intake, either by applying pressure to the opposite nostril while inhaling, or by more forceful inhalation, can bring about a balance or synchrony with EEG activity in both hemispheres (Brain Mind Bulletin 1983). Such a balance is noted in deep, harmonious stages of meditation (Hutchison 1994). Breath-control, in conjunction with meditative focusing of awareness towards parts of the body, can also be used for entrainment of physiological processes [see above].

Ideally, breathing should be at an even pace, inhaling [through the nostrils] and exhaling [through the nostrils or mouth] deeply and smoothly, whilst in between holding the breath for a few seconds. This is suitable for meditation or simply to become mentally calm and energised. As a trance state deepens, breathing usually becomes more shallow and rapid. Sometimes forms of extended hyperventilation are used to aid entry into trance, such as 'rebirthing' and Stanislav & Christina Grof's 'holotropic breathing', which can induce powerful psychedelic states (see Wells & Rushkoff 1995). I suspect these may have something to do with accumulation of carbogen in the blood; carbogen is a mixture of oxygen and carbon dioxide [usually 70/30%] that some people champion as a safe and legal powerful psychedelic drug. The drawback is that inhalation of psychotropic amounts is unpleasant and initially induces strong feelings of suffocation, despite sufficient oxygen being present (pers. comms.).

Chanting a 'mantra' [a brief phrase, word or 'seed sound' repeated rhythmically] can also aid greatly in achieving trance, both through harmonising brain waves, and by channelling vibrations through the skull and brain, particularly the pineal-pituitary axis, as the blood circulation of the nose and the base of the brain are intimately connected. The pineal-pituitary axis can be stimulated by deep nose breathing, or by singing or chanting that vibrates the base of the nose and the roof of the mouth (Kapp 1958). The consequence of this will be discussed later. Vibrations of the skull produced in this way can also exert a massaging effect on the brain, facilitating elution of neuro-chemicals into the cerebrospinal fluid (Jindrak & Jindrak 1988). According to these authors, our evolution to our present mental capacity was crucially linked to the thinning of our cranial bones, which makes them more sensitive to vibration.

Mantras are in some ways analogous to the 'icaros' sung by Amazonian ayahuasqueros; likewise, each has specific effects. A suggested simple mantra to start with is OM or rather AUM [meaning 'I am' according to some], "the sound of the universe" or the "primordial sound", which is very conducive to producing a low, monotonous vibration cycle, appropriately evoking the eternal oscillation of matter and aiding deep trance. A commonly-used extrapolation on this is OM MANI PADME HUM [translated by some as 'I am the jewel in the lotus' – see **Nelumbo**]. There are many other possible mantras that can be used, and nothing is stopping you from improvising or constructing your own. Chanting of harmonic overtones, such as practiced by some Tibetan monks, achieves the same effect on a more dynamic level. Mantras can be very powerful tools. The human voice has the potential to be developed as a healing agent in its own right, both for one's self, and for others (eg. see Garfield 1987). Interesting discussions of the power of mantras can be found in Berendt (1987) and Müller-Ebeling et al. (2002).

The control of heart-rate through breath-control may have consequences for consciousness, also. According to one hypothesis (Bentov 1977), aimed at explaining part of the kundalini phenomenon [see below], if the heart system is induced to produce an oscillation of about 7Hz vibrating through the skeletal system, the skull accelerates the brain up and down, producing acoustic plane-waves which reverberate throughout the brain, being focused in the brain ventricles, particularly the lateral- and third-ventricles, which lie above the pineal gland. The resulting stimulation may produce looped currents around each hemisphere of the brain, producing a pulsating magnetic field, with fields of opposite polarities. This radiates from the head, possibly interacting with environmental energy fields. See the section on magnetic fields above for more discussion. Also, it should be noted that many people competent in meditational practices at some point in the process experience an audible vibrating tone frequency [called the 'holy nad' or sound current] which seems to run through the middle of the head, apparently intersecting and focused through where the pineal gland would be situated. This is frequently noted also after ingestion of *DMT* or *5-methoxy-DMT* [and sometimes β-carboline alkaloids such as *harmaline*]. This has been suggested to originate from a phase-locking of oscillating standing-waves in the brain, occurring in a deep meditative state [occurs with high frequency spectrum of heart sounds, above 2000Hz] induced via the process summarised above. These harmonic changes may possibly stimulate the release of neurochemicals from the pineal gland (Bentov 1977; Chaney & Messick 1980; Strassman 1991; pers. obs.).

Meditation

Meditation is probably the best-known non-drug means of achieving an altered state, and is a relatively passive practice utilising breath-control, and often chanting, as aids. Meditation has long been acknowledged as an effective way to induce deep relaxation, improve mental outlook, and promote a healthy immune-system. Many people find it helps them give up bad habits, including the use of drugs they wish to quit. Meditation should be practiced at the same time each day for best results. Initial attempts may be frustrating, but persistence will pay off. Most people who attempt meditation give up before they have really given it a dedicated shot. People who have meditated for many years often may enter a quasi-meditative state as soon as they take position and close their eyes [or simply whenever they wish], quickening the transition into deeper states. In other words, it should become easier the more you keep at it.

Position of the body is the first important factor – this is known as 'asana' – and the classical posture for most people is sitting cross-legged with a straight back and neck. Some prefer to lie down flat on their backs – whatever is most comfortable, without being so comfortable as to induce sleep, should be appropriate. 'Mudras', or hand-gestures, may also be used. Many spiritually-inclined people, particularly healers, perceive prana, or vital energy ['ch'i'], as flowing in and out of the fingertips and palms, as well as through the nadis. Mudras thus help control this circulation of energy to concentrate it within the body, or to harmonise its flow. An easy to learn mudra is to rest each hand on the knee or thigh, palm facing upwards, with the thumb and forefinger [or index finger] touching at the tips. The efficiency of these methods in aiding meditation will speak for themselves with practice, as the sensitivity to subtle influences increases.

Meditation can be a means of entering trance or contemplative trance-like states, but there are some differences between these and the trances used by shamans, some healers, or [for example] followers of the Vodoun religion. Meditative trances are often [but not always] focused inwardly [if one believes in any real difference between inner and outer], and usually are intended to lead the meditator to stillness of mind, sometimes even to enlightenments. This is not to say that meditation is always a peaceful or even boring affair – in the course of regular meditation, the mind may have to pass through great turmoil and intrigue before reaching stillness. Shamanic or healing trances, on the other hand, are usually more active affairs requiring close involvement between both the spirit dimensions [encountered in trance] and the world of the patients [who require the efforts of the shaman in trance to produce some tangible and helpful result].

To aid the transition into trance, you must gradually relax the whole body to the point that you are no longer aware of it, and relax the mind by cutting out mental 'noise' distractions – this can be quite difficult to do at first, and for success you must train yourself to use the power of single-pointed concentration. Gaining control over this will aid you greatly in your explorations of altered states, and help give you the mental discipline that is needed to successfully utilise the benefits. Many suggest mentally relaxing each part of the body systematically, until total relaxation is achieved. The mind can be calmed by focussing on one image, object, or a visualised mantra. Chanting that same mantra also amplifies this effect; with time, one does not even need to vocalise the mantra – just thinking it will serve virtually the same purpose. It has been observed that for a trance-like altered state to occur, it is desirable for the muscles to be relaxed, and for the person to be in a receptive state of mind – this has been called 'passive concentration' by some. Actually 'trying' to enter this state usually prevents it from happening [the same goes for a lot of things!].

Meditation can induce a wide variety of states after mental stillness is achieved, ranging from pronounced calm and relaxation, to dissociation, euphoria and 'hallucinations'. More extreme states can also be reached, which will be discussed below. The meditative state is usually characterised by alpha-wave EEG activity, with theta activity in deeper stages of the experience – though some yogis have been shown to enter higher frequencies [c.20Hz] when in deeper states. When in deep meditation, advanced yogis were exposed by scientists to various external stimuli [strong light, loud banging, touching with a hot glass tube, touching with a vibrating tuning fork], though these were unsuccessful in disrupting the alpha-wave state.

Meditation should continue for as long as possible – at first, people usually find it hard to maintain the necessary attention for more than 5 minutes or so, though more experienced people can continue for hours. Generally, 20-30 minutes is a good time-period to aim for. When coming out of meditation, you should not move suddenly, as this can instantly dissipate most of the benefits you have just reached – analogous to filling a bucket with water, only to kick it over. It is advised to sit still in silent contemplation for at least 5 minutes or so afterwards (Anand et al. 1961; Chaney & Messick 1980; Das & Gastaut 1957; Deikman 1963; Kasamatsu & Hirai 1963; Shafil et al. 1974; Stoyva 1973; Temple 1972; White ed. 1990; Williams & West 1975; pers. obs.). It should be noted that some people react adversely to the mental detritus that is brought to the surface during meditation and yoga practices, developing psychotic symp-

toms or simply experiencing altered states and seeing them as abnormal, and may go on to seek psychiatric help rather than processing these experiences and pressing on through them (Brundage & Teung 2002; Lu & Pierre 2007). It is important that teachers of these practices are themselves well-versed in helping people work through these stages, or can refer their students to someone who is, so that potential positive transformation does not instead become a psychiatric disorder, as it most likely will if cut off in mid-stream and dragged to a conventional 'head shrinker' for rationalisation, categorisation and medication (pers. obs.).

Transcendental meditation [TM] can reduce prolactin and *serotonin* levels [due to increased *serotonin* uptake], cause increased alpha- and [later in the meditation, with skilled practitioners] theta-wave power in EEG readings, and increase blood levels of *dehydroepiandrosterone*, and prevent its decreases with ageing (Crenshaw & Goldberg 1996; Hutchison 1984). With TM and other periods of deep relaxation, blood levels of pineal indoles are raised (Lewis & Clouatre 1996).

For more interesting information on trance-states and their induction, have a look at this web-site if it still exists – http://www.trance.edu/

Sexual intercourse

Amongst the most widely enjoyed means of altering consciousness is, of course, sex and the ecstatic release of orgasm, achievable alone or with a partner or partners. Unfortunately, most people are still quite prudish about the subject or have various sexual hang-ups, which can inhibit their capacity to really get the most out of it. Others may see sex as something to be enjoyed only by married couples, and even then, only for the purpose of procreation, which has the side effect of contributing overly to the population crisis, because let's face it, even Catholics find it hard to resist their biological urges. The fact is, good sex between loving partners is one of the best ways to [at least temporarily] relieve stress, create feelings of profound wellbeing and goodwill, and even kiss the face of God. It is sad that a large portion of adult humanity has never had truly great sex. Part of the secret to doing so is to understand sexual intercourse not as mere screwing, but as a divine or spiritual act; this also requires shedding notions of sex as 'dirty' or 'shameful', and seeing it and our flawed bodies as beautiful things with which we can express the rapture of the cosmos and become one with it once again.

Given this perspective, it shouldn't be too surprising that sexual union is used ritually in some of the most powerful forms of yoga and magic. Sex can be seen both as a form of meditation [see above] and as a yogic means of awakening our kundalini energy [see below]. The purposeful awakening of kundalini is an extension of some meditational practices designed to allow one to attain 'samadhi', enlightenment, realisation, completion or self-actualisation. It is the ultimate goal of all yoga practices, 'yoga' meaning union. This rediscovery of union is most obvious in the practice of tantric sex yoga [sometimes referred to as 'sex magick', often involving little movement and sometimes avoiding male ejaculation altogether], in which the participants experience their partner as the literal embodiment of God/Goddess, and culminating in an ecstatic total union of energies – that is, becoming one being rather than remaining as two. This, however, is but one way of describing the process and interested readers should consult books or competent practitioners for more information on the practice of tantric sex yoga. Tantra [which is more than tantric sex yoga alone] and its relationship with shamanism is explored in Müller-Ebeling et al. (2002), an excellent work that is highly recommended – and also includes mention of some Nepalese shamans who are able to apparently raise kundalini at will almost instantaneously in themselves or others [with the aid of mantras and other ritual components] in order to enter a healing trance or to travel shamanically.

On a more mundane level, we can identify some of the neurochemicals which accompany 'regular' sex. *Oxytocin* plays a large role, from the initial pleasurable touch through to its peak at orgasm and the 'afterglow'. This hormone interacts with a host of other chemicals released during the act, including *dopamine*, *epinephrine*, LHRH, prostaglandin, estrogen [in women], testosterone and *vasopressin*. In male rats, *GABA* levels are increased after orgasm, reducing *vasopressin* levels; this, along with the action of *oxytocin*, may explain why some men are so liable to want to roll over and go to sleep immediately after sex (Crenshaw & Goldberg 1996)! When going much deeper through tantric sex, it is likely that neurochemicals more associated with kundalini, such as *DMT*, also come to the fore.

Kundalini

It is very difficult [and inappropriate] to generalise or reach conclusions about the nature of kundalini and its many manifestations, which I ask the reader to take into account. Try to ingest as many different viewpoints as possible to gain a better idea of what kundalini may mean to you. In one concept, the kundalini may perhaps be seen as a manifestation of the fundamental energy that gives rise to life and consciousness, which is everywhere. It also carries the information 'matrix' that is briefly discussed in the next chapter. It is when this potential energy is aroused from dormancy in the human organism, concentrated and making its presence felt by a variety of manifestations as it flows through the body [all involving a profound alteration or expansion in consciousness], that we know it as kundalini. No doubt others have different interpretations, and I do not regard my own as solid, but a transitory definition for the sake of discussion. Kundalini may inspire healing and creative potentials, as well as great depths of insight, though to those who do not understand what is happening to them, and in whom the kundalini has manifested unintentionally, it can bring about torment, 'delusion' and 'insanity'. There is a fine line – "the awakening encompasses both the state of being in harmony with Tao and the knife-edged path with its violent purifications and sudden, catastrophic perils...unless one understands the symbolic language of the psyche very well, one may be drawn into a labyrinth from which it is very hard to get out. And where is the [psycho]analyst who has reliable knowledge of the workings of kundalini?" (Tontyn Hopman, in White ed. 1990).

Usually considered important to the kundalini process is an understanding of the 'chakras', or 'energy discs', that escalate the central nadi [see above]. There is variation between traditions as to the number of major chakras, though 7 is often seen as a standard model, and the existence of many minor chakras is also acknowledged. These major chakras [not material in the usual sense] seem to correspond with the endocrine glands [as well as major nerve centres] in their positioning. Their positioning, as well as brief descriptions of their representations and properties in tradition, are as follows:

Root chakra ['muladhara'] – mantra: LAM; represented by 4 red lotus petals; corresponds with the base of the spine; represents the physical form, basic survival instincts; this is usually where the kundalini energy is said to lie coiled at rest

Naval chakra ['svadhisthana'] – mantra: VAM; represented by 6 vermilion lotus petals; corresponds with the gonads; represents the 'etheric' form, territoriality

Solar plexus chakra ['manipura'] – mantra: RAM; represented by 10 grey lotus petals; corresponds with the pancreas and adrenals; represents the 'astral' or emotional form, formation of language and ideas

Heart chakra ['anahata'] – mantra: YAM; represented by 12 vermilion lotus petals; corresponds with the heart and thymus; represents compassion, personality

Throat chakra ['visuddha'] – mantra: HAM; represented by 16 smoky purple lotus petals; corresponds with the thyroid; represents the 'causal', neurosomatic form

Brow or Third-eye chakra ['ajna'] – mantra: OM; represented by 2 white lotus petals; corresponds with the pineal and pituitary [which work in union to awaken the brow and crown chakras; they, of course, also act to regulate all the other endocrine glands]; represents the Buddhic form – the state of awareness and enlightenment

Crown chakra ['shoonya', or 'sahasrara'] – mantra: silence, or a thunderous roar; does not correspond with any endocrines, or is seen as merged in union with the 6th chakra – it is the culmination of the awakened kundalini, and usually perceived as extending outwards and upwards through the top of the head, some of the energy circulating down again around the front of the head, looping down into the heart chakra – directing the energy back to the heart chakra is sometimes said to be the most important step, to complete the process.

In most people, most of the time, kundalini rests more or less dormant in the root chakra. The kundalini energy is often depicted as a serpent, and here it lies coiled at rest. When roused, this energy [often referred to as a kind of 'holy fire'] usually flows upwards, following the nadis described previously, meeting chakras along the way. Sometimes, the energy is reported to enter the body from above, and such experiences are usually prolonged and painful, both physically and psychologically. This seems to occur more frequently when the kundalini is roused unintentionally, or forcefully without adequate preparation, or when its manifestation is resisted [see below].

Each chakra represents, to the individual, specific aspects of physical, psychological and spiritual existence that must be brought into harmony, or 'opened', so that kundalini may pass through. In many people, most [if not all] of the chakras are in a state of major disorder or 'blockage'. This usually goes unrecognised until such a person starts exploring states of consciousness and spirituality. Awakening kundalini without first clearing the blocks of each chakra can result in a very uncomfortable, even painful and psychologically-distressing experience, as this potent energy requires a clear path to flow freely and become fully actualised. Yoga consists of exercises geared towards making the awakening of kundalini more natural and painless, linked with meditational practices and personal psychological work that aim to systematically evolve the practitioner through each chakra. However, this does not always occur in chronological order, from root to crown, but differs in each person with individual circumstances.

Due to the overall delicacy and depth of the kundalini process, and to the fact that patience is an important lesson of this process, it is generally considered best to work on the kundalini gradually over a long period of time, letting it rise when it is ready, and when you are ready for it. This is the way of Raja yoga. Forcing the kundalini to rise more rapidly via physical and meditational exercises, with the important element of breath-control, is the way of Hatha yoga, which carries more physical and mental

dangers for the unprepared. In meditation, the third-eye chakra is often focused on, and short, rapid violent breathing is practiced along with specialised asanas, mudras, kriyas, mantras and other techniques. Although I initially intended to, the details of some of these methods will not be covered here, as I feel I could not reproduce them fully and safely in the space given. I also don't believe it is beneficial to tempt people into forcing the kundalini process. The path in itself is vital in preparing for the awakening of kundalini, and just as important as a learning process. Striving for kundalini arousal as a goal, as with striving for visions and becoming attached to them, can ultimately be counter-productive, even destructive. Seeking 'experiences' themselves rather than seeking to learn through experience is a very common pitfall, both with psychedelics and with kundalini yoga. The experience of enlightenment is not enlightenment itself, except as a glimpse of what can be. The premature and forced arousal of kundalini may also result in pride in the mistaken assumption of enlightenment, without having learned the discipline required to maintain it and apply it, and thus anything that was gained is quickly thrown away. This is also true for the use of psychedelics without an accompanying framework of spiritual practice.

However the information, though hard to find, is out there, and if you think you wish to attempt Hatha yoga, you should pursue it with caution and respect [see some of the references below for further reading]. These are life-changing events being evoked, not games for the curious. Some 'New Age' folk seem to believe kundalini is manifested as a kind of pleasant tingling sensation in the spine. This is wishful thinking. Kundalini actualises a vital energy so intense that it can [according to many] literally knock you dead or at least drive you mad if you are not ready for it and channel it too intensely, though such extreme results are very rare. I wish to stress again, that to work with the energy of kundalini [or equally with any techniques of altering consciousness], it is highly recommended that you be in good to excellent physical and mental health. Inability to deal with the results through impatience, lack of proper groundwork, and poor health can result in physical injury and/or insanity.

When this energy is fully realised and harnessed, which may take many years of learning and practice, the practitioner has theoretically taken the kundalini process as far as it can go without crossing the veil to physical death [due to the intensity of energies channelled]. The common idea is that, at this point, there is nothing further to learn, being able to reside in eternal bliss and all-seeing wisdom. This is a somewhat romanticised view, depending on how the resultant healing force is used. This path does not end in a glorious plateau, where one can sit back and say, "okay, so here I am, now I'm enlightened forever!". There is always further to go – in this path, to stop means stagnation, and eventually, regression. Indeed, this is the fate of most people who pursue spiritual paths, because the above notion of what 'enlightenment' is all about is so prevalent. The 'fall from grace' that usually follows often occurs so gradually that it is not even noticed. 'Enlightenment' is relative, and is not a fixed point – one should not become complacent with perceived 'enlightenment' and undo progress with the pride of the ego, or unfitting words and actions. There are already enough religious zealots who do not practice what they preach, without adding more to the world. As stated earlier, having a 'kundalini experience' does not automatically make one enlightened. A glimpse of the absolute does not automatically make one enlightened. You must live your learning in every moment, spread the seeds of light for others, and commit your life to this purpose, in whatever way is appropriate. Only then will it stay with you, and you will still never stop learning. If you are running around telling everyone that you are enlightened, then that's a good sign that you probably are not!

It is now believed in some quarters that a fair number of people in our society appear to be experiencing spontaneous kundalini-awakenings, either gradually over time or rapidly and intensely all at once. The symptoms, not being recognised in most societies, are often misinterpreted by subject and physician alike as manifestations of schizophrenia and biological disorders, deemed as unnatural and in need of suppression.

Both adverse and positive symptoms of sudden or impending kundalini-awakening can include many of the following phenomena:

- cramps, muscle twitches
- itching, vibrating, tingling, or crawling sensations on the skin
- intense sensations of heat [sometimes felt as burning] or cold
- headaches and pressures in the head, often like a steel band around the head
- racing heartbeat, chest pains
- digestive disturbances
- pains or blockages in back and neck, particularly where chakras are located
- numbness
- involuntary body movements or compelling forces
- energy rushes, particularly up the spine, or feelings of immense electrical energy flowing in the body
- overwhelming fatigue, or conversely, hyperactivity
- alterations in eating habits, and sexual drive [increase or decrease]
- spontaneous vocalisations, or speaking in tongues
- emotional outbursts and rapid mood shifts
- hearing of inner or distant sounds, or buzzing in the head
- visual distortions and hallucinations
- expansion of consciousness and blissful sense of union and harmony
- development or manifestation of psychic phenomena and extra-sensory perception

Of course, many of these symptoms, in isolation, may have little or nothing to do with kundalini and more to do with simple physical illness or poisoning, depending on individual circumstances. It is when many of these symptoms are seen together, that kundalini might be considered as a cause. Some of these symptoms are likely to be physical manifestations of chakra-blockages. As well as by the methods or circumstances mentioned above, kundalini may be roused by the use of psychedelics over time in some individuals. Such experiences can also serve to prepare the mind for kundalini, so that the progression of expanded consciousness is not as much of a shock as it would otherwise be (Chaney & Messick 1980; Collie undated; Hannigan 1997; Johari 1987; Rele 1960; Sannella 1977; Temple 1972; White ed. 1990 [highly recommended]; Yatri 1988; pers. obs.).

It is relevant here to mention that *DMT* potently stimulates pineal function, and *mescaline* enhances the pineal's synthesis of *serotonin* (Lyttle 1993; Prince 1980). The pineal [see brow or third-eye chakra, crown chakra], in conjunction with the pituitary and [to a lesser, but important extent] the other endocrines, seem to be intricately involved in secretion of neurochemicals involved in some aspects of kundalini manifestation [see below].

The pineal gland, closely associated with the control of our perceptions of awareness, is often considered to be the 'seat of the soul' in many distinct cultural traditions. It is interesting to note that in Tibetan tradition, after death the soul is believed to transit a 'limbo' period of 49 days, during which it 'decides' on its next incarnation. It is now known that it takes 49 days for the pineal and gonad cells in a human embryo to separate as distinct entities. This could be interpreted as the 'soul' or consciousness entering the new physical being, at the moment of differentiation between the 'poles' of the kundalini-axis.

The pineal is quite capable of synthesising potent chemical substances and releasing them into cerebrospinal fluid, and it is most likely to do so under the influence of the diverse practices outlined in this chapter. The pineal has no blood-brain barrier, and possesses specialised blood vessels which allow the transport and accumulation of large molecules in the pineal. The primary chemical activation in the pineal, in relation to kundalini, most likely involves the *tryptamine*s *5-methoxy-DMT* and *DMT*, with some probable contribution from *bufotenine* and *5-methoxytryptamine*, all in combination with endogenous MAO-inhibiting β-carbolines such as *pinoline* and [possibly] *6-methoxyharmalan*. These chemicals are all known to be synthesised and concentrated in the pineal gland [also contained in blood, urine and cerebro-spinal fluid] of mammals, including humans, although the endogenous presence of *6-methoxyharmalan* still requires further evidence. *DMT*, in particular, is known to be actively transported into the brain, something which occurs for only relatively few chemicals with which the brain is most familiar and in need of. *Tryptamine*s are also synthesised in the retina, and the connection of the optic nerves and the pineal gland bears some food for thought. *Serotonin*, and the enzymes HIOMT and INMT, are all most concentrated in the pineal. The pineal also contains abundant *methionine*, aiding in the conversion of pineal *serotonin* to *DMT*-derivatives using the methyl-donor SAM. The kundalini 'flash' has been compared to smoking *DMT* or *5-methoxy-DMT* by some. The pineal also has neurotransmitter systems for *melatonin*, *norepinephrine*, *dopamine*, *GABA*, *glutamic acid* and *taurine*, and has been found to contain the hormones LHRH, TRH, CRF, somatostatin, *oxytocin*, *vasopressin*, *adrenocorticotropin*, α-melanocyte-stimulating hormone, β-*endorphin*, *met-enkephalin*, *leu-enkephalin*, dynorphins A and B, α- and β-neo-*endorphin*, VIP, cholecystokinin, bombesin, arginine-vasotocin [AVT], substance P and neurotensin. It is quite clear that the pineal is potentially capable of releasing an exceedingly potent cocktail of psychoactive chemicals, and is known to affect the secretions of the other endocrine glands, which could in theory account for the symptoms of kundalini as outlined above (Axelrod 1961; Barker et al. 1981; Binkley et al. 1979; Bosin & Beck 1979; Christian et al. 1977; Ciprian-Ollivier & Cetkovich-Bakmas 1997; Collie 1997; Gillin et al. 1976; Hannigan 1997; Kveder & McIsaac 1961; Lewy 1983; Liss 1989; Lyttle 1993; Pevet 1983, 1985; Pomilio et al. 1999; Relkin 1983; Sannella 1977; Shulgin & Shulgin 1997; Strassman 1991, 2001; Temple 1972; Yuwiler 1983; pers. comms.; pers. obs.).

Some final thoughts

It seems that in many areas science is simply rediscovering and confirming in its own language what mystics and shamans have known for millenia. We think we have come so far in moving away from this ancient knowledge which we have called 'superstition', yet we now appear to find ourselves turning full-circle, returning to whence we came with new layers of understanding in order to begin a new cycle.

The observation of neurochemical correlations to the forms of consciousness-alteration discussed in this book does not diminish the significance of these states. Recognising that stimulation of certain areas of the

brain can induce 'religious experiences', or that activating sub-groups of *serotonin* receptors by smoking *DMT* results in profound changes in consciousness, is only a small part of the picture and does not equate to explaining such phenomena, especially regarding the content and significance of subjective experience. To see such mechanistic reduction as a complete explanation of what is going on simply glosses over the vast gaps in our understanding.

Many people consider the use of psychoactive drugs, and the experiencing of altered states of consciousness, as being unnatural and decidedly harmful. However, it should now be clear that these states are not alien to our nervous systems – rather, they are expressions of neural pathways built into all of us, which only require the necessary conditions or stimuli to be triggered. If you think of your nervous system as a radio antenna, this is analogous to temporarily tuning to a different frequency, or fine-tuning your 'normal' frequency to give a clearer signal. [Certainly, some substances such as lead may affect consciousness as a result of the brain damage they cause, but these are not the kind of drugs we are discussing here.] Following this line of thought, these other frequencies encountered through retuning are not illusory fantasies, but valid extensions of reality, of which we are usually unaware. As mentioned previously, it is impossible to conclusively prove that any reality, including especially what we take to be our 'normal' waking reality, is not fantasy, or conversely, that it is fantasy. I take the opinion that all of these altered states and what we experience in them are valid as their own perspective of a fluid reality. Whether they are made 'real' to us by the very act of perceiving and experiencing them, or whether they exist independent of our attention, is unknown. In the science of physics, too, the question of whether anything exists independent of observers has perplexed many. One current view leans towards acknowledging that 'reality' appears to be a creation of consciousness itself, with the two being unable to exist independently. Whichever model may turn out to be most seemingly accurate is perhaps irrelevant to the truth of the belief held by many people today, that expansion of consciousness is both necessary and integral to our continued survival and socio-spiritual evolution, for us to re-create ourselves and our reality in an image of vibrant harmony.

It is now more widely known that people are capable of learning to exert a degree of control over bodily functions once thought to operate unconsciously [eg. blood pressure, heart rate, immune activation, healing processes, hormone secretion, neuron firing]. The learning of these skills can be enhanced by biofeedback techniques (Hutchison 1994; Rogers et al. 1979), meditation and yoga (White ed. 1990). In other words, our health and state of mind are not mutually exclusive, and are not solely under the control of external or unconscious internal forces over which we have no influence. The fact that we only appear to utilise the information from a small portion of our DNA, and that we only exercise a fraction of our cerebral potential, might suggest that we are built with capabilities that are just waiting to be activated or awakened. Scientists often refer to this mystifying extra genetic material, for example, as 'junk' DNA, and for many years it was dismissed as just that, with the exception of the more curious. Recent theories suggest it is merely 'padding' or 'stuffing', whilst others are finding that these portions have functions we do not yet understand; regardless, nature does not make true 'junk'. Everything serves some purpose in a greater process [that is the basis of understanding ecology] of which we are largely unaware. Whether it be found in DNA or elsewhere, or more likely everywhere, the potential exists to become aware of our place in this process, to re-unite with the whole, and in that process achieve positive transformation.

A PRIMER IN TRIPPING – TAKING THE JOURNEY

Ever since the large-scale rediscovery of psychedelics by western cultures in the mid-1960's, many curious people have been inspired to experiment with them. These pioneers and those few in the decades before them faced what was, for their cultural background, completely uncharted territory. Although some such folk had access to spiritual, philosophical, or other literature from which parallels could be drawn for guidance, or to someone already familiar with the terrain who could offer support and assistance, many did not. Most people would begin the psychedelic path with little or no understanding of what they were getting into, or of the attendant implications, which then were little-known and often exaggerated. The majority of people who approach drugs appear to do so because they desire change without having to put in any real effort themselves. People who expected psychedelics to magically transform them and the world encountered disappointment when they found that the drugs would not do all the work on their own. After experiencing the psychedelic state to some degree, and the initial awe had subsided, most people [but of course not all] realised that they did not have the faintest idea what to do with it. Rather than admit their own deficiencies, many came to denounce the drugs in later years as useless and deceptive distractions.

Little has changed today, except that the average strength of LSD 'hits' [LSD or purported LSD being the only psychedelic that most people ever try, not including **Cannabis**] is much lower than in the mid-1960's. As a partial consequence of this, current generations have a greater number of people who have only ever had relatively mild psychedelic experiences. They often remain unaware of the greater depths, but believe they know all about 'tripping'. This helps the spread of misconceptions, as a strong psychedelic experience that brings up deep psychological and emotional issues, for example, is now often seen as being abnormal, whereas an aesthetically-enjoyable experience with minimal psychological impact is seen as the ideal. It is commonplace to desire all the positive effects without the negative, but when exploring inner space, things simply don't work that way. The paths of personal growth and spiritual development [which are being tinkered with when using psychedelics, whether it is realised or not] are not all rosy. One must pass through both heavens and hells to pursue true transformation. Even if that is not what you are after, you may be pushed in that direction anyway by a particularly powerful experience. Unlike the general mood of psychedelic experimentation in the 1960's, today it is often seen as unusual and delusional for people to take psychedelics for spiritual purposes, or for that matter, even to believe in anything that happens during a psychedelic trip as being real in any way.

Many who dabble with these drugs do so looking for a good time, today largely in association with dance culture, or to enjoy a spectacular visual show as a detached observer. These people usually abandon psychedelics after a short period of experimentation, sometimes confused and disillusioned, as mentioned above. Indeed, LSD [except in very low doses] seems to have lost much of its popularity in dance culture to MDMA, or 'ecstasy', which is not even generally considered to be a true psychedelic, and rarely brings one into contact with the darker sides of the mind [not to deny that MDMA has usefulness]. Others try to use psychedelics earnestly, but still end up being disappointed by the difficulty in integrating these experiences for long-term benefit.

The aim of this chapter, therefore, is to discuss some of the things that may be expected from a psychedelic experience, and some of the known ways in which psychedelics can be used more effectively. It is important to remember, however, that every psychedelic experience is different and exceedingly complex in content. At best, this information should be seen only as a collection of fragmentary observations and convenient analogies, rather than a comprehensive guide to the psychedelic experience. And as the old saying goes, "the map is not the territory" and ours is only a fragmentary map. It is almost universally reported by psychonauts that our current verbal means of expression is inadequate to describe accurately what is being experienced in these states. Even if new words are created for these purposes, they will still be self-limiting tools, as it is a seemingly intrinsic characteristic of words that they attempt to separate and define. This is a tendency largely alien to the psychedelic realm [which tends to expose the continuous whole], and usually does not help much in understanding what is going on. This is at least similar, at most identical, to notions of Zen and Taoisim, in that the Tao or Zen which can be described in words is not the true Tao or Zen. Words are at best pointers, but the essence is beyond words. Having said that, words will have to suffice for us, for now, or else we might as well just throw this book out of the nearest window!

Setting the Stage

Psychedelics offer such profound potential for learning, positive change, and ultimately an evolution of consciousness, that it seems [to those who have explored deeply] to be a virtual insult to use them casually for entertainment. Deeper aspects of reality can be highly disturbing to those who are not prepared for such a psychic confrontation. [Most people are not prepared, even amongst those who think they are, so it's nothing to be ashamed of!] The *tryptamine* psychedelics in particular, as well as *salvinorin A*, show the ability [in moderate to large doses] to reprimand those who attempt to use them casually, in no uncertain terms. This is not to mention the great power of the tropane hallucinogens such as *hyoscyamine*, with plants containing them [such as **Datura**] sometimes being used in tribal cultures to reprimand unruly children! At lower doses, one may be able to evade such psychic confrontation for some time, but the unpredictable potency of, let's say, **Psilocybe** mushrooms, make it a relative certainty that one will eventually have a torturous experience if one continues to use these substances for idle entertainment or attempted escapism.

A proper respectful approach is thus essential if one is to have good results. One should approach the psychedelic experience as one would approach the most sacred oracle. A purpose is required for consuming these sacraments, a context into which to frame the experience. Failing to provide a clear purpose often results in a vague, unfocused experience of little apparent meaning, compared to what can be achieved otherwise. On the other hand, doing so does not at all guarantee an 'easy' or pleasant trip, but it does help ensure that you get something meaningful from the experience. Indeed, these more difficult experiences are often the most useful.

Peoples of the world who use these plants regularly generally do so in a ritualistic setting – that is, their purpose and expectations of the experience and their way of approaching it are intricately interlaced with their spiritual beliefs and cosmological worldview, in a way that creates, for the group or the individual, a safety net to help ensure a successful visionary journey. Unfortunately, most westerners have been conditioned to feel pretty silly doing anything approaching 'ritual', a word that has a decidedly negative occult connotation for the average person. This might not be a problem if less people believed what they saw in movies or on television, and more people realised that 'occult' simply means that which is hidden, or beyond ordinary human understanding, rather than just puerile satanism and black magic. Of course, this is still a problem to those who refuse to believe in the existence of anything that might be 'beyond ordinary human understanding'. As I see it (and this may anger some), the kinds of 'mystical groups' who do for example actually dress up in fancy robes, adopt titles of elitist spiritual authority, perform elaborate and stereotyped 'magical rituals', and take themselves very seriously, are just as lost as almost everyone else, and use the external cloakings of secrecy and man-made occult dogma to mask their lack of genuine insight from others, as well as from themselves. [It should be noted that not all practitioners of ritual magic have missed the point, and such practices can be of value if undertaken wisely.] The awakening of consciousness that can be brought about with the aid of psychedelics or other means is a process of removing the veil of secrecy, of bringing the ineffable into human awareness, rather than keeping it as the claimed secret property of an elite few. So, we have no need here for secrets, spiritual pomposity, and unnecessary physical props. What is meant here by ritual is that one makes a conscious, formal entry into the 'otherworld' with displays of respect and declarations of intent, whether these be expressed internally or externally. This mode should be adhered to throughout the journey, but that does not mean you must remain deadly serious as though attending a funeral. Happiness and laughter may be quite appropriate! You should not feel that you need to follow a ritual that someone else has set out, as this may not be appropriate to you, your culture, or your beliefs. Find something that feels right for you. This is firstly about developing control over and honestly understanding yourself, something that is difficult to accomplish when following the rules of others without thought.

I prefer to create ritual more or less spontaneously, leading up to consumption of the chosen sacrament. However, there are some constants I have chosen which are used as a basic framework. Firstly, the time of the ritual is usually planned at least a few days to a week in advance, to give time to mentally and physically prepare for the experience. I prefer to fast at least for the day, or most of the day before the experience, as do many traditional shamans, though the fasting period may be extended for longer if so desired. This ensures a degree of physical cleansing, as well as more rapid assimilation of the substance consumed. According to some, it also reduces the severity of any potential nausea or vomiting, though some find it easier to hold the contents of their stomach if a small amount of light food is eaten beforehand. Nevertheless, vomiting once the substance has been sufficiently absorbed can be therapeutic in some instances, if treated as an opportunity for a kind of purifying, 're-birthing' catharsis. Vomiting after consumption of 'ayahuasca' [see **Banisteriopsis**], 'peyote' [see **Lophophora**] or 'San Pedro' [see **Trichocereus**], in particular, is often considered quite a normal part of the experience, though some are lucky enough to experience little nausea and no vomiting. In the case of San Pedro, K. Trout suggests that this is almost entirely related to the

method of preparation, with the exception that regular beer drinkers will generally vomit regardless (Trout pers. comm.). Some report that with ayahuasca, excessive fasting can actually diminish the effects, and they prefer instead to abstain from food for the second half of the day before the consumption.

Bouts of meditation throughout the day, but particularly immediately preceding and following the ingestion, are also recommended. This gives time to focus on your intentions for the experience, as well as to induce a state of calm [to counter the jitteriness and tension that often come with the anticipation and fear of an impending psychedelic experience] and reduce mental 'noise' and distractions, including the distraction of nausea. I find it also places me into a more receptive state to learn from the experience. I usually make use of incenses with 'purifying' and calming effects, both to 'cleanse' with smoke the plant or beverage to be consumed, as well as to purify the area and centre myself with the vapours. Some examples are 'frankincense' [see **Boswellia**], 'sandalwood' [see **Santalum**] and 'white sage' [see **Artemisia**, **Salvia**]. The sacrament is handled carefully and respectfully at all times, and any parts not used, or residue left from a tea, are never simply discarded as waste. The discipline involved in following ritual procedures, including the discipline involved in consuming and keeping down foul-tasting sacraments [at least until sufficient absorption has taken place], ensures to a degree that one is serious about learning from the plants, and prepared to earn wisdom rather than be handed it on a platter.

Getting to Know the Plants – the Amazonian approach

It is worth mentioning here an interesting practice in parts of the Amazon. Shamanic initiates, or others seeking knowledge or in need of deep healing, often will undergo diets in which a 'plant teacher' is consumed. This is done in order to become imbued with the spirit of the plant, to learn its properties and 'icaros' [sacred songs; see the previous chapter], and gain healing knowledge. Once one has undergone this process, singing the icaro of the plant can be used to call upon its healing powers, without the plant itself actually being used. Diets are completed in seclusion in the forest, and the initiate abstains from sexual relations, focusing their energy and intent on the task at hand. In regards to food, the diet is similar or identical to that undergone for consuming ayahuasca [see **Banisteriopsis**, *Methods of Ingestion*]. Foods which are allowed are cooked plantains [see **Musa**], smoked fish [though 'pana' (Serrasalmus natterei, S. rhombeus and S. spilopleura) and 'zungaro' (Trichomycterus spp.) are not allowed], and sometimes rice and manioc. The flesh of only some animals may be eaten – boa constrictors [Boidae family], the caiman 'lagarto blanco' [Caiman sclerops], and the birds 'panguana' [Crypturellus untulatus], 'pungacunga' [Penelope jacquacu], 'perdiz' and 'pava' [unidentified]. All spices, sweeteners, fats, cold beverages and alcohol are prohibited. Diets are often taken in succession, with a different plant being taken for each diet. Many shamans feel diets should be taken in a particular order, but this order varies depending on individual preferences. Usually a short break may be taken between diets, as each may last for up to 1 month [sometimes more]. When one is under the diet, the chosen plant is prepared and consumed. Sometimes the initiate will have been told by his or her shaman how to prepare it – sometimes the initiate will be told by the plants themselves, either during the previous diet, or otherwise through dreams or intuition. It may be taken either only once, at the beginning of the diet, or consumed more or less continuously throughout. Sometimes it may be taken mixed with **Banisteriopsis**. During this time, it is best to be near living specimens of the plant being used, in order to further mingle with its essence. Some of the plants used in diets have direct psychoactive effects, whilst others are psychoactive only with ayahuasca, or have subtle effects that manifest over the next few days, or in dreams. Others are not considered psychoactive, but have mildly toxic effects, which later develop into long-term benefits of improved stamina and spiritual strength (Bear & Vasquez 2000; Luna 1984). This is an efficient method of becoming acquainted with a healing plant. Though the required seclusion and time-devotion may be difficult for many people today, it will be valuable for those who can make the necessary efforts.

Setting the Stage Revisited

The importance of set and setting in the psychedelic experience can not be understated. What is meant by this, is that to give the best chances for a successful trip, it should be done in surroundings you feel comfortable with, with people who you like and trust, and in a good frame of mind. If feeling at all depressed or unstable, taking a psychedelic is generally not a good idea. Sometimes, even if feeling this way, a psychedelic experience may be just what is needed, though it is much more likely to be a difficult one. Unless you are experienced at this, it is not a good idea to trip completely alone. Some people do not like to have company whilst tripping, but it is still a good idea to have a friend within shouting-distance, just in case assistance is needed. You can never know what might happen, even if you are very experienced with psychedelics. If you must do it alone, it is at least a good idea to let someone else nearby know what you are doing, and where you will be.

The sensory input received whilst tripping is greatly amplified and subject to synaesthesia, and can greatly affect the nature and outcome of the experience. If you have control over any of these inputs, use that control wisely with this in mind. Some music that may be enjoyable under normal circumstances may become unbearable or excessively disturbing with psychedelics. It can take a lot of trial and error before gaining a feel for what works best for you in different situations or with different purposes in mind. Excessive sensory input [and output] may sometimes have the effect of 'burning up' a lot of the energy of the trip, resulting in a perceived fading of effects much more rapidly than would usually occur. I have found this to happen particularly when listening to a lot of very intense music, or after making love intensely. Another benefit of moderation, or even minimalism, with regards to sensory input is that it facilitates an easier perception of the subtle, more significant aspects of the psychedelic experience.

A natural environment is highly recommended as a setting. Contact with nature whilst tripping seems to offer far greater potential for a highly positive experience than an indoor or urban setting. Even so, the area should be chosen with an eye for potential dangers, such as slippery rocks and cliffs! Trip with people who you know will not annoy you during the experience, with inane questions or attempts to 'trip you out'. Such people, however well-intentioned, can very much disturb the mood of a trip and make it difficult to focus. Tripping in public or at crowded events may be tolerable for some, but it is generally not conducive to a good experience. I have a few friends who have had severe panic attacks as a result of doing so, one of whom was taken away in an ambulance after collapsing from distress in the midst of a crowd at a rock festival. If you are not inclined to want to interact with people whilst tripping, steps should be taken in advance to ensure some degree of privacy, free from disturbing background noises or unexpected interruptions, while still having a trusted friend somewhere nearby. Taking the phone off the hook is generally a good idea.

The time of tripping may also be considered. Some prefer to do it in the daytime, when colours and visual detail can be best appreciated with eyes open, but many traditional peoples prefer to do it at night, when the surroundings do not cause as much of a distraction from the inner experience. This can also serve to provide a dark 'canvas' on which the visions manifest, or as an excuse to build a fire, which can be meditated on for a similar purpose, and bring the group (if there is one) together in a circle of contemplation. However, with short-acting tryptamines such as *DMT*, *5-methoxy-DMT*, and *bufotenine*, visual phenomena are best perceived in low-light conditions, as opposed to total darkness. In the modern world it is a simple matter to trip at night while still having indoor light available, depending on what is desired at the time. Some people prefer their trips to coincide with phases of the moon.

If at all possible, the inexperienced should undertake the journey accompanied by someone who has successfully used psychedelics for a long time, and who shows a competent handling of psychedelic states. Preferably, such a guide should be present if needed, but should not make his or herself the central focus of the trip. Avoid those who attempt to use psychedelics to exert control or influence over others. These people may be known as 'power-trippers', and do no good for anyone in the long run, including themselves [in the usual sense of the term, a power-tripper is someone who gets off on having power over others and abusing that power, and does not refer to 'tripping' such as on psychedelics]. Look for someone who treats you as an equal, and does not patronise or exhibit self-inflation. These are the kinds of people most likely to be able to help you with the first steps of your path, if you feel you need such a person. Of course, no guide can teach you everything [though some will pretend they can], nor should you expect them to. Ultimately, it is the plants that will show you the way if you choose to walk with them.

It is still possible to more or less ignore set and setting, and have successful trips. Some people feel that this is the best way, as there is no conscious erection of any comfort barriers between the mind and the surrounding world. Although this approach is more risky, it does bring the valuable challenge of coping with the 'real world' and all of its unexpected distractions and dangers, whilst in a strong altered state. After all, what good is it to become awakened on one level while being unable to cope with the mundane, or deal with things you would rather avoid? Ken Kesey and his group of Merry Pranksters are a wonderful example of psychedelic experimenters who took such an approach, with certain rules [such as being out-front with the group, and everyone providing each other with freedom to 'do their thing'], more or less successfully (see Wolfe 1968). A synthesis of these two major approaches may be the best, though individuals should work with whatever they feel most appropriate on each occasion of consuming a psychedelic substance. Remember, however, that the paths we are discussing do not end when the effects of a drug wear off, to resume when the next dose takes effect – we are discussing both a spiritual/magical path and a way of life, in which individual psychedelic experiences are dramatic and catalystic events, but are not the whole path in themselves.

The Turbulence of Lift-Off

After respectfully consuming your chosen psychedelic sacrament, you will need to cope with the first phase, which is sometimes easy, sometimes not. The period until first onset of effects will vary depending on the substance involved, the dose taken, the method of ingestion, and the contents of your stomach. The transition from 'ground-state' can often be turbulent, as you adjust to the changes taking place. What follows is difficult to relate verbally. There will be some generalisation, because many of these substances produce qualitatively different effects, yet with some strong binding similarities. Added to this is the fact that the psychedelic experience is very hard to put into words [see above] that will mean anything to someone who has not been there before by some means, and that it is different every time for every person – thus, the only way to really find out is through direct experience. I will use *tryptamine*-based psychedelics [*psilocybin*, *DMT* in combination with harmala alkaloids, LSD], and the prototypical *phenethylamine*-based psychedelic, *mescaline*, as standard 'reference-psychedelics' for the purpose of this discussion.

Transition is marked initially by physical and mental restlessness, sometimes with odd gastric sensations, and vague body aches that may often be partly relieved by stretching and deep, slow breathing. Some people experience mild nausea, though actual vomiting is rare except with intense-tasting brews such as ayahuasca or those prepared from *mescaline*-containing cacti, for which both nausea and vomiting are relatively common accompaniments [see above]. Pupils become dilated and all of the senses slowly become heightened beyond the usual thresholds of perception, a phenomenon that will increase in intensity up to the peak of the experience. These effects can be rather uncomfortable and disorientating at first, particularly if they are resisted. It is generally best to sit or lie in a comfortable spot breathing deeply, whilst contemplatively adjusting to the changes taking place. It should be said, however, that as the effects increase in strength, the deepest and most intense states can be reached by continuing to remain still and meditating, though it can be difficult to do so at first.

Feeling Out the Territory

Often a profound euphoria is felt, and a sense of awe and wonderment. Visual effects begin from the amplification of colours, shapes and textures, and may progress to actual hallucinations, although the perceiver involved is usually aware at this point that what they are seeing is related to the neurochemical changes taking place, and is not necessarily visible to anyone else. With the eyes closed, visual phenomena seen behind the eyelids are often exceedingly spectacular and vivid, having a tendency to metamorphose so rapidly into different detailed moving images that it can be difficult to keep pace with them. Visual effects often correlate with the equally rapid thought processes occurring in the individual, and with any music or sound that may be present, and may seem laden with meaning and significance. This synaesthesia may extend across all of the senses [ie. seeing sound, tasting colour, etc.].

Thought takes on a dimension not generally encountered in the average waking state. Thoughts are usually directed inwardly towards self-analysis or beyond, with a startling clarity. The thought process is often witnessed as a visual and symbolic one. Here one may have an extraordinary capacity for assessing the 'big picture', temporarily freed from one-dimensional perspectives. Deeply entrenched personal problems and their roots can be accessed from the subconscious into which they had been banished, and consequently viewed and worked out with an honesty and insight that is rarely displayed when 'sober'. It is with carrying these solutions back to the 'sober' state and applying them, that real positive change can occur. If one has no prevalent personal issues to resolve, then this stream of consciousness can be directed towards external problems or tasks, or to the nature of reality itself, down to a subatomic level and beyond. Sometimes, however, one may seem to have little control over the direction things take.

When in a psychedelic state, we become sensitive to things that, due to the editing processes of our brains, we are generally unaware of in everyday life. The human nervous sytem in this state can become a conscious conduit or receptor for, amongst other things, what some refer to as the 'information matrix' – an omnipresence in which can be found all thoughts, psychic 'noise', all the records of everything that ever was, is, or is still to come. Some people refer to it as the 'one mind'. This is a concept difficult to swallow for most people, I am sure, but many of us throughout human history have experienced it as a reality. Developments in physics seem to support the probability of such a system. Its likelihood is also reflected in the 'holographic' theories of consciousness and reality [which may indeed be one and the same!], as mentioned previously (see Narby 1998 for some excellent discussion; also Wilber ed. 1985). Again repeating myself [because the context seems right], there are many accounts of people who have taken psychedelics in clinical studies [or privately], and as a result, gained knowledge about things which they could not have previously known, or reached breakthroughs in problems that had been troubling them for some time in a professional work project or the like. This has occurred with chemists, architects, computer programmers, physicists, and other 'professionals'. The effective prohibition on human research with many of these substances means that there is, unfortunately, a lack of much published data in this field. As was mentioned earlier [see *Questions & Answers*], such events are experienced far more frequently in non-clinical settings, where the results are either dispersed anecdotally, or simply kept in privacy.

It is precisely this aspect of psychedelics, the exposure to valid aspects of reality outside of 'normal' experience, that enables shamans to practise their craft, and its timelessness and universality is what makes shamanism still relevant today. Shamans have learned to use plant psychedelics in order to go where they need in these experiential realms, to find the information required for their task at hand. This is a learned skill that can not be taught in a book. It is also where many psychonauts fail to grasp the greater potentials of psychedelics. The experiences can be so fascinating in themselves, that it is easy to become distracted by sensory phenomena, and to forget that the psychedelic state can be applied to far more useful ends than intellectual entertainment. The most important point to remember when using psychedelics in a shamanic and/or spiritual context is to remember why you came. Focus on your purpose for the ritual, and whenever you notice your thoughts wandering, re-focus. This needn't be a case of forced concentration. It seems best to adopt a degree of detached concentration, which allows a greater flexibility of abstract thought – and this is how thoughts evolve in psychedelic experience, rather than always in linear, logical progression. The successful integration of the experience, which will be discussed below, is in part important because it weds the fruit of abstract thought with that of rational thought, thus bringing the ethereal into the material [or vice versa!]. Become a receptacle for seeds of insight; water them, nurture them, and let them grow and become strong; then share the fruit wherever possible, so that new seeds may be planted.

Stormy Weather

The psychedelic state manifested at higher doses can be very confusing and distressing. There is always potential for negative or unpleasant psychological reactions to psychedelics, usually known simply as a 'bad trip' or a 'bummer'. Such labels unfortunately obscure a very important fact – that a 'bad trip' usually offers the greatest benefit, as it exposes your own weaknesses, which are where the greatest self-work needs to be done. In 'ordinary' consciousness, it is common to suppress awareness of one's own faults and weaknesses, either by projecting them onto others, or simply ignoring them or creating excuses for them. In the throes of a 'bad trip', it is no longer possible to run away from these things. Continuing to deny them at this point, and choosing not to learn from the experience, is a recipe for even greater neurosis and maladjustment in the long-run, as well as a hellish trip. According to Rick Strassman (1984), people "with a fear of closeness of same-sex others" and "primary defensive mechanisms including projection, denial, and tendency towards psychotic thought disorders" are more likely to experience negative reactions. Being exposed to one's darker thoughts, or aspects of the personality or self-image with which one is not comfortable, can also precipitate a negative reaction. Here, I will try to cover the most common things that may go wrong, and some of the ways in which they can be dealt with.

Sometimes the influx of energy and information can become a bit too much for comfort, and 'information overload' sets in. This can result in a state of panic, where the person involved feels everything flooding over them too rapidly, becoming anxious and fearful when they find they can not stop the experience, or escape from it. Sometimes the person may be gripped by fear that is all-consuming, often leading to a paranoid state where delusional ideas are constructed, and one feels they can not ask for help, because they do not trust anyone to tell them the truth. Even if knowing that people around them have truthful intentions, there is still the very real awareness that people may believe they are telling the truth, whilst still being wrong or ignorant of possibilities.

Psychedelics open your awareness to many things, particularly to what some call spirit and 'paranormal' forces, which should be accepted rather than feared. Let them pass through, rather than identify with them as objects of fear – without fear, they can do you no harm. Greet them with love and they may even teach you. Sometimes voices may be heard or imagined, or thoughts seeming not to be your own may enter your mind. This in itself is not necessarily a bad thing, depending on what messages are being received and in what manner you react to them. The problems can arise from forgetting that one is in a highly suggestive state of mind, and coming to believe voices or thoughts that may be misleading or easily misinterpreted. Similarly, it may become difficult to discern the meaning or significance of the visions or inner voices, which can be problematic if the content seems menacing or sinister. Some say that 'only bad spirits' are heard in the left ear. Sometimes actual entities are encountered, which may seem to have visual and/or physical form, or may be purely 'felt' as a presence. Here it is worth remembering that just because an entity or voice in the head presents itself, it does not mean that that entity is necessarily being honest with you or that it has your best interests at heart.

Those experienced with peyote [see **Lophophora**] suggest that it is a noble exception, with the advice or information thus received proving unfailingly to be truthful (Trout & Friends 1999). Still, even in these cases, it is generally best to suspend judgement on information received, until you are better able to assess whether it seems to make sense, or whether it tallies with the ethics that you hold to be honourable. With practice, you will hopefully learn to listen only to the teachings that speak to your heart and offer you truth and love as a path. Whether these perceived entities are simply projections of the human psyche is a matter of debate that may be impossible to settle. One explanation with a ring of truth, in the context of Tibetan Buddhism, is that "the Buddhist deities could be understood ultimately as the mingling of the creative forces of nature and human consciousness, and demons came to be perceived as the dissonant and obsessive forces of greed, fear, and aggression arising from the illusion of a separate self" (Dunham et al. 1993). However you choose to interpret such phenomena, these perceived encounters certainly do occur.

Sometimes, with high doses, you may lose awareness of your body. The feeling of this happening can be very frightening, and often a fear of dying may emerge. Psychotherapist Ann Shulgin has advised that if you wish to let go and fall into 'ego death', promise yourself you will return to your body, and find a safe and comfortable place where you can lie or sit undisturbed whilst going through the process. If you wish to remain rooted on the physical plane, breathe deeply and get active whilst remaining calm – move around, try to talk with a friend who is present, anything to keep your attention on your surroundings.

Psychedelics can bring you to question everything that you had previously accepted as fact, so it is important not to work backwards and erase psychological progress you have already made, by making destructive decisions in an impulsive moment. Only you can know what this means to you. The deeper realms of the mind can become quite a minefield, or a labyrinth from which some never fully return.

You may feel that you have gone insane, and that you will never 'come down' [see *Questions & Answers*]. Sometimes people become overwhelmed by strong feelings of an 'evil' presence, and may believe that they have unwittingly entered into some kind of demonic pact by partaking of psychedelics. Many people from Christian backgrounds have already made up their mind that this is indeed so, without having actually tried these substances themselves. This is understandable, as I can not imagine any Christian choosing to enter a demonic pact, if that is what they believe they might be doing. It is noteworthy, however, that some Christians who have taken the plunge, in settings appropriate to their beliefs, have had profound spiritual experiences as a result! Early accounts from missionaries in the 'New World' frequently described 'Indians' as consuming sacred plants in order to 'converse with the devil'. Unfortunately, because of such ignorance, and the dogma that is fuelled by it [and conversely, the ignorance fuelled by dogma], Christians who do decide to experiment with psychedelics are more likely than others to have trips with frightening and confusing 'evil' overtones. If such people are not scared away by this, these perceptions can take a long time to come to terms with. Having gone through this painful process myself, I believe that this constituted a valuable lesson in understanding the nature of light and darkness and their fundamental interrelation, as opposed to the immobile human constructs of polarised and mutually exclusive good and evil trying to crush each other, which can promote an unhealthy psychospiritual fear of the unknown. To add to that, things are not always as they seem [see also the quote from Dunham et al. 1993 above]. Sometimes a scary facade can be merely a veil behind which truth may be found by those wise enough not to be swayed by gross appearances. However, detailed discussion of this dilemma of good and evil could form a lengthy treatise of its own. An excellent entry into such a discussion can be found from Alan Watts (1978). Rejecting the firm separation of good and evil need not be a rejection of any sense of morality, 'decency' or 'goodness' but rather a recognition and acceptance that fluid and inconstant 'reality' is not bound to such fixed points of view.

Most people in our societies are ruled by subconscious fear and self-loathing, and can not accept themselves for who they are, or communicate with others, without hiding behind masks. Clinging to these masks, and/or allowing fear or despair to cultivate themselves, are the cause of many 'bad trips'. At their roots, nearly all difficulties that may be encountered within a bad trip derive from fear. Everyone has fears of some kind, though in many of us they are mostly buried so deeply within our psyches that it can take a traumatic experience such as a bad trip before we even know that they exist, and what they are. It may help to realise that fear only has the power that you give to it by allowing it to take root and grow. Knowing that whatever will happen, will happen, and that we can do nothing more than live moment by moment honourably and humbly, can sometimes help release the grip of fear. How you deal with these fears as they become apparent is a personal and individual matter, which depends very much on the nature of you and your fears. Psychedelic states of consciousness can give us the opportunity to learn how to discard these shackles of destructive thought, in order to move towards our highest aspirations, rather than stagnate or dig deeper holes for ourselves. The choice is yours, and yours alone.

The Eye of the Storm

A special aside must be made regarding *DMT*, *5-methoxy-DMT* and *salvinorin A*. The effects of these psychedelics are the strongest of any yet discovered, and in moderate to large doses are the most likely to precipitate negative reactions in the unprepared. Despite having a similar time-course, regarding onset and duration, these three substances all have very different effects, and *salvinorin A* is in a bizarre class of its own. When smoked [or more preferably, vapourised], these substances act very rapidly, and their effects subside slightly less rapidly. The intensity of the peak of the experience, when a fully-active dose has been consumed, is indeed awe-inspiring and overwhelming. No awareness [or only vague awareness] of physical surroundings, body or self remains, but from there the effects can differ widely between the compounds, and between different people at different times. These substances can absolutely shred any preconception of 'normal' reality. Often extreme time-distortion is experienced [when there is an ego present to experience it], to the point that the peak may seem to last for hours, days, or rarely even weeks, existing in a reality far removed from the familiar. Do not worry – where your body remains, time moves at a rate by which you will be aware of your physical-self within 5 minutes or so, and relatively 'sober' within the hour. Fortunately, however, many people who have had a terrifying experience during the peak find themselves quite joyful and ecstatic once surroundings begin to return to familiarity, at least in part because of being so happy that the alteration was not permanent! Time-distortion is also a common subjective phenomenon with other psychedelics, though generally to a less-extreme extent. Fischer et al. (1961) gives a very interesting discussion on the nature of time, and its perception as affected by psychoactive drugs.

Don't Panic!*

There are several simple little tricks that can be useful if a person is experiencing problems or difficulties in their trip, such as those discussed above. The principal one is the use of laughter, to dispel gloomy thoughts and break negative thought-cycles. The distracting and healing influence of a good laugh can truly work as wondrous medicine, and the most profound realisations may often be found in the midst of such moments. A comforting foot and/or body massage can also be very soothing and calming to a distressed tripper. They should be encouraged to try to discuss their thoughts and feelings with others present – this act alone can be very reassuring, and can distract the person long enough to break the negative thought-cycles mentioned earlier. Of course, the others present would need to be sufficiently well-adjusted and intelligent not to actually agree with the person that they are losing their mind! It certainly helps if at least one other person present is thoroughly familiar with psychedelics, as discussed earlier.

A simple change of environment can work wonders in improving mood and outlook, which is largely why the importance of set and setting was emphasised earlier. Small things, such as adjusting light levels, vapourising or sniffing your favourite essential oils [or being around scented things that you find comforting], careful choice of music, being around plants, finding pleasing and inspiring things to look at, enjoying some fresh fruit, and doing things that one knows to be relaxing and reassuring, can together help to suddenly lift a cloud of gloom that only a moment ago seemed eternal.

It may be useful to bear in mind the Buddhist philosophy of non-attachment, which is also applied to visions and experiences, no matter how profound. As well as occasionally bringing about negative reactions, attachment to imagery and concepts impedes long-term spiritual progress. Learn from them and appreciate them, by all means, but do not cling to them because they are, like everything, impermanent. This can also be applied to thoughts that are overly distressing. Simply observe them, learn from them, and let them go, rather than becoming absorbed in them to the point of obsession. Such distressing thoughts can easily turn into vicious cycles of despair, fear and/or paranoia that quickly spiral in intensity, and are best dealt with before they develop any further. Maintaining the detached vigilance discussed earlier makes it easier to catch these potential problems and transform them as soon as they arise. It may help to remember that if your mind can think itself into such a sticky situation, it is also capable of thinking its way out, and you will almost certainly learn a lot about yourself in the process. The 'Four Noble Truths' of Buddhism also tie into this line of discussion. The first is the recognition that there is suffering; the second is recognition of how suffering has arisen; the third is recognition that the cessation of suffering is possible; and the fourth is following the path that leads to cessation of suffering. This path is called the Noble Eightfold Path; readers interested in an accessible and insightful discussion on this should see Hanh (1998). [Note – though Hanh takes the most conservative interpretation of the Buddhist stance on drugs, this is not the case with all Buddhists (see Forte ed. 1997), and it may be that Hanh is unaware of the potential positive spiritual uses of psychedelics or entheogens. In any case, his books are recommended for those interest-

ed in Buddhism.]

Drinking large amounts of orange juice [see **Citrus**] is a practice used in Holland to counter mushroom trips that are too intense [see **Psilocybe**, **Panaeolus**], and this is reported anecdotally to have proven effective. I have also heard rumours of this being used in the same manner for LSD, in relation to the vitamin C content of the juice. However, I am not aware of the mechanisms behind this phenomenon, which other psychedelics it is likely to be effective for, or how much orange juice or vitamin C is needed to relieve the effects.

If all else fails, try to remember that you will come down, and that everything will be fine tomorrow. Don't do anything rash, and wait until you are at 'ground-state' before putting into effect any major decisions that will affect your life. You will not always be able to properly assess your feelings when you are still tripping. Remember that unlike your mind, your body can not fly. Remember that public nudity and disruptive behaviour are discouraged, and could earn you a come-down in a prison cell. Even if it all seems too much to bear, don't give up on yourself, and wait it out. You'll be proud of yourself in the end, for going through it and coming out the other side in one piece. Keep a smile on your face, and don't lose faith in what you know to be right for you. If it's appropriate, repeating an affirmation to yourself, such as "I believe in truth and love", can be a positive anchor to lay down, until you are feeling more secure [or until you see God!].

As mentioned earlier, these most intense and frightening of experiences can offer the greatest opportunity for leaps forward, as they can teach you the most about yourself. Some spiritual paths [amongst those often termed 'left-handed paths'] involve travelling into the depths of 'darkness' in order to break through into the 'light', transformed by the journey. In this sense, exploring realms of consciousness that may drive the unprepared or insincere to varying degrees of insanity can, for the truly devoted seeker, be a process of deep cleansing that culminates in an awakening and increased integration. As Gopi Krishna [a well known kundalini researcher] once wrote, "psychophysical stress and storm is a part of spiritual adventure" (in White ed. 1990). Another appropriate quote comes from Lama Chögyam Trungpa (in Forte ed. 1997) – "My advice to you is not to undertake the spiritual path. It is too difficult, too long, and it is too demanding... This is not a picnic. It is really going to ask everything of you and you should understand that from the beginning. So it is best not to begin. However, if you do begin, it is best to finish."

Coming Down

Once you're past the peak of the experience [which generally occurs about 1/3 of the way into the entire duration, or earlier, depending on the substance and circumstances] you enter the 'come-down' phase, which can sometimes seem very long and drawn-out. Some people often choose to use **Cannabis** at this point, to help ease the transition and calm the still-hyperactive nervous system. It is a good time for contemplating and elaborating on what has just been experienced [which also makes it less likely you'll forget important details the next day]. Write down anything which comes to mind, if it feels appropriate. At the end of the trip, one may feel mentally and physically exhausted. Some people, on the other hand, after a particularly constructive trip, feel as good as new, or better, even for days afterwards. Feelings of profound calm and integration often emerge during and following such constructive experiences. After a nutritious meal and a good night of sleep, there is usually no hangover in the sense that alcohol produces a hangover. Near the end of a session involving psychedelics that act on serotonergic and catecholaminergic neurotransmitter systems [see *Neurochemistry*], supplementation with *5-hydroxytryptophan*, *choline*, B vitamins and antioxidants [or simply eating a good, healthy meal and resting] will often help reduce any next-day 'fuzziness' resulting from over-excitation and general system stress from an intense experience. The user may feel sluggish and introspective the next day while the body recovers, and the information from the experience is processed and assimilated. There may occasionally be slight residual psychedelic effects [usually positive] for the next week or so, depending on the dose consumed and the psychological impact experienced.

The most important stage of the experience actually occurs after the bulk of the effects have passed, and that is the stage of assimilation or integration. Successful assimilation of the experience into life is the only way you can get anywhere with altered states, otherwise they are effectively wasted. Many people who use psychedelics skip this last step, preferring instead to evade the implications of the realities which they have been exposed to, pretending after they have come down that it was all 'just a trip', and not attaching any meaning to the experience. I believe that using psychedelics in this way is a sad insult to human potential. It is very important to actualise what you have learnt in the psychedelic state. As stated earlier, integration is the part most people find to be the most difficult. How is it done? The most direct answer is to live what has been learnt – not to cling to it as a permanent form or idea, but to integrate it into your everyday behaviour and use it as a foothold to climb towards your next step. I can not tell you exactly how to do this – you will have to apply it yourself to your own situations, in ways that are appropriate to you.

Responsibility

Incidentally, throughout this chapter, mention has been made in passing about making 'right' decisions, and practicing 'appropriate' behaviour. As a guide to what is meant by this at the simplest level, it is merely suggested that you consider the results of any action from every viewpoint, use a bit of your own moral judgement, and as a result, choose not to do things which unnecessarily interfere with another persons right to peace in their own reality. In other words, do what you need to do to be free, but without harming the freedom of others. In this pursuit it is worth setting an example worth following, so that those who don't live by such guidelines [and harm others in the process] might come to reassess the way they relate to other beings.

In brief, psychedelics can't do the job for you, but they can certainly open up the doors, revealing what is possible and providing valuable lessons. Once the trip is over, it is up to you and your own efforts to implement your enlightenments in this world. It is easy to lose sight of your path by falling back into old ways of being, or forgetting what has been learnt in the past, repeating the same mistakes again and again. Complacency resulting from being overly proud of one's 'spiritual progress' is one of the quickest and surest ways of falling into this trap. The process of learning, and growing, is ongoing. The most can be learnt through admitting that we know nothing, as truly knowing the absolute requires the innocence of an absolutely clean slate.

Some Nuggets for The Road

It seems fitting to quote from Ram Dass (1971) some selected helpful points regarding 'sadhana'. Sadhana is 'spiritual practice', and is a concept that can embrace or define the purposeful use of psychoactive substances, particularly those with psychedelic properties [see also the sections on meditation and kundalini, in the previous chapter].

> "Each stage that one can label must pass away. Even the labelling will ultimately pass. A person who says, "I'm enlightened" probably isn't.
>
> The initial euphoria that comes through the first awakening into even a little consciousness, except in a very few cases, will pass away... leaving a sense of loss, or a feeling of falling out of grace, or despair...
>
> Sadhana is a bit like a roller coaster. Each new height is usually followed by a new low. Understanding this makes it a bit easier to ride with both phases.
>
> As you further purify yourself, your impurities will seem grosser and larger. Understand that it's not that you are getting more caught in the illusion, it's just that you are seeing it more clearly. The lions guarding the gates of the temples get fiercer as you proceed towards each inner temple. But of course the light is brighter also. It all becomes more intense because of the additional energy involved at each stage of sadhana.
>
> At first you will think of your sadhana as a limited part of your life. In time you will come to realize that everything you do is part of your sadhana.
>
> One of the traps along the way is the sattvic trap – the trap of purity. You will be doing everything just as you should – and get caught up in how pure you are. In India it's called the 'golden chain'. It's not a chain of iron, but it's still a chain.
>
> At some stages you will experience a plateau – as if everything has stopped. This is a hard point on the journey. Know that once the process has started it doesn't stop; it only appears to stop from where you are looking. Just keep going. It doesn't really matter whether you think "it's happening" or not. In fact, the thought "it's happening" is just another obstacle.
>
> You may have expected that enlightenment would come ZAP! instantaneous and permanent. This is unlikely. After the first 'Ah Ha' experience, the unfolding is gradual and almost indiscernable. It can be thought of as the thinning of a layer of clouds...until only the most transparent veil remains."

And finally, some humorous and slightly less esoteric tips from Robert Anton Wilson (1977) broadly regarding such matters:

> "Chapel Perilous, like the mysterious entity called 'I', cannot be located in the space-time continuum; it is weightless, odorless, tasteless and undetectable by ordinary instruments. Indeed, like the Ego, it is even possible to deny that it is there. And yet, even more like the Ego, once you are inside it, there doesn't seem to be any way to ever get out again, until you suddenly discover that it has been brought into existence by thought and does not exist outside thought. *Everything you fear* is waiting with slavering jaws

> in Chapel Perilous, but if you are armed with the wand of intuition, the cup of sympathy, the sword of reason and the pentacle of valor, you will find there (the legends say) the Medicine of Metals, the Elixir of Life, the Philosopher's Stone, True Wisdom and Perfect Happiness.
>
> That's what the legends say, and the language of myth is poetically precise. For instance, if you go into that realm without the sword of reason, you will lose your mind, but at the same time, if you take only the sword of reason without the cup of sympathy, you will lose your heart. Even more remarkably, if you approach without the wand of intuition, you can stand at the door for decades never realizing you have arrived." Also, there are "those without the pentacle of valor who stand in terror outside the door of Chapel Perilous, trembling and warning all who would enter that the Chapel is really an Insect Horror Machine programmed by Death Demons and dripping fetidly with Green Goo."

For further reading on the positive uses of psychedelic drugs as sacraments, see Forte ed. 1997, Saunders et al. 2000 and Strassman 1984, 1995.

*In memory of Douglas Adams, r.i.p.

PRODUCING PLANT DRUGS – CULTIVATION, HARVESTING, CURING AND PROCESSING

Organic horticulture

It is quite important to develop a relationship with the plants to be consumed, and preferably, this begins with cultivation of your own plants. In caring for them and maintaining their health, an empathy will emerge that will enhance any experiences gained through later ingestion.

For reasons of purity, overall plant vigour, and soil restoration, cultivation using organic techniques is preferable. Producing your own fertile organic compost is not difficult, and use of permaculture techniques will also prove invaluable and relatively simple once grasped. The reader should consult their local libraries and bookshops to gain a greater footing in these systems. For permaculture, the works of its best-known protagonists, Bill Mollison and David Holmgren, are suggested. However, it should be noted that permaculture often encourages the planting out of invasive weed species with little regard for native ecosystems, and it is suggested that the invasive potential of non-indigenous plants be seriously considered before cultivation. Plants that spread vigorously from underground runners should preferably be cultivated in large pots or other contained areas. Plants that seed profusely should also be watched carefully, and if possible, should be harvested or cut back before seeds ripen and disperse.

Some horticulturalists plant their seeds and time harvest according to the phases of the moon, which can optimise the benefits gained in cultivation by aiding healthy germination and helping in the development of high potency, according to those who go by such methods. Horticultural moon-charts can be obtained from many 'esoteric' and health stores, published yearly. Place your plants in positions and environmental circumstances that emulate their natural habitat. If known to the author at the time of writing, habitat and cultivation details are mentioned under individual plant entries. Regardless, research by the reader is strongly suggested whenever attempting to cultivate a plant with which one is unfamiliar.

Plants in the wild

In cases where cultivation is not practical, plants may sometimes be collected in the wild with relative ease. It is here that at least a basic understanding of botany will become invaluable, as a mistake in identifying a plant can, in some cases, cause poisoning and even death if that plant is later consumed. Some toxic plants do not even need to be directly consumed to be effective, as the active chemicals may be absorbed through unbroken or pierced skin. **Brugmansia**, for example, as well as being absorbed through porous skin, is known to sometimes intoxicate from the scent of the flowers alone! On this last note, see also **Tanaecium**.

Although at first glance, botanical terminology seems alien and cumbersome, it is actually more or less vital in providing a concise and accurate description of a plant, necessary to differentiate it beyond doubt from any other plant species. There are many morphological aspects and traits which are difficult to adequately summarise with everyday language, and for this reason, an attempt should be made to become familiar with some of the most commonly used terms and their meanings. With time, when you become more familiar with some basic Latin and begin to recognise some meaning in the root words that make up the terminology, it will become easier, and botanical names will eventually roll off of the tongue. Remember, even trained botanists sometimes have to refer to their terminology dictionaries. The glossary should be of some minor help in interpreting some of the descriptions provided, however, many terms are not listed, and the serious reader should obtain their own botanical dictionaries for a fuller understanding.

If not available locally in the wild, you may wish to visit your local nursery – you'll be surprised what you might find in some, if you look closely enough. There are a number of specialist herb nurseries that deal direct to the public, also, and investigation of seed company catalogues will also prove fruitful. It is useful to consult libraries to learn about the native vegetation and introduced weeds in your area, as well as to locate local species related to those mentioned in this book, for possible evaluation of activity.

Harvesting

Harvesting of the plant, as with cultivation, should be done with gentle care and respect, as it is this plant that you would be asking to help you, and, as such, should be treated accordingly. Firstly, though, consider the species you think you are harvesting [it is wise to be sure on this point] – do you know its chemistry? Does it have a history of human usage to draw from? Is it likely to react badly with any medical conditions you have, or medication you are taking? Is it known to be physically dangerous, or even lethal? These are all questions which you should ask yourself when considering a plant for consumption. If you are at all uncertain on any of these points, don't consume it! It's better to be safe than sorry, as injury and/or death are distinct possibilities with uninformed experimentation.

Many factors can influence the optimum time and place for harvesting – the time of day or year, the physical location and exposure of the plant, its health, stage of development, amount of rainfall, etc. All of these can positively or negatively influence potency and chemical makeup, varying from species to species – this will be indicated under individual entries, if the data is known. Few plants have been examined chemically with this viewpoint in mind, so this information is lacking in many of the entries. Different chemicals are often found in different parts of the plant, at different stages of growth, and at different times of year. Different specimens from the same area may even yield different compounds, or different levels of compounds. Also, many plant species exist in distinct chemical 'races' or 'strains' within the one species classification, further complicating matters, and occasionally, 'mutants' may be found with exceptional chemical content. For even more confusion, sometimes closely related species may interbreed in the wild, producing hybrids that are difficult to identify and may have different chemistry – this has been known to occur at least with some **Acacia** spp.

Soil acidity can influence levels of alkaloids and cyanogenic glycosides in plants; pH levels affect the ability of the roots to absorb available nitrogen [more available in ammonia-nitrogen fertilisers than nitrate ones], which affects the levels of nitrogenous compounds such as alkaloids. Sugar should be added to free ammonia solutions, to avoid damage from excess fertilisation. Optimum levels differ from species to species – however, here we will look at a selection of genera that have received study in this regard:

Convolvulus – pH 6-8
Cytisus – pH 5-6
Lupinus – pH 6-7
Lycopodium – pH 5-6
Magnolia – pH 5-6
Papaver – pH 6-8
Solanum – pH 5-6
Senecio – pH 5-6
Symplocos [see *Endnotes*] – pH 6-7
Taxus – pH 6-8 (McNair 1942)

Alkaloid levels may also, in general, be increased by shading [though only light shading can actually decrease alkaloid content], and stress by water deprivation or wounding. Increases take place gradually over time, and can not be expected to occur greatly in a few days (Eilert 1998; James 1950; Manske 1950). For the sake of maintaining a positive interaction with the plant, I would personally discourage the use of excessive stress, especially deliberate wounding. I believe they indicate a certain lack of respect towards our plant friends.

If you have a choice, select plants that display particular vigour and good health. In many plants, alkaloids are usually not present in significant amounts in dead plant matter – actively growing plant tissue is usually best (James 1953). It is probably not a good idea to collect from near busy roads, due to the likelihood of heavy metal contamination. If collecting in the wild or in public places, be discrete so as not to make it more troublesome for yourself or other collectors in the future.

In very general terms, the best time for harvest is in the early morning, at a time of the season in which the plant is just beginning to flower, if the vegetation is to be collected. Flowers are often collected at various stages between budding and maturity. Berries are collected when ripe or slightly under-ripe; seeds are usually collected when they are naturally released from the plant. Roots and tubers are often collected after the aerial parts have died back for the season, in the case of annual plants. For others, if there is an extensive root system, roots may sometimes be harvested without digging up the entire plant. Bark is best harvested by removing a branch to strip of bark, rather than cutting bark from the trunk, or from branches which are still attached to the plant. The time of optimum bark harvest varies from species to species. In plants containing volatile oils, content in the leaf usually increases with time and leaf size. In some species, the youngest growth may be the most potent.

Approach the plant with respect, and ask it to give of itself to you, preferably some time before you actually intend to harvest. This is often the preferred method amongst shamans and some herbalists. You may discover that plants will seem to appreciate being sung to or talked to in soothing tones when first approached, and whilst harvesting. If wishing to try this, focus your mind on the plant and project an attitude of tender respect and communion. Open your mouth and let the voice emerge with its song as it comes naturally. This is usually found easier if there are no other people within earshot, unless you are a natural singer! You need not neces-

sarily sing with words, nor particularly loudly [if you have a good feel for this you can simply do it in your head and project it mentally towards the plant], but sincerity is the most important quality here. It may also be appropriate to leave an offering for the plant [or on the place where it grew, in the case of the whole plant being harvested] as a sign of gratitude. In many parts of Central and South America, tobacco [**Nicotiana**] is a customary offering, notably when harvesting peyote [**Lophophora**] or 'yajé' [**Banisteriopsis**]. Otherwise, other herbs, or objects precious to the harvester, may constitute a suitable symbolic offering.

All needed vegetation should preferably be removed with a clean and sharp blade, or clippers. Roots are best recovered with the aid of a small hand-held pick or a shovel, and a stick for finer work closer to the roots. In some cases [eg. **Arundo**, **Phragmites**], heavier tools such as a mattock and crowbar may be needed to excavate roots, though care should still be taken to not damage the plant beyond what is strictly necessary. When collecting bark, never cut from the whole circumference of the branch or trunk ['ring-barking'], as this will kill the upper reaches of that branch. If this is done on the main trunk, the whole tree will die if it can not regenerate from the stump.

You should make all efforts to avoid gouging or damaging the plant, or treating it in a way that will cause it stress and sickness. Never remove too much from one plant, or strip entire branches of their foliage. It is important to leave the plants intact enough to survive and continue to thrive. In some cases, the stress resulting from rough handling may be sufficient to injure the health of a plant. In the case of annual herbs, harvesting an entire plant is less objectionable, provided they are common, or have already gone to seed. It may be advisable in some instances to only harvest from one plant or several from a patch, in order to stabilise the estimation of dosage over time. This is particularly suggested with the Solanaceous tropane alkaloid-bearing plants [eg. **Brugmansia**]. It is not advised to collect plants if they are the only representatives in the locality, or if they are known to be rare or threatened. Always attempt to restore the ground and surrounding area to their previous state before leaving the space.

Mushrooms should be picked preferably when the caps have opened enough to release spores. Many people prefer to lightly tap the mushroom caps, to release a last cascade of spores before harvesting occurs, however, this practice is thought by mycologists to be inconsequential. Mushrooms should preferably be cut off cleanly at the base, taking care not to disrupt the web-like network of mycelium beneath the surface of the growth-medium, unless the bases are to be used for further mycelial propagation. Fungi should always be stored in a porous material [such as paper or cloth bags] when collecting. Other plant matter may be collected into plastic if necessary, though unless the material is dried, it should not be stored for long in plastic as the moisture and humidity generated as the plant material sweats can encourage the growth of moulds and bacteria.

Cacti are harvested in different ways, depending on their growth habit. Columnar cacti are generally cut at a slight incline across a branch, so that when the cut heals, water can run off freely, without collecting in the concave hollow that forms. Small, globular cacti are harvested by cutting off the 'heads' or 'buttons' above ground-level, leaving the rootstock to regenerate. New shoots, often affectionately called 'pups', usually form months later from the areoles near the cut portion. A very sharp and clean knife is strongly recommended for harvesting cacti, to minimise stress to the plant, and reduce the chance of infection. However, some cacti with very tough vascular bundles may require a pruning saw to sever. After a brief drying of the surface, the fresh cut is often dusted with sulphur-dust or charcoal-dust, which keep the cut dry and help deter fungal growth.

Some Quick Field Tests

If harvesting plants of unknown chemistry, a few safety tests can be carried out relatively simply.

Testing for presence of saponins

Thoroughly grind or pound a sample of the plant, and shake it vigorously with water, preferably after a brief boiling and cooling. The appearance of a froth, stable for at least 30 minutes, indicates presence of saponins.

Testing for presence of cyanogenic glycosides

You will need sodium picrate testing paper for this – to make it, dip some blotting or filter paper in a 1% solution of picric acid, and let it dry before dipping briefly in a 10% sodium carbonate solution, and drying again. The crushed plant sample is placed in a small receptacle. A strip of the testing paper is moistened, then inserted into the container to be held in place with a lid or cork for the receptacle. In the presence of prussic acid [which is a substance released when cyanogenic glycoside-containing cells are crushed], the yellow testing paper gradually turns orange-yellow or brick-red after a few minutes to several hours (Cribb & Cribb 1981).

Testing for presence of some amatoxins and some tryptamines

Some mushrooms contain deadly toxins known broadly as 'amatoxins' [see **Amanita**]; the presence of the amanitin-type amatoxins can be tested for with the 'Meixner test', devised by A. Meixner. Juice from a piece of fresh mushroom is dripped onto a piece of lignin-containing paper [not newsprint as it is too thin and usually bears ink, both of which can affect the results]; once dry, a drop of concentrated hydrochloric acid [HCl] is applied to the same spot. Under these conditions, amanitins [when present at 0.2mg/ml or higher] react with lignins in the paper to form a blue or light greenish-blue coloured stain within several minutes. This test may also be done with dried mushrooms, either by soaking and crushing a small piece of the mushroom in a small amount of absolute methanol, and applying this liquid to the paper, followed by HCl treatment; or by directly extracting the contents of the mushroom in a mixture of methanol and concentrated HCl, and applying this solution to the paper. This test should be done away from strong light, which can produce some 'false' reactions. Judgement should be made on any results within 15min., as the colour reaction usually fades and changes hue after this time.

The Meixner test can also be applied to testing for the presence of some *tryptamine*s; though it works best for 5-substituted *tryptamine*s [such as *bufotenine*, *5-methoxy-DMT*, *5-hydroxytryptophan*, *5-methoxytryptamine* and *serotonin*], it does not distinguish between them. After application of HCl, presence of such compounds is indicated by the development of a reddish-brown stain, turning 'greyish-purplish-red', then 'moderate reddish-purple', ending with a bluish colour like that shown with amanitins. *Tryptamine*s with 4-substitution [such as *psilocybin* and *psilocin*] were not tested directly via this method but **Psilocybe** cyanescens was, giving at first a grey stain, within 1 minute turning greyish-blue to pale blue; low concentrations gave a light greenish-blue stain. Although similar to the colour reaction of the amanitins, it could be distinguished by the quickly fading colour and the initial grey hue. However, untrained people may find it difficult to distinguish between such similar colour reactions, especially without known reference standards for comparison, and as such the Meixner test can not be relied upon to identify compounds definitively.

It is advisable to use a 'control sheet' of non-lignin paper [such as filter paper] to check for false reactions, which may be seen when the same colour reaction occurs on both types of paper, indicating the presence of other compounds not undergoing a 'Meixner reaction'. Of course, such a test should not be seen as definitive proof that a mushroom contains no toxins (Beuhler et al. 2004; Beutler & Vergeer 1980), yet in the case of the 5-substituted *tryptamine*s, it could serve as a useful field indicator for plants worthy of further chemical analysis.

Curing

Herbs are usually cleaned and dried after collection. The former involves removing traces of dirt and foreign debris, and stripping away unwanted portions such as stem wood or dead leaves, which should preferably be added to your compost. Some herbs may be, or should be, consumed fresh, and in such cases of course no drying is needed. Most herbs should be dried in a warm, well-ventilated, dimly lit room. Usually, they are either hung upside down in bunches, spread out on a mesh tray, or packed loosely inside a paper bag. Some herbs, however, are preferably sun-dried or dried through baking or heating over a fire, a quicker process often used when it is desirable to halt enzymatic activity in the herb. Roots dry best once sliced or chopped. Drying herbs should be inspected regularly for signs of decay, or insect and fungal infestations; if found, such samples should be removed from unaffected herbage and destroyed or buried. Different herbs take different times to dry [dry here usually meaning still slightly flexible, but not overly brittle or powdery]. Some take a few days, some more than a month. I find wormwood [see **Artemisia**], for example, takes a particularly long time to approach dryness. In general, plants that are naturally aromatic due to active essential oil compounds should not be dried or cured with heat or sunlight.

Curing sometimes also involves sweating, fermenting or even lightly frying the plant matter. These processes are usually done in order to either activate or terminate enzymatic processes within the plant cells that may affect the flavour, aroma and potency of the herb. In instances where this is a specific practice, it will be discussed under relevant plant entries. Fermentation usually occurs when fresh plant matter is stacked and allowed to generate heat; such stacks are turned at intervals, to prevent mould and decomposition.

Storage

Dried or cured herbs are usually kept in a sealed jar or other container, preferably one that is dark or opaque, as light can speed the degradation of many active chemicals. This also applies to heat, oxygen and moisture, all of which should be guarded against in the storage process. Those people living in humid climates may need to store their herbs in open drawers to avoid accumulation of moisture and resultant decay. For most, room-temperature or lower is sufficient, though some herbs with unstable constituents [such as some species of **Psilocybe** mushrooms, which should

be dried as much as possible without crumbling when handled] require freezer storage under airtight and moisture-proof conditions [the herbs should be dried first, especially in the case of mushrooms]. In general, the lower the temperature of storage, the better. Freezer life may be almost indefinite, depending on the chemicals involved, though storage at normal temperatures usually results in considerable loss of potency after several months or longer. This also depends largely on the other ways in which the herbs are stored, as mentioned above. Aromatic plants lose potency more quickly, due to evaporation of active compounds. Conversely, non-aromatic plants often store well for longer periods; many roots, seeds and berries may be kept for years. Herbs will last even longer if plant parts are stored relatively intact until intended for use.

Final Processing

The final processing involves preparing the herb for use. The first stage is usually that of finely chopping, shredding or powdering the herb for further processing into a consumable form. Sometimes herbs are soaked in cold water before processing. This may be to leach out tannic acids, chlorophyll, and other water-soluble compounds that may or may not be desired; or to make them easier to process; or to absorb some water before heating [such as with roots] to allow for better extraction. The next step often may be for the herb to be extracted into another medium for consumption, or further extraction to obtain either crude or pure active chemicals. The following are some common forms of extraction processes that may be used.

Infusions

An infusion is what is accomplished when one steeps tea leaves in a teapot [see **Camellia**] – it basically involves placing the herb in a teapot or similar lidded receptacle, and pouring freshly boiled water over it. The lid is usually closed, and the whole left to infuse for up to 10-15 minutes [much less with teas for culinary purposes], or until it reaches drinking temperature. It should be lightly shaken or stirred every few minutes. Where longer infusions are required, the pot may be wrapped in blankets for insulation. Honey may be added for sweetness and to counteract bitter flavours, or simply for its own health-giving properties [in the case of pure non-heated honey]. Infusion is best suited to aromatic herbs – most active constituents of essential oils are not water-soluble, but boiling will evaporate them in the steam – so the infusion is, when working with just-boiled water, a compromise that will allow a partial miscibility of the oils and the water, and/or a limited suspension of these compounds.

Decoctions

Here the herb is boiled with water in [preferably] a pyrex or stainless-steel receptacle – water is added to the herb, a lid is sometimes placed on top, and the whole brought to a boil slowly over heat. If using dry herbs, they should be allowed to soak in the water beforehand to become rehydrated. Once boiling temperature is reached, heat is reduced and a low boil or simmer is maintained for an extended time, depending on the plant, ranging perhaps from 5 minutes to 8 hours or more. With extended boiling, further liquid will need to be added at regular intervals to avoid burning. With shorter decoctions [say 5-20 minutes], after straining the liquid for consumption, fresh water may be added to the plant matter and up to 2 more decoctions carried out. Stirring will often be necessary to avoid burning, and increase the efficiency of the extraction process. Sometimes lemon juice may be added [c. 30% lemon juice/70% water] to increase the acidity of the water [due to its content of acetic, citric and ascorbic acids], and hence increase the water-solubility of some basic alkaloidal compounds, such as *DMT* and *harmaline*. Where necessary, research should be done to find out what pH level is beneficial for extracting particular compounds.

Tinctures

Tinctures are made by soaking the herb in grain alcohol [45-100%] inside a tightly sealed bottle [which is kept in a dark place and shaken daily] for several months to a year. After this time, the liquid is strained thoroughly [with the herbs being squeezed out, and sometimes washed with fresh alcohol] and stored in a tightly sealed dark bottle, in a cool place. Such tinctures should retain usefulness for a year or more, but this will vary widely with the chemistry involved in individual preparations. This is, in general, a simple and highly efficient technique for extracting plant constituents.

Ointments and salves

These are used for external application. The herb is infused or decocted, and the liquid is strained. Oil or fat [sesame or olive oils, lard, ghee, coconut butter, cocoa butter] is added to the resultant liquid, which is heated in until the water evaporates. Sometimes, the herbs may simply be infused or decocted directly in the oil or fat, then later strained out whilst the mixture is still hot and fluid. Finally, beeswax is added until the desired consistency is reached.

Pills

Herbs may be made into pills to be swallowed. One method involves mixing the powdered herb to a firm consistency with water, syrup or honey, which is pressed into pellets. Or, a decoction may be gently boiled down to a thick gum to be used in the same way. Sometimes powdered herbs [or a concentrated extract thereof] are simply encapsulated and swallowed. Pills or capsules are sometimes coated with powders such as plant ashes, flour, or **Lycopodium** spores if they are to be stored. This prevents them from sticking together and slightly delays degradation.

Distillation

Distillation is the process whereby a tincture, or other plant extract in a volatile solvent medium, is heated in an appropriate glassware flask, the vapours from which are guided into a long, water-cooled condensing-tube, which drips the cooled concentrate [distillate] from the other end. Fractional distillation is where the temperature of the solvent is regulated to retrieve specific chemical fractions from the extract, exploiting knowledge of their boiling points. Steam distillation involves heating water to produce steam, which is then fed into a pre-heated vessel containing the extract. The evaporating essence from this secondary vessel is condensed in the manner described above. Steam distillation is useful in extracting more delicate aromas and essences from plants. The aim of distillation is to provide a concentrated or more purified extract of the original extract.

Alkaloid extraction

Any but the most basic of chemical extractions should not be carried out by the amateur. This author is not a chemist, and does not claim to offer any chemical advice that should be followed. The following is merely intended to describe some of the different approaches used in the extraction of alkaloids, summarised from readily available published works and communications with other researchers. Anyone wishing to pursue chemical extractions should educate themselves further, to ensure they do not encounter disaster. Working with chemicals without proper awareness of their toxicity and special requirements for handling and use, coupled with ignorance of the principles of organic chemistry, is asking for a dangerous accident that could ruin or end your life. Legal implications must also be kept in mind. In some countries, it may be legal to grow a certain plant, but illegal to extract the alkaloids it contains, if any one of those alkaloids is a prohibited substance. Please take the advice that if you don't understand what is written below, then you probably shouldn't be attempting it. If you choose to attempt any method described here, at least educate yourself as to the precautions that must be taken with any chemicals used, and become acquainted with some basic chemical reactions and procedures so that you know what you are doing, and can avoid physical injury through unnecessary error. At the very least, equip yourself with protective gear [for all exposed skin and facial openings], and avoid breathing fumes or splashing chemicals on yourself, into the soil, or into bodies of water.

Equal care must be paid towards disposal of chemicals after use. Wherever possible, distil solvents for re-use rather than simply evaporating them into the air. If chemicals can not be re-used they must be taken to a chemical waste disposal service, never simply poured into the earth or down the drain. Wherever possible, substitute milder or non-toxic chemicals for use in extraction procedures. For example, using tartaric acid or acetic acid rather than hydrochloric acid. Moves towards such low-tech and low-toxicity techniques are vital both in maintaining personal health and reducing environmental contamination.

These methods may differ slightly in practice, as there are alternative ways to achieve the same results, and different examples of plant matter may present unique difficulties in the extraction procedure and require a refinement or modification of the method being used. If beginning with dry herbs, it is usual to allow them to rehydrate in the initial solvent before topping up, as the material will expand as it absorbs moisture.

Extraction of free-base alkaloids in an acidic medium

The pulverised herb is placed in a clean receptacle, and enough water is added to make a pourable soup. An acid [eg. distilled white vinegar, lemon juice (sources of acetic acid) or sulfuric acid] is added to bring the pH to 3-5 [which converts the alkaloids from their freebases to their hydrochloride salts, thus rendering them water-soluble]. This is simmered in a pyrex container for several hours or overnight with the lid on, with the herb being filtered out, and the process repeated 2-3 times; the fractions are combined and strained thoroughly. It is suggested not to squeeze the pulp except after the last extraction. Next, an amount of a defatting-solvent [eg. methylene chloride, petroleum ether, chloroform or naptha] equivalent to 10-15% of the combined fractions [by volume] is added; the mixture is shaken [not too hard, as an emulsion may form – see below], and the defatting-solvent layer [containing unwanted fats and resins] retrieved after it separates, and discarded. Often a small third layer is seen between the other two. This is a portion of emulsified material which should also be kept from the desired portions. In the case of *DMT* [and probably some other alkaloids], if acetic acid is used, with chloroform as the defatting agent, some alkaloid may be lost to the defatting solvent, as

DMT acetate is soluble in chloroform. This might also be the case with methylene chloride. If petroleum ether is used, some *DMT* N-oxide may be lost, as this chemical becomes soluble in petroleum ether, when the petroleum ether also contains fatty material. This process may be repeated to ensure removal of all unwanted lipids. Defatting may not be necessary if the plant material does not contain appreciable quantities of lipids. Sometimes, defatting is performed as the initial step. In that case, the material is moistened with an acid, and defatted directly before extraction.

A base [such as ammonia or ammonium hydroxide, which are preferable to sodium hydroxide; do not use ammonium carbonate] dissolved in a small amount of water is added carefully in small increments to bring the pH above 9, rendering the alkaloids basic, and no longer water-soluble. The desired pH will differ depending on the alkaloid/s being recovered. This critical point is referred to as the pKa, the pH at which the alkaloid is liberated from its salt form to its freebase form. Many alkaloids are not very stable in an alkaline aqueous solution, so once this point has been reached, the final extractions should be performed quickly. *DMT* is an exception in that it is reportedly quite stable under these conditions, though it is still preferable not to leave it sitting for too long in solution as it may form emulsions over time and become more difficult to retrieve.

Sometimes the alkaloids will simply precipitate from the solution and can be retrieved by filtering. Otherwise, the freebase alkaloids are extracted with an organic solvent such as ether – petroleum ether is not the same thing, and works poorly in the case of *DMT*, except when hot, in which case it can be used and later cooled to precipitate the alkaloids out of solution. An amount of the chosen solvent equal to about 10% of the solution is added, and the whole is kept in a tightly sealed glass container, to be shaken twice a day. Extracts high in tannins should not be shaken too vigorously, as a stubborn emulsion may form – it is unfortunate that tannins often form this emulsion with the alkaloids, when in an alkaline medium, making them difficult to retrieve. The emulsion can usually be broken by shaking the mixture thoroughly and filtering. If this doesn't work appreciably, then repeating the acid/base phase may be necessary.

After about 24 hours or less, collect the organic solvent layer and set it aside. The solution is extracted several more times with fresh solvent in the same manner, except the intervening time period is stretched to 1 week for each. The organic solvent fractions are combined, and distilled or evaporated to dryness. The end product will be a crude, gummy mix of freebase alkaloids and should be kept away from air or moisture. If very lucky, pure crystals might be obtained. The crude alkaloids should preferably be recrystallised several times for greater purity, if internal consumption [eg. via capsules] is intended, though this will involve some loss of alkaloid.

Extraction of free-base alkaloids in a non-acid medium

Many of the points made above are also of relevance here.

Extract the powdered herb into an organic solvent [such as ethanol] for up to several weeks, shaking regularly; this procedure can be carried out in a much shorter time if one has access to good reflux equipment. The mixture is filtered, with the biomass thoroughly squeezed out and washed through with a small amount of fresh solvent, before being concentrated by distillation to remove most of the solvent. This last step is very important if using an alcohol, which will mix with the water-based solutions to be used later. Be careful not to distil the solution to the point that it becomes thick.

Lower the pH of the solution to 3-5 with dilute hydrochloric acid [about 20ml per 2 litres of water]; sometimes this step is done before the concentration of the extract, as above. This is then defatted as above, if required. A lengthier, but perhaps more thorough approach to defatting is as follows. The boiled extract, after concentration and acidification, should be set aside and not disturbed for 24 hours, before being placed in a refrigerator for several days. After this period, the aqueous layer can be decanted, and filtered of traces of insoluble substances through charcoal.

Finally, the solution is made strongly basic and the alkaloids extracted as above (De Korne 1994; Manske 1950; Trout 1997-1998; pers. comms.).

For educational purposes, below are several examples of alkaloid extraction tailored for specific plants. These are by no means the only workable methods for extracting alkaloids from these plants, but they illustrate a variety of different simple and fairly low-tech approaches. However, when applied to plants containing prohibited chemicals, such procedures may be illegal to perform. The reader is advised to become familiar with their local laws regarding such matters.

Extraction of mixed alkaloids from Tabernanthe root bark

This procedure is similar to standard alkaloid extractions described above, and may prove useful for future therapeutic use of 'iboga' alkaloids [see **Tabernanthe**].

Powdered root bark was stirred with vinegar or acetic acid [0.5% conc.] for an hour or less, before filtering; heating the mixture impaired the filtering process, and initial extractions longer than 1hr or with stronger concentrations of acetic acid did not improve the yields. Repeated three times and the vinegar extracts combined, c.87% of the alkaloids were extracted. These solutions should not be left sitting for more than a few days as they easily become contaminated with bacteria. The solution was basified with ammonia, resulting in the alkaloids precipitating as solids, which settle at the bottom of the vessel. Filtration of the alkaloids was aided by first siphoning off most of the solution after settling. The mixed alkaloids can then be washed with distilled water, and dried at room temperature or with the aid of a gentle heat source. They can be further purified by dissolving in acetone, which separates a large amount of dark, insoluble material; gradually and incrementally adding concentrated hydrochloric acid to the solution until it becomes acidic precipitates the alkaloids as their hydrochlorides, which can then be filtered, washed with a small amount of acetone and dried [the solution may need refrigeration overnight for precipitation to develop]. However, this does not remove all alkaloids present from solution; the remainder can be mostly retrieved by evaporating the acidic acetone solution, then dissolving the resultant unstable oil in water and basifying with ammonia to precipitate the alkaloids. This procedure was observed to be more efficient than extraction with ethanol or chloroform, and can also be applied to **Voacanga** africana trunk bark (Jenks 2002).

Alcohol extraction of Ipomoea seed alkaloids

This method for avoiding the gastric upset and fogginess of the 'morning-glory effect' [see **Ipomoea**, **Turbina**, **Argyreia**] was retrieved some years ago through the internet, from the old newspage alt.drugs. I have encountered no one who has attempted this method or tested its claims, but it would seem to be a sensible approach, although illegal in many places.

If seeds to be used have been treated with chemicals, wash thoroughly in detergent and cold water. Dry them thoroughly and ensure they are free of residual detergent. Grind the seeds throughly in a coffee-grinder. Place the powder in a clean jar and cover with petroleum ether [about 360-500ml per 500 seeds]. Seal the jar and shake vigorously; let stand for 20 minutes and shake further. Pour the whole through coffee-filter paper [in a well-ventilated area], and set aside the petroleum ether, which can be re-used up to 4 more times for the same purpose. Dry the seed powder thoroughly, and wash and dry the jar before again putting the seed powder inside. Add a drinking-grade alcohol [40% or more], using 1 shotglass for every 30-250 seeds, depending on the desired strength [by volume of alcohol] of the end extract. Soak the seed pulp in the alcohol for at least 3 days, shaking regularly, before filtering it for consumption. If the alcohol solution is taken orally and held in the mouth before swallowing, effects should be rapidly apparent, allowing one to more accurately gauge the dose.

The experience is said to last 8-12 hours, and to be 'cleaner' than from the seeds ingested via simple cold-water extraction, as is done traditionally. The petroleum ether extract is claimed to remove fractions of the seed chemistry which cause side-effects such as headache, blurred 'fish-eye' vision, and counter-action of the psychedelic effects; this fraction is claimed to reside in the seed husks, and to be miscible with petroleum ether, and insoluble in water. Compounds causing nausea are said also to be found in the seed pulp, and are water-soluble and soapy, forming long strands in water; they are not soluble in alcohol or petroleum ether.

As stated above, the accuracy of this latter information is not known to me, though the extraction process described appears to be sound. I once tried this procedure on a batch of commercial 'morning glory' seeds, however the batch used did not seem to be particularly psychoactive and further experiments were not performed. The least I can say is that this method will not produce wondrous effects unless the seeds bear a useful chemical profile. See **Ipomoea** for further discussion.

Isolation of *harmine* and *harmaline* from Peganum harmala

Cover crushed seeds with 3 times their weight of water [containing 30g acetic acid per litre of water] and steep for 2-3 days; the seeds swell to form a dough which is pressed dry. The dry seed-mass is again soaked with twice its weight of a similar solution, macerated, and again pressed out. The filtered liquid is combined, and to this is added sodium chloride [salt – 100g per litre of liquid] – this transforms the desired alkaloids from their acetate to their hydrochloride forms, which are insoluble in cold sodium chloride solutions; they thus precipitate during cooling. The crystalline precipitate is retrieved and thoroughly filtered and dried [preferably with suction] and redissolved in hot water. To this is added further sodium chloride in small amounts until the alkaloids precipitate as a crystalline mush; this is repeated until they have turned a yellow colour.

The next step involves redissolving and separating the major alkaloids, *harmaline* and *harmine*, as bases. Ammonia is added to the solution in carefully incremented amounts, which makes the solution alkaline and causes *harmine* to precipitate as long needles. *Harmaline* does not precipitate until all of the *harmine* present has dropped out of solution. As soon as *harmaline* crystals [plates under a microscope] are detected, the addition of ammonia is stopped, and the *harmine* filtered off. The *harmaline* is recovered from the filtrate by further addition of ammonia. The freebase alkaloids may then be purified by recrystallisation as the hydrochlorides if desired (Marion 1952a).

It should be noted that many amateur chemists have had difficulty in getting these last steps [regarding separation of *harmine* and *harmaline*] to work well, without access to laboratory equipment. However for many people it is unnecessary. A mix of the freebase alkaloids may be obtained by avoiding the attempted separation, and instead simply adding ammonia until no more precipitate forms. The resulting filtered precipitate, which consists of fairly pure alkaloidal material, can then be dried and used either by vapourisation and inhalation of the vapours, or encapsulated and taken internally.

Extraction of *cocaine* hydrochloride from coca leaves [see Erythroxylum]

The following is from a DEA summation of the processes used in illicit *cocaine* manufacture. It will give a further understanding of some of the potential contaminants of 'coca-paste' and 'street' *cocaine*, as discussed under **Erythroxylum**.

The leaves are initially soaked in a solution of sodium bicarbonate and water. Kerosene, petrol or another water-immiscible solvent is added; the coca-alkaloids migrate into the solvent layer, which separates from the water and the leaves. The solvent layer is decanted, and treated with a hydrochloric acid solution. Sodium bicarbonate is added to the hydrochloric acid solution; the precipitate that forms is filtered and dried, and is known as coca-paste [containing up to 40% *cocaine*].

This is next dissolved in a weak solution of sulfuric or hydrochloric acid. Potassium permanganate mixed with water is added to this; a precipitate forms, which is discarded after being filtered out. Ammonia in water is added to the solution, and the new precipitate that forms is dried [often with heating lamps] – this is *cocaine* in its free-base form [up to 90% pure].

The free-base is dissolved in ether or acetone and the solution filtered for purity. Hydrochloric acid diluted in ether or acetone is added to the solution, causing *cocaine* hydrochloride to precipitate, to be filtered and dried with heat and/or fans [up to 99% pure] (Clawson & Lee 1996).

Other Miscellaneous Techniques

Hash oil production

There are various methods of producing hash oil, which is a concentrated oily extract of **Cannabis** that may be smoked, but is preferably vapourised for inhalation. I will discuss a few basic methods here for educational purposes, but for more detailed coverage, the reader should consult any of a number of commercially-available books on the subject (eg. Hoye 1973; Starks 1990). An internet search will also turn up plenty of information on this widely illegal activity.

A good hash oil will probably follow a procedure similar to the following:

Separate seeds from the herb, chop the herb finely, and put in a jar with enough alcohol to cover it well. Put the lid on, shake a few times, and let sit for 2 weeks, shaking several times daily. Filter the alcohol extract through coffee filters, and repeat for 1 further week with the remaining herb. Combine the alcohol extracts. The next step consists of isomerisation of the resins, which in simple terms converts the inactive or lesser-active cannabinols [eg. *cannabinol* (CBN)] and cannabidiols [eg. *cannabidiol* (CBD)] into active forms of *THC*. This procedure is only really necessary for low-quality **Cannabis**. For every ¼ cup of alcohol, carefully add 3 drops of sulfuric acid. Put the whole solution in a glass receptacle that can both a) be heated from below without breaking, and b) allow a glass filled with ice to sit in the opening at the top. Heat to a slow simmer [with the ice-filled glass in place] for 2 hours. Let the mixture cool. Next, for every ½ cup of solvent, add ¼ cup of a water/sodium bicarbonate solution [½ tsp sodium bicarbonate for every ¼ cup of water]. Shake well, and add about ¼ cup naptha [Coleman fuel], and shake well again. Retrieve the top layer when it separates. Repeat this last step on the solution, and combine the two top fractions, discarding the bottom fractions. The remaining combined fraction is evaporated in a glass baking dish until no smell of solvent remains. To further purify the oil by 'washing', it is redissolved in alcohol, with water added [½ as much as the alcohol]. This is shaken well, ¼ cup of naptha is added, and the whole shaken well again. The top layer that separates is evaporated as above. The oily residue that remains is the hash oil (Hoye 1973; Starks 1990).

If not trying to impress anyone, a cruder oil may be made, usually from leaf. The chopped herb is soaked first in lukewarm water for several hours, after which the whole mixture is filtered through a fine cloth, and the water discarded. The herb is spread out to dry completely, before being soaked in alcohol as above for a week or more, with daily shaking. The alcohol is filtered and saved, with the herb being extracted in the same way a second time. The thoroughly filtered alcohol extracts are combined and evaporated, for a hash oil that is less pure and correspondingly less potent than an oil obtained by the previous method (pers. obs.).

Other concentrated extracts for smoking

I sometimes use a simple alcohol extraction, soaking for several days, for aromatic plants such as many **Artemisia** and **Salvia** species, which can then be dried and smoked as above for a more definite effect than smoking the dried herb itself. I find this useful in assaying plants of the mint family [Labiatae] for psychoactivity [see **Salvia** for more discussion]. A very potent smoking extract is often prepared from **Salvia** divinorum, by soaking in high-proof alcohol for only several hours, before filtering the solvent, and evaporating thoroughly onto ¼ the amount of leaves originally used in the extraction. For example, soak 100g of dry, finely-chopped leaf material in alcohol, then, after filtering out the plant matter, add the alcohol extract to 25g of dry, finely-chopped leaf material, and evaporate the alcohol from this in a flat dish. The relative potency of such extracts is termed as related to the amount of leaf material that the extract is evaporated on to – so, the extract just mentioned would be referred to as a '4x' extract – if I had used 1/10th the original amount, the extract would be '10x'. The 4x and 5x are the most commonly used with this exceedingly potent plant. This approach has also been effectively applied to the flowers of **Nymphaea** caerulea. In the 60's and 70's, the usual method of smoking *DMT* was to evaporate it onto a herbal medium - often parsley [**Petroselinum**] - in the same manner. Today this has become a popular method again, often using **Banisteriopsis** leaf, which provides an extra synergy rather than being a relatively inert carrier. Such *DMT*-enriched smoking material is known as 'changa'.

Beginner's Plant Alchemy

Alchemical extraction methods may also be attempted, though the theory behind them is complex and beyond the scope of this work. There are several excellent books available on plant alchemy. One text, 'The Alchemist's Handbook' [by Frater Albertus, publ. Weiser, 1974; unfortunately I've never actually seen this] gives a technique, which was attempted by an internet psychoanut, with 'lemon balm' [Melissa officinalis – see *Endnotes*].

Grind the herb, place it in a glass container, and fill the container 1/2-2/3 full of alcohol [food grade], preferably brandy. The container is then covered, and kept warm to macerate for a few days. The liquid is poured off into a clean glass container, and the remaining herb dried and burned until it is a light grey – the salt or crystals from the herb should be separated from the ashes [there will probably only be a small amount]. While still hot, the ashes are added back to the liquid [which is heated previously to keep the hot ashes from cracking the glass]. This mixture, the liquid essence, is then tightly sealed, and kept slightly warm for about 2 weeks.

A few grains of the salt, together with a teaspoon of the liquid essence, is diluted in distilled water and consumed to produce [in the case of lemon balm] what were described only as 'exhilarating results' (pers. comm.).

METHODS OF INGESTION

Oral ingestion

via the digestive tract

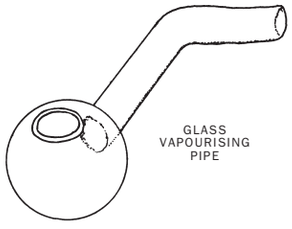
Drugs that are both soluble and stable in stomach fluid may be consumed in this way, where, from the stomach, they enter the intestine and pass into the bloodstream; or, they may enter the blood directly through the stomach lining. Drugs taken in this way are better absorbed if already in solution, rather than in tablets or capsules. Only lipid-soluble particles will diffuse readily across cell-membranes. Generally, about 75% of the drug may be absorbed by the body, over about 1-3 hours. Side-effects noted with some substances taken by this route are more likely to include nausea and vomiting (Julien 1995).

via the mucous membranes

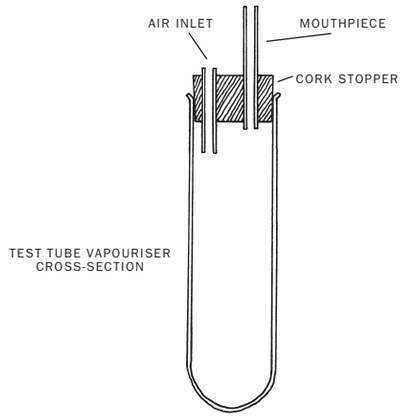
Using this pathway, drugs that may be destroyed by the acidity of the stomach [or enzymatic activity therein] are taken sublingually – that is, chewed and held under the tongue or in the cheek, and the saliva held in the mouth for some time rather than swallowed immediately. This is the preferable route of administration for **Salvia** divinorum – the herb is usually held in the mouth for about 10-15 minutes, before being spat out or swallowed. Other drugs may be used this way purely for more efficient and rapid absorption, as compared to the gastrointestinal-route, such as is practiced with coca leaves [see **Erythroxylum**] and **Areca** nuts. These are usually chewed and sucked for hours with an alkaline reagent, such as calcinated lime, to aid in liberation of the alkaloids from the plant matter. After an initial chewing, the wad may simply be left in place between the gum and the inner lip. Many materials have been used to create this alkaline reagent. Limestone [calcium carbonate] chunks are often heated on a fire until red-hot [releasing carbon dioxide], then cooled suddenly with a small amount of water, causing the stone to fissure and give off a fine, white powder [calcium hydroxide, a powerful alkali]; sometimes seashells are used, yielding an end result also bearing traces of potash; bones may also be used. Sometimes plants are used instead [burnt slowly down to an alkaline ash], where limestone or shells are not available – corn cobs, **Theobroma** pods, **Musa** roots and leaves, cacti fruits, roots and stems of haba beans, and quinoa stalks have all been used. The ashes are usually mixed with agglutinants and flavourings such as dry powdered potato, boiled corn grains, salt, sugar, **Citrus** fruit juice, water, even human urine, and sometimes a little lime if available, to make a fairly dry paste. The mass is then compacted and dried in the sun. In more recent times, some coca-chewing cultures in South America have come to use sodium bicarbonate ['bicarb soda'] as an effective and easily-obtained mild alkaline reagent (Antonil 1978; Davis 1996; Hilgert 2001; Schultes & Raffauf 1990).

Smoking

Here the powdered, chopped or shredded drug is burned or vapourised, and the fumes inhaled, to be absorbed through the lungs into the bloodstream. This is a very rapid and efficient route; effects of administration are felt usually within 5-60 seconds. Smoking has the advantage of quick onset of effects, which allows one to more accurately gauge dosage. Usually, after oral ingestion, if one has taken too much there is little that can be done to end the experience, and vomiting may be required to avoid poisoning with the more dangerous compounds. However, the effects also wear off more rapidly compared to oral administration, where more of the substance may be required for the same level of effect, but effects are more prolonged. Burning plant-matter produces tars and other dangerous substances which can injure the sensitive tissues of the lung, and hot smoke can also irritate the airways. Vapourisation is preferable,

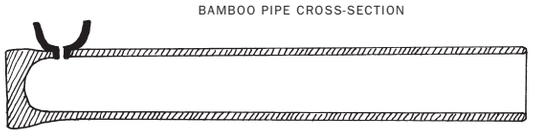


as the finely-powdered plant matter, or extract, is simply heated through glass or metal until the active components reach their boiling points and give off vapours. Hence, no smoke or pyrolysis by-products are inhaled, and no active compounds are destroyed by flame, which occurs partially with burning. Plans to build home-made vapourisers are available on the internet; ready-made vapourisers are also legally available from a number of commercial suppliers. Many people have experienced dissatisfaction with some of these products, particularly home-made devices [due to taking too long to heat up, not getting hot enough to work well, not very suited to efficient group smoking etc.], so anyone considering buying one should shop around, as they are an expensive purchase.

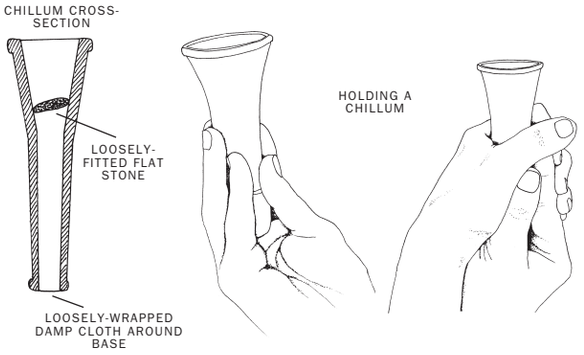


One straight-forward approach to vapourisation is known as 'free-basing', and takes advantage of the low boiling-points of some alkaloids in their free-base form [eg. *DMT*]. This involves the use of a specially designed or conveniently shaped glass pipe or tube, open at each end [see diagram]. The drug is placed inside a chamber or hollow at one end of the pipe, and is heated from beneath the glass with, usually, a gas flame, until the material begins to melt, boil and send off vapours. The vapours are immediately inhaled deeply and slowly, until all the vapour has been inhaled. In many cases, if vapour is allowed to fill the chamber and touch the sides of the glass, it will rapidly cool and re-solidify, making it harder to smoke efficiently. Vapourisation in this manner is often the preferred route of administration for *DMT*, opium [see **Papaver**] and sometimes *salvinorin A*. Alkaloids used in this fashion should both be in their free-base form, and have a low boiling point, for vapourisation to be practical without the use of destructive levels of heat. For maximum effect via this route, at least with the two substances just mentioned, the vapour should ideally be inhaled in one breath, and held in the lungs for as long as possible before being exhaled. Some people say that with *DMT* it is best to only hold the first inhalation briefly, and to hold subsequent larger inhalations for as long as is practical. Breathing vapours out through the nasal passages has also been suggested to increase absorption into the brain.

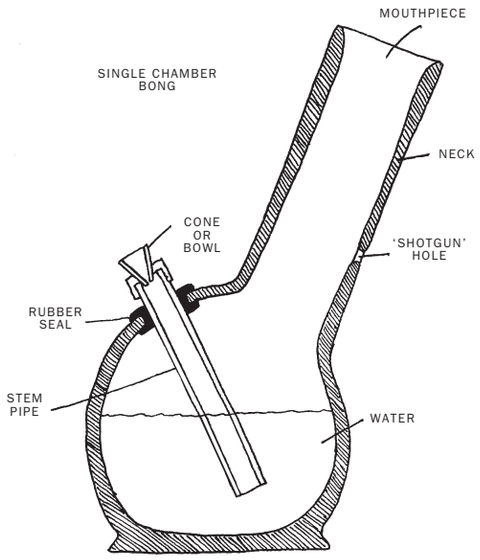
Another straight-forward approach to vapourisation, often applied to hashish [see **Cannabis**], is known as 'hot-knifing'. All that is needed is a heat source [such as the flame of a gas stove-top], a pair of metal knives [or spoons], and something through which the vapours can be collected and inhaled [such as an inverted funnel, or a bottle with the bottom cut out]. The two knives [or spoons] are heated over the flame, and when sufficiently hot, the powdered or resinous substance to be vapourised is placed on one of the knife blades [or in one of the spoons]. The second utensil is pressed against the first, sandwiching the drug between two pieces of hot metal, and the vapours that are emitted can then be collected and inhaled. In more primitive circumstances, plants have been known to simply be thrown on hot coals and the smoke inhaled. Sometimes, this operation is performed within an enclosed structure to maximise retention of the valued fumes.



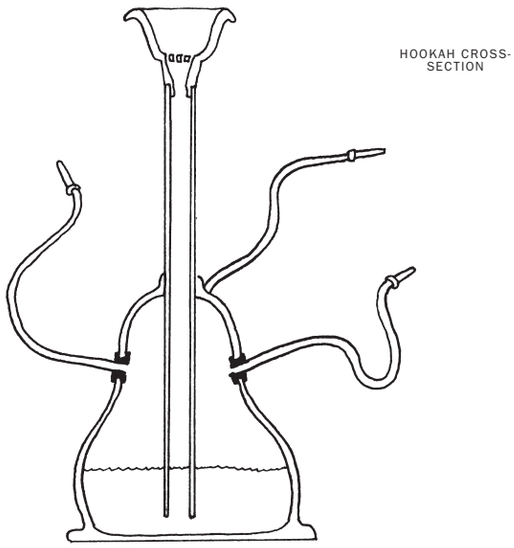
Burning [or pyrolysis] is usually accomplished with a dry-pipe, a water-pipe, or a hand-rolled cigarette. The former is generally the harshest on the lungs. At its most basic, a dry-pipe consists of a hollowed out cone, or bowl, with a small hole in the bottom, joined to a hollow tube that is sealed at one end [see diagram]. The bowl is packed with the herbal material, and with a flame held just above the herb, the smoker seals the mouth to the pipe and inhales [which draws the flame into the herb, setting it aglow but not flaming]. The smoke is either taken in large breaths, held in for a while, and then exhaled; or it is sucked in in increments, or layered, and breathed out in the same manner, in a mild form of hyperventilation. This latter practice gives a more rapid and overwhelming effect, and is usually the preferred means of smoking from a classical 'chillum' [see diagram], much used by Rastafarians and Hindu saddhus [in Afghanistan, straight-stemmed water-pipes (see below) are called chillums].



Water-pipes, commonly called 'hookahs' or 'bongs' [depending on the design; see diagram], bear one or more water chambers, which serve



to filter and cool the smoke. Water-pipes basically involve the dry-pipe design just described, extending downwards into the water chamber. This is open at the top as a mouthpiece, or instead being sealed, with tubes or hoses leading out for multiple-person inhalations. Often a hole, about



0.5cm in diameter, is located on the neck of the final chamber; this is often termed the 'shotgun' hole [sometimes 'shotty' (in Australia), or 'carburettor' (in the US)]. It is covered with a finger or thumb during inhalation [as the smoke is pulled through the water by suction], to be released near the end to produce a final rush of smoke that clears the chamber, due to being pushed out by the incoming air through the shotgun hole. Unexpectedly, in the case of **Cannabis**, water pipes have been found to filter out some of the water-insoluble *THC* from the smoke, as well as being relatively ineffective at filtering out tars (Gieringer 1996). However, it is still clear that such devices do filter out some harmful portions of the smoke. This is self-evident when cleaning a water pipe that has been used with the same water for any extended period! Tars that would otherwise enter the body also collect inside the stem and inner walls of the chamber.

Herbs are most simply smoked by wrapping them [once well-chopped] into a cigarette, which may consist of 1 or more rolling papers stuck together. With many herbs, a double layer of papers is used to slow combustion and make the cigarette last longer. Hand-rolled herbal cigarettes are often called 'joints' [generally when containing **Cannabis**], except if they contain only tobacco [see **Nicotiana**], in which case they are sometimes termed 'rollies' [in Australia]. Herbs for smoking are often chopped with tobacco, both to help the herb burn evenly, and to add extra flavour and potency [and unfortunately, addictive power]. The disadvantage of joints is their inefficiency – a large amount of smoke dissipates into the air between inhalations, being lost to the smoker, and the remaining herb burns away more rapidly due to greater availability of oxygen than occurs in a pipe. This method is just as effective subjectively as the others, yet more herb needs to be used to make up for wastage incurred during smoking.

When smoking herbs, care should be taken not to inhale too forcefully, as this sucks a greater amount of oxygen into the burning herb, increasing the temperature of combustion – thus, more of the active compenents may be destroyed by heat before they can enter the smoke. It should of course be mentioned that smoking anything can cause damage to the respiratory system, and increase the risk of associated cancers.

Amongst enthusiasts of smoking herbs, experimenting with the manufacture of different blends has always been a popular pastime. Often interesting effects are gained which would not be experienced with any of the individual component herbs smoked by themselves. Also, small amounts of each constituent may synergise to provide a potency that would not be expected with such a small amount of the herb alone. Smoking blends are not discussed in depth below, under 'Combinations', as apart from the need to use herbs that are actually smokable and will not burst into flames, the only limits are your imagination! See also Brounstein (1995) and Rätsch (1990) for discussions on blending herbal smoking mixtures.

Aromatherapy

Aromatherapy is a science growing rapidly today, and consists of treating emotional and some physical complaints through inhalation of aromatic vapours from essential oils. This may be accomplished either through smelling the oil at room temperature, or inhaling the fumes from dilute oils heated from below in an essential-oil vapouriser. The mood-enhancing, calming or stimulating properties of aroma, often in the form of incense, have been long known to many indigenous cultures. Modern science still has a relatively poor idea of how essential oils interact with the brain to produce the effects that they do. To my knowledge, several European research groups have been working for quite a while in this area of study, but are only publishing findings in an extremely expensive and difficult to obtain journal. Here is a tiny hint of what the public has been allowed, culled from a poster (Tisserand 1988) circulated through In Essence® Aromatherapy in Australia:

Essential oils of 'clary sage' [see **Salvia**], 'jasmine' [see **Jasminum**], 'patchouli' [see *Endnotes*] and 'ylang-ylang' [see **Cananga**] are aphrodisiac and appear to act on the pituitary gland, possibly stimulating *endorphin* release.

Essential oils of 'bergamot', 'geranium' [see *Endnotes*], 'frankincense' [see **Boswellia**] and 'rosewood' appear to have a mood-regulating effect through the hypothalamus.

Essential oils of 'clary sage', 'grapefruit' [see **Citrus**], 'jasmine' and 'rose-otto' are euphoric, and appear to act on the thalamus, possibly stimulating *enkephalin* release.

Essential oils of 'chamomile' [see **Anthemis**/**Matricaria**], 'orange blossom' [**Citrus**], 'marjoram' and 'lavender' [see *Endnotes*] are sedative, and appear to act on the raphe nucleus in the brain, possibly stimulating *serotonin* release.

Essential oils of 'cardamom', 'juniper' [see **Juniperus**], 'lemon grass' [see **Cymbopogon**] and 'rosemary' [see *Endnotes*] are invigorating, and appear to act on the locus ceruleus, possibly stimulating *norepinephrine* release.

Anyway, it is known that, like other aromas, those of essential oils interact with neurons via the olfactory membranes, in the upper nasal cavity, which offers almost direct interaction with the brain (Battaglia 1995).

Snuffing

Snuffing involves inhalation into the nostrils of a finely powdered herb or herbal extract [sometimes a viscous liquid – see **Nicotiana**], and its subsequent absorption into the bloodstream through the nasal mucosa. Also, from deeper into the nasal cavity, certain blood vessels with no blood-brain barrier interact directly with the cranial cavity, which might offer a very rapid course to the brain. The efficiency of absorption may depend on the force of inhalation – if one is snuffing from the palm of the hand, or through a tube off of a smooth surface [with a finger held on the other nostril], the force is relatively low and little of the substance reaches

the more permeable membranes higher in the sinuses. If the snuff is blown into the respective nostrils by a second person using a long tube, the substance is received quite forcefully, and some particles may even reach the lungs, which is not desirable (Holmstedt & Lindgren 1967; Wassén & Holmstedt 1963). Some pure chemical substances may be snuffed less painfully by dissolving in a suitable solution and administering with a nose-spray bottle, which has the added advantage of the snuffer being able to calibrate the dose fairly accurately. Side-effects of snuffing appear almost instantaneously, and may include runny nose, burning sensation in the nasal cavity, headache and irritation. Long-term snuffing damages the nasal mucosa.

Jonathan Ott has recently published a dense overview of psychoactive snuffs (Ott 2001c), which the interested reader will no doubt wish to consult.

Optically

Drugs in relatively pure form, usually diluted in fluids, are sometimes administered as eyedrops (see Samorini 1996c) or simply smeared on the eyes [eg. see **Elaeophorbia**]; effects via this route are often very quickly felt, but some substances applied this way may cause painful irritation or optical damage. I have observed a friend administer LSD [in paper 'tab' form] to herself by placing it under her eyelid, removing it when she began to feel the effects. Personally I don't care to go poking around my eyes in such a fashion, but this provides some further evidence of optical administration as an effective route.

Rectally

Here the drug is administered in either a suppository or a liquid enema form, for absorption into the blood from the rectal- and intestinal-lining. It is usually used for those who are unconscious, or unable to swallow or keep things down, and the absorption from rectal administration is usually irregular and incomplete. However, in some cases rectal administration has proven fatal [eg. with coffee enemas (Eisele & Reay 1980) – see **Coffea**], and many drugs also irritate the rectal membranes.

Injection

This is not recommended unless if undertaken with medical supervision, due to the very real possibility of infection and air embolism associated with injecting substances directly into the bloodstream. Crude plant extracts should never be injected – if you really must use this approach to ingestion, use pure compounds only and clean, sterile equipment.

Pure substances may be injected intravenously [i.v.], directly into a vein; intramuscularly [i.m.], directly into skeletal muscle; subcutaneously [s.c.], under the skin [in crude conditions this may include the application of a drug to burns or wounds made especially for this purpose – eg. see **Phyllomedusa**]; or intraperitoneally [i.p.], into the gut. Absorption with i.v. and i.p. methods is very rapid; i.m. and s.c. injections are absorbed more slowly. Injection is the most dangerous of all of these methods of ingestion. It is easy to overdose, as the substance involved is introduced directly into the blood without any biological hindrance from the gastrointestinal-tract to modify the effects to a safe level. Overdose is also more difficult to treat, as stomach-pumping or vomiting make little or no difference, since the substance never entered the digestive tract.

Cutaneously

Some substances, such as *nicotine* and *hyoscine*, may be absorbed directly through unbroken skin and into the bloodstream. Such topical administration is more delayed and prolonged in effect, particularly if the substance is kept in place on the skin. Some spots on the body absorb compounds more easily due to being more porous, such as the areas between the toes, in the armpits, on the temples and behind the ears. Substances may be topically administered by preparation of an ointment or salve, by bathing in a decoction or infusion of the herbs [see *Producing Plant Drugs*], or by direct application [such as wearing a head-band of bruised herbage, or inserting a chewed cud of tobacco (see **Nicotiana**) behind the ear].

Distribution and expulsion from the body

Once a drug enters the bloodstream, it disperses throughout the body via the circulatory system, with a small portion reaching the brain and other bodily organs after contending with lipid-barriers, enzymes and other biological modifiers. Those chemicals that enter the brain from the blood interact with neurotransmission or neuronal function [see *Neurochemistry*], after which they are usually enzymatically degraded, and removed from the brain to be transported by the bloodstream into organs of excretion. Some volatile substances, such as alcohol, can be partially excreted as fumes via the lungs. Alternately, for most other substances, the chemicals are filtered from the blood by the kidneys, and the liver enzymatically turns them into less lipid-soluble forms, which are later excreted in urine and faeces. Chemicals may also be eliminated via the bile, saliva, sweat and breast-milk, or in drastic situations, vomit.

Combinations

Often plants are consumed in combinations designed to increase or modify the desired effects. This may take the form of a synergy, where the different components complement each other to increase effectiveness beyond the sum of the parts. It may be done to add different aspects to the whole experience, or to counteract unwanted or hazardous side-effects. Other types of combination are intended to render active plants which would not normally be effective alone [such as in the Amazonian 'ayahuasca']. To illustrate the possibilities of combinations, we will look at a number of important examples of plant-combining in both historical and modern-day practice. Please bear in mind that some combinations may be much more toxic and potentially dangerous than the individual substances. In some cases these combinations are known of and are warned against, but the gaps in our knowledge of drug interactions are vast, and any new combinations should be treated with utmost caution until their properties have been evaluated. Both with herbs and pure chemicals, experimenting with new combinations has become a popular pastime amongst drug enthusiasts - sadly this has occasionally resulted in deaths. Be smart and don't become a statistic!

Wines, Beers, and Meads

Although wines are primarily prepared from the fermentation of grapes [fruit of Vitis vinifera], usually producing 8-14% alcohol, it is lesser-known that the ancient Egyptians and Greeks quite often fortified their wines with intoxicating herbs. Thus, the potent Greek wines of legend [which had to be diluted with water for safe use] do not merely owe their effects to alcohol content. It should be noted, however, that some older texts do not always clearly distinguish between wines, beers and meads, yet all are alcohol-containing products of fermentation. This method of fortification with herbs works well, as the alcohol provides a solvent and preservative for the additive plants. However, alcohol can synergise with some other herbs to produce a dangerous degree of depression [ie. of the respiratory system; eg. see **Papaver**], so care should be taken with choice of additives.

The Egyptians are known to have fortified their wines with plants such as **Datura**, **Hyoscyamus** and **Mandragora**; as well as possibly **Catha** edulis, **Papaver** somniferum and **Nymphaea** caerulea. The Greeks were known to have used **Atropa**, 'hellebore' [Helleborus spp. (Ranunculaceae), or **Veratrum** spp.], **Hyoscyamus**, **Mandragora**, **Papaver**, **Crocus** sativus, Oleander spp. [Apocynaceae; highly toxic!], Cyclamen spp. [Primulaceae] and a variety of incenses as additives.

Beer is produced from the fermentation of malted grain with brewer's yeast [Saccharomyces uvarum (S. carlbergensis); S. cerevisiae is used for ales] in water, along with herbal additives, today usually hops [see **Humulus**]. Belgian lambic beers instead use over 30 different types of wild yeast. The alcohol content of beer is generally 2-5[-10%]. However, in our earlier history, many beers were made using additives more intoxicating than hops. The same can be said for meads [mead being a more ancient preparation than beer or wine], which basically consist of fermentations of water and honey [generally 2-4% alcohol]. Such additives [in Europe] included 'ash' leaves [Fraxinus excelsior (Oleaceae)], **Cannabis**, **Datura**, **Atropa**, 'hellebore', **Hyoscyamus**, **Ledum**, **Lupinus**, **Mandragora**, 'myrtle' [Myrtus communis (Myrtaceae)], 'bog myrtle' [Myrica gale (Myricaceae); see *Endnotes*], oak bark [Quercus spp. (Fagaceae)] and **Papaver**. Celtic druids were associated with the use of magical beers or similar ritual or healing beverages; **Hyoscyamus** and **Amanita** muscaria have been hypothesised as likely ingredients for these Druidic beverages. The narcotic Erica spp. ['heather' (Ericaceae); see *Endnotes*] were a popular ingredient of meads and beers for centuries across Europe, Scandinavia and the British Isles (Buhner 1998; Rätsch 1992, 1998, 1999b; Simpson et al. 1996).

African groups have been hypothesised to have once made mead using *psilocybin*-containing fungi [see **Panaeolus**, **Psilocybe**]. A west African 'millet' [Sorghum vulgare (Gramineae) – see *Endnotes*] beer called 'dolo' has used additives including **Acacia** camplyacantha, 'balanos' [Balanites aegytica (Zygophyllaceae)], **Datura** seeds, **Grewia** flavescens and Hibiscus esculentus [Malvaceae; see *Endnotes*] (Rätsch 1992). Millet beer made in Tanzania, known as 'pombe', has been found to contain c.4-5% alcohol. The related 'sorghum' or 'guinea corn' [S. bicolor] is also widely used in Africa as a source grain for fermented beers (De Smet 1998).

A South African beer/mead called 'khadi', which is prohibited in some areas, has many regional variations, but is generally based on water, sugar or honey, a fungus that grows inside termite mounds, and roots [sometimes fruits] of various tuberous plants. The latter ingredient may consist of Coccinia spp. [Cucurbitaceae], **Delosperma** spp. [Aizoaceae], Eriospermum spp. [Liliaceae], Euphorbia spp. [Euphorbiaceae; see *Endnotes*], Glia spp. [Umbelliferae], **Grewia** spp. [Tiliaceae], Kedrostis spp. [Cucurbitaceae], Khadia spp. [Aizoaceae], **Nananthus** spp. [Aizoaceae], Rhaphionacme spp. [Periplocaceae], Stapelia spp. [Asclepiadaceae][S. gigantea is a Zulu remedy for hysteria (Watt 1967)], Trochomeria spp. [Cucurbitaceae] and/or Tylosema spp. [Leguminosae] (Hargreaves 1999).

Apparently in Australia, Physalis peruviana [Solanaceae] has been used to make a psychoactive beer (Rätsch 1998); tropane alkaloids are found in the genus [see *Endnotes*].

Traditional beers are usually not strained, thus retaining some of the yeast and its accompanying noteworthy nutritional virtues (Buhner 1998). Forms of wine have also been made from the fermentation of plants other than Vitis, such as the palm wines popular in tropical areas, produced from immature coconuts [Cocos nucifera; Palmaceae], which may reach an alcohol content of over 7%. Gabonese palm wine may sometimes be strengthened with Chasmanthera welwitschii root [Menispermaceae], bark from Garcinia klaineana, G. mannii and/or G. ngouyensis [Guttiferae; see *Endnotes*], Morinda confusa leaves [Rubiaceae; see *Endnotes*], Turraea vogelii leaves [Meliaceae; see *Endnotes*], Xylopia aethiopica leaves [Annonaceae], **Dioscorea** latifolia var. sylvestris tuber and Gardenia ternifolia [Rubiaceae; part used not reported, though the root has been used as a homicidal poison]. The date palm Phoenix dactylifera (Arecaceae) was tapped for its sap by the Mesopotamians, who fermented it to make wine. Palm and date wines have a reputation for aphrodisiac properties, but the same could probably be said of alcoholic beverages in general; however, sometimes it has been fortified with **Datura** seeds for this purpose. Bananas [see **Musa**] have likewise been used in parts of Africa to prepare fermented beverages. 'Manioc' or 'cassava' root [Manihot esculenta (Euphorbiaceae)] is also widely used to prepare alcoholic beverages, both in Africa and S. America [see 'chicha' below, and *Endnotes*]. In South Africa Hyphaene crinata sap is sometimes used, and in Malawi the fruit of **Ziziphus** abyssinica is used. The main requirement for a plant part to ferment is a reasonable content of sugars and/or starches; the potential range of choice for starting materials is therefore enormous (De Smet 1998)!

Balché

This Mesoamerican brew is further discussed under its own entry [see **Lonchocarpus**]. It is also a mead-like drink, based on honey, and the bark from **Lonchocarpus** violaceus [probably psychoactive on its own]. It is sometimes further fortified with inebriating plant and animal substances, such as the following [with some Mayan names]:

Acacia cornigera – 'akunte''
Agave spp. [see 'pulqué' below] – 'kih'
Bufo marinus – 'bab'; **Bufo** spp. – 'wo''
Capsicum spp. – 'ik'
Datura inoxia – 'xtohk'uh'
Nicotiana spp. – 'k'uts'
Nymphaea ampla
Plumeria alba, P. rubra [Apocynaceae] – 'nicte' [see *Endnotes*]
Polianthes tuberosa, P. spp. [Amaryllidaceae] – 'bac nicte'
Tagetes erecta, T. lucida – 'macuil xuchit'
Theobroma bicolor – 'ninichh cacao'
Theobroma cacao – 'hach kakaw'
and Vanilla planifolia ['vanilla bean'; Orchidaceae; see *Endnotes*] – 'bukluch'

The following additives are suspected of having been incorporated into balché:

Dendrobates spp. [see **Phyllomedusa**] – 'xut''
Lophophora williamsii – 'wi''
Panaeolus subbalteatus – 'kuxum lu'um'
Passiflora spp. – 'poch', 'pochil-ak'
Psilocybe spp. – 'lol lu'um'
Solandra spp. – 'bak nikte''
and **Turbina** corymbosa – 'xtabentum' (Rätsch 1992, 1998)

Chicha

'Chicha' is a generic term referring to mildly alcoholic beverages popular throughout Central and South America. The fermentation is usually based on germinated and masticated corn [Zea mays (Gramineae)], though other plants have been used as the basis including **Acacia** aroma fruits, Berberis congestiflora, B. darwinii, B. linearifolia [Berberidaceae], Chenopodium quinoa [Chenopodiaceae], **Gaultheria** phyllireaefolia, Manihot esculenta [Euphorbiaceae; 'manioc'], Mauritia spp. [Palmaceae], **Pernettya** spp., **Prosopis** alba, P. chilensis, P. tamarugo fruits, Schinus spp. [Anacardiaceae] and Ugni spp. [Myrtaceae]. The drink is often fortified with other psychoactive additives, or thus used as a delivery agent for the additives. Plants used as additives have included **Anadenanthera** colubrina, **Ariocarpus** fissuratus, **Brugmansia** spp., Chytroma gigantea and C. turbinata [Lecythidaceae] dried and powdered flowers, **Coryphantha** spp., **Datura** inoxia, **Lolium** temulentum, **Lophophora** williamsii, **Mammillaria** spp., **Nicotiana** glauca, **Pachycereus** pecten-aboriginum, **Passiflora** rubra fruit, **Paullinia** yoco and **Tabernaemontana** muricata (Cobo 1990; Cutler & Cardenas 1947; Festi & Samorini 1999a; Rätsch 1992, 1998; Schultes & Raffauf 1990).

Pulqué

'Pulqué' is a Mexican alcoholic beverage, produced from succulents of the genus Agave [Amaryllidaceae/Agavaceae; also known as 'maguey' or 'century plants']. It was popular with the Aztecs and other related cultures, who usually held it to be sacred, and its consumption was generally restricted to either ritual or medicinal purposes. The drink is made by first severing the top of the middle stem as it elongates and prepares to flower. The wound resulting from this is left to heal over for several months, and is later pierced repeatedly, hollowed out to form a cavity, and left for sap to collect and age. The sap is collected periodically, with fresh wounds to the plant cavity being covered over each time. Once collected, the sap is further fermented for 1-2 weeks. The drink was once frequently fortified with other ingredients, some of which have been identified or tentatively identified, including **Acacia** albicans, A. angustissima, **Bursera** bipinnata [Burseraceae; see *Endnotes*], **Calliandra** anomala, **Datura** spp., **Lophophora** williamsii, **Mimosa** spp., Phaseolus spp. [Leguminosae], **Prosopis** juliflora, **Psilocybe** spp., **Rhus** schinoides, **Sophora** secundiflora, Triticum aestivum [Gramineae] and **Turbina** corymbosa (De Barrios 1997; Rätsch 1992, 1998). A variety of Agave spp. are used in Mexico to make 'mezcal', a liquor distilled from the plants [and also a name for the plants themselves]. Mezcal quality varies considerably, due to the species used and the methods and materials used to prepare it - much mezcal is 'bootleg' liquor made in rural areas. 'Tequila' is a kind of high quality mezcal which is made only in the region of Tequila, and only from A. tequilana (Bahre & Bradbury 1980; De Barrios 1997; Rätsch 1998). For discussion of the 'Agave worm' or 'mezcal worm' see *Endnotes*.

Although Agave spp. have sometimes been used in Mexico to stun fish, it is unclear whether they have psychoactivity of their own without fermentation, although pulqué has been observed to have a 'clearer' mental effect than many similar low-alcohol beverages, which does suggest some pharmacology of interest. They generally contain saponins, steroid saponins, papain, sugars, hecogenin glycosides, polysaccharides, minerals and vitamin C. A. americana has yielded 0.4-3% hecogenin, oxalic acid, saponins and an essential oil (Rätsch 1998). *GABA* has been found in Agave americana var. marginata (Durand et al. 1962).

Chhang

'Chhang', a word with many variations in spelling, is the name of a fermented beverage with even more variations of recipe from region to region. It is prepared and used in various parts of Asia, especially Nepal, n. India, and Tibet. Based on rice, barley, and/or millet, the beverage is distinguished, despite its variations, due to the use of specially prepared yeast cakes [also made with many local variations], which are added to initiate fermentation. The major ingredients of these cakes are usually rice or barley flour, as well as crushed ginger root; ginger is used because it often carries **Aspergillus** spores, which develop when the ingredients are crushed together and fermented in a moist cloth. This mould [as well as members of several other genera sometimes found, such as **Rhizopus**, Hansenula and Mucor] converts the starches present into sugar, which are fed upon by wild yeasts (Buhner 1998). Psychoactive plants, such as **Tribulus**, are sometimes added to chhang to fortify the beverage (Navchoo & Buth 1990).

Absinthe

'Absinthe' is an alcoholic liquor produced using primarily **Artemisia** absinthium, as well as other herbs, some of which are also psychoactive. There are many different recipes, but here is one:

- **Artemisia** absinthium 30g
- **Acorus** calamus 1.8g
- **Coriandrum** sativum seed 3.2g
- Hyssopus officinalis 8.5g [Labiatae; 'hyssop']
- **Foeniculum** vulgare seed 25g
- **Illicium** verum fruit 10g
- Melissa officinalis 6g [Labiatae; 'lemon balm' – see *Endnotes*, *Producing Plant Drugs*]
- and **Pimpinella** anisum seed 30g

Place the dry herbs in a jar, moisten with a little water, and add 800ml 85-95% alcohol; steep for 1 week, shaking every day; add 600ml water, and leave for 1 more day. Strain out the liquid finely, squeezing out the herb pulp; wet the herbs with some more alcohol, and squeeze out again. This must be distilled, changing the receiver when distillate turns yellow. To the distillate, add another 3g A. absinthium, 1.1g M. officinalis, 4.2g Mentha spp. [Labiatae; 'mint' – see *Endnotes*], 1g **Citrus** spp. peel and 4.2g **Glycyrrhiza** spp. root. Macerate for 3 days, before straining finely, and add a small amount of sugar syrup. Makes 1 litre.

Absinthe has a special procedure for serving. A small amount is poured into the glass; a slotted spoon is placed over the glass, holding a sugar cube; and water is poured over the sugar cube into the glass, changing the colour of the absinthe from green to yellow (Conrad 1988; Pendell 1995).

Taoist elixirs of immortality

Taoist alchemists in ancient China, and likely still today internationally, long strived in secret to ritually prepare combinations of plant, animal and mineral substances in order to obtain a legendary 'elixir of immortal-

ity' or of 'enlightenment'. The ingredients of such combinations are mostly shrouded in obscurity, and could be expected to have differed from one practitioner to the next. However, some are known, and include substances with actions ranging from tonic and adaptogenic, to psychedelic. As qualities may overlap, I will not attempt to categorise them, but such constituents have reportedly included **Amanita** muscaria, **Camellia** sinensis, **Centella** asiatica [ancient useage in dispute – see the **Centella** entry], **Ganoderma** spp., **Nelumbo** nucifera, **Nymphaea** spp. and **Panax** ginseng (Cooper 1984; Hajicek-Dobberstein 1995; Rätsch 1992).

Mushrooms containing *psilocybin* might have been used (Sanford 1972), such as possibly species from **Gymnopilus**, **Psilocybe**, or **Panaeolus**. Other representatives of the wide array of tonics used in Traditional Chinese Medicine [TCM], such as Polygonatum cirrhifolium [Liliaceae; 'huang jing'], might also have been used for these pursuits. This latter herb is considered a "food of the immortals" – it is a tonic that aids in building bone and sinew, promotes semen production, and retards ageing processes (Hsu et al. 1986; Reid 1995). Some other Chinese tonic herbs will be discussed in the main text and the *Endnotes*.

Witch's brews and flying ointments

It is now known that there was [and still is] a pharmacological basis for the 'witchcraft' exercised in Europe and North America. Most real-life witches were experienced herbalists, and prepared decoctions [to be drunk] and ointments [to be applied, sometimes through the vaginal membranes from application to a broomstick, for example] which produced the state of mind conducive to reports of flying through the night, having intercourse with the devil, etc.

Some documented ingredients, with some brief comments, are listed below.

Aconitum spp. [Ranunculaceae; 'monkshood', 'wolfsbane' – see *Endnotes*]
Acorus calamus [Araceae]
Allium sativum [Liliaceae; 'garlic'] – in India, A. cepa bulb is considered aphrodisiac and stimulant; in Norway, A. schoenoprasum ssp. sibiricum [Siberian chives] has been reported as an ingredient of a witch potion used to cause harm, and is reputed to protect against sea serpents
Amanita muscaria [Agaricaceae]
Apium graveolens [Umbelliferae; 'celery' – see *Endnotes*] – probably seeds used
Artemisia spp. [Compositae]
Atropa belladonna [Solanaceae]
Ballota nigra [Labiatae; 'black horehound'] – bitter medicinal
Boswellia sacra resin [Burseraceae]
Cannabis sativa [Cannabaceae]
Claviceps purpurea [Clavicipitaceae]
Conium maculatum [Umbelliferae]
Crocus sativus [Iridaceae]
Datura spp. [Solanaceae]
Euphorbia spp. [Euphorbiaceae; see *Endnotes*]
Ferula asafoetida [Umbelliferae]
Foeniculum spp. [Umbelliferae]
Helleborus spp. [Ranunculaceae; 'hellebore'] – narcotic, toxic
Hyoscyamus spp. [Solanaceae]
Iris spp. [Iridaceae] – aphrodisiac?
Lactuca spp. [Compositae]
Lolium temulentum [Gramineae]
Mandragora officinalis [Solanaceae]
Myristica fragrans [Myristicaceae]
Nasturtium spp. [Cruciferae; 'watercress']
Nicotiana tabacum [Solanaceae]
Nymphaea spp. [Nymphaeaceae]
Papaver spp. [Papaveraceae]
Pastinaca sativa [Umbelliferae; 'wild parsnip' – see *Endnotes*]
Petroselinum crispum [Umbelliferae]
Piper nigrum [Piperaceae]
Populus balsamifera, P. nigra [Salicaceae; 'poplar'] – stimulant and analgesic
Potentilla spp. [Rosaceae; 'cinquefoil' – see *Endnotes*]
Scopolia spp. [Solanaceae]
Solanum nigrum, **Solanum** spp. [Solanaceae]
Taxus baccata [Taxaceae]
Veratrum album [Liliaceae]
and **Verbena** officinalis [Verbenaceae].
Unspecified orchids [eg. see **Vanda**, **Cypripedium**, **Oncidium**, **Stelis**, many species in *Endnotes*] were also used (Alm 2003; Bremness 1994; Chiej 1984; De Vries 1991; Nadkarni 1976; Ott 1993; Rätsch 1992, 1998; Rudgley 1993, 1995, 1998; Schultes & Hofmann 1980, 1992).

The following is a recipe for an alleged "traditional English flying ointment", with the ingredients as follows [for actual ointment preparation, see the previous chapter]:

- 3g 'annamthol' [an old name for Aconitum spp. – see *Endnotes*]
- 30g **Areca** catechu nut
- 50g 'opium' [see **Papaver**]
- 15g 'cinquefoil' [Potentilla spp. – see above]
- 15g **Hyoscyamus** nigrum
- 15g **Atropa** belladonna
- 15g **Conium** maculatum
- 5g 'cantharidin' ['Spanish fly', Lytta vesicatoria – a ground beetle with highly toxic excitatory and genital-inflammatory effects]
- and 250g **Cannabis** indica (Robinson 1996)

It is of interest to note that Aztec priests also used magical ointments, said to have contained ingredients such as spiders, scorpions, salamanders, caterpillars, vipers [all burnt to ashes][see *Endnotes*], tobacco [see **Nicotiana**] and **Turbina** corymbosa (De Acosta 1604; Robicsek 1978). Inca priests were also known to have used magical ointments of uncertain composition (Cobo 1990).

Betel packages

See the **Areca** entry for more on this topic. The stimulating betel nut [**Areca** catechu] is chewed widely in India, where it is known as 'paan' or 'tambula', and is also a commonly-used drug over much of south-east Asia. At its most basic level, the crushed nut is wrapped in a 'betel leaf' [**Piper** betle – see **Piper 1**] with a dash of lime for mastication. However, a wide array of other plants may be added to this package to alter the effect or palatability. Some combinations or blends are available commercially, with the betel nut and lime already mixed in. Ingredients that have been added to betel packages, with some brief comments, include:

Acacia catechu [Leguminosae] gum
Amomum subulatum [Zingiberaceae; 'greater cardamom'] fruits – digestive
Anethum graveolens [Umbelliferae; 'dill'] fruits
Aquilaria agallocha [Thymeleaceae; 'eaglewood'] resin – see *Endnotes*
Beta vulgaris [Chenopodiaceae; 'beetroot'] – sugar produced from the root is used
Carum bulbocastanum, C. carvi [Umbelliferae; 'caraway'] fruits – digestive
Cinnamomum cassia, C. zeylanicum [Lauraceae; 'cinnamon'] bark
Cinnamomum camphora ['camphor laurel'] crude *camphor*
Cocos nucifera [Palmaceae; 'coconut palm'] dried kernel – mature liquid endosperm contains *GABA* (Durand et al. 1962)
Coriandrum sativum [Umbelliferae; 'coriander'] fruits
Crocus sativus [Iridaceae; 'saffron'] stigmas
Cucumis melo [Cucurbitaceae; 'melon'] seeds – see *Endnotes*
Cuminum sativus [Umbelliferae; 'cumin'] seeds – tonic, stimulant, digestive
Dryobalanops aromatica [Dipterocarpaceae; 'Borneo camphor'] crude *camphor* – see *Endnotes*
Elettaria cardamomum [Zingiberaceae; 'cardamom'] fruits – digestive, antispasmodic, stimulant, aphrodisiac; essential oil is 'stimulating and invigorating'
Erythroxylum coca [Erythroxylaceae] – *cocaine* added
Foeniculum vulgare [Umbelliferae; 'fennel'] fruits
Myristica fragrans [Myristicaceae; 'nutmeg'] kernel
Nicotiana tabacum [Solanaceae; 'tobacco']
Nigella sativa [Ranunculaceae; 'nigella'] seeds – digestive, treats nerve defects [in Germany, N. damascena has been known as 'hexenkraut' ('witch herb') and 'hexli', and N. sativa as 'hexenanis' ('witch anise') (De Vries 1991); N. arvensis is used to ward off the evil eye in parts of Turkey (Ertug 2000)]
Pimpinella anisum [Umbelliferae; 'aniseed'] fruits
Saccharum officinarum [Gramineae; 'sugar cane'] – sugar produced from the stems is used
Smilax calophylla [Liliaceae; 'sarsaparilla'] rhizome – male tonic [see *Endnotes*]
Syzygium aromaticum [Myrtaceae; 'clove tree'] dried immature flower buds
Tamarindus indica [Leguminosae; 'tamarind'] young leaves – antipyretic, astringent
and **Uncaria** gambir [Rubiaceae; 'pale catechu'] gum (Bavappa et al. 1982; Bremness 1994; Chopra et al. 1958; Gowda 1951; Nadkarni 1976; Rätsch 1990).

Ayahuasca

'Ayahuasca' is discussed more fully under the entries for **Banisteriopsis**, **Diplopterys** and **Psychotria**. However, here we will look at some of the wide array of plants that have also been used in its preparation. Most of the major known pychoactive additives, and some of the medicinal ones, are covered under their own entries, and in the *Endnotes* [under 'Latin American Obscurities'], so this will be a selection of plants not discussed elsewhere, with their native names. Their individual properties, if known, will also be briefly covered.

Anthodiscus pilosus [Caryocaraceae] – 'tahuari' (McKenna et al. 1995).
Bauhinia guianensis [Leguminosae] – 'motelo huasca'. 'Two pieces' of the ground vine are added (Luna & Amaringo 1991).

Cabomba aquatica [Nymphaeaceae] – 'murere', 'mureru' (McKenna et al. 1995).

Calathea veitchiana [Marantaceae] – 'pulma'. Added to "see visions" (Schultes 1972); contains *tryptophan* (McKenna et al. 1995).

Calycophyllum spruceanum [Rubiaceae] – 'capirona negro'. Treats diabetes; the **Banisteriopsis** caapi vine also grows up this tree (Luna & Amaringo 1991); bark added to ayahuasca (Trout ed. 1998).

Campsiandra laurifolia [Leguminosae] – 'huacapurana'. Bark added (Trout ed. 1998).

Canavillesia hylogeiton, C. umbellata [Bombaceae] – 'puca lupuna', 'lupuna colorada'. Strict diet required, otherwise can cause death. Also taken alone under 1 month diet. The bark is stripped and rasped before being decocted in water. Consuming the brew initially causes fever and tinnitis, followed by a lucid visionary state in which one can learn icaros and other knowledge from the tree's spirit. The spirit of the tree is a female who usually provides knowledge to sorcerers (Bear & Vasquez 2000; Luna & Amaringo 1991).

Capirona decorticans [Rubiaceae] – 'capirona negra'. May be taken alone under diet as a plant teacher (Luna 1984); said to be dangerous if the strict diet and sexual abstinence are broken (McKenna et al. 1995).

Ceiba pentandra [Bombaceae] – 'lupuna blanco'. Sometimes used in sorcery (Luna & Amaringo 1991); tentatively identified as an additive (Luna 1984). Considered a strong 'doctore' which may kill if the required diet is broken (McKenna et al. 1995). Ceiba spp. trees are sacred to the Maya (Rätsch 1999a). In African traditional medicine, C. pentandra has been used to treat a variety of disorders, including "mental troubles", dizziness, headache and fever. The stem bark has yielded the isoflavones pentandrin and pentandrin 5'-O-β-D-glucoside (Ngounou et al. 2000).

Chorisia insignis, C. speciosa [Bombaceae] – 'lupuna'. See **Capirona** decorticans; bark is added (Trout ed. 1998). The Aguaruna say that lupuna [either referring to **Ceiba** spp. or **Chorisia** spp.] can be used to become a sorcerer, by drinking tobacco-water at the base of the tree to become intoxicated, then entering the city that is said to reside inside it, to receive magical darts from the spirit of the tree (Luna & Amaringo 1991).

Clusia sp. [Guttiferae] – 'miya', 'tara', 'appane'. One or two leaves chewed, or boiled with the drink (Rivier & Lindgren 1972).

Cornutia odorata [Verbenaceae] – 'shinguarana'. Leaves tested negative for alkaloids (McKenna et al. 1984a).

Couroupita guianensis [Lecythidaceae] – 'ayahuma'. See Capirona decorticans; considered a powerful plant teacher, even alone. When used alone [shamans who use primarily this plant are known as 'paleros'], the flower is soaked in a bowl of water for three days, before it is removed and the infusion drunk. A diet lasting three years must be kept before acquiring this plant as an ally [some say it only requires a 30-day diet]; its spirits are said to be a tiger [odd in this part of the world], and a headless dead man, who "teaches evil things". When added to ayahuasca, the bark is used. The fruit has been used to treat alcoholics, and the plant is also given to dogs to increase their strength and hunting abilities. It is reputed to 'cure strong sicknesses' and 'fortify the body' (Luna 1984; Luna & Amaringo 1991; McKenna et al. 1995). Contains indole alkaloids (McKenna et al. 1995).

Coussapoa tessmannii [Moraceae] – 'renaco' (McKenna et al. 1995).

Dieffenbachia alba [Araceae] – 'patiquina'. Occasionally a small piece of the stem is added; the plant is also used to kill sorcerers. Toxic compounds are found in the genus (Luna 1984; Luna & Amaringo 1991), which is common in horticulture ['dumb cane'] (pers. obs.). See also D. sequine below.

Fittonia sp. [Acanthaceae] – 'mamperikipini'. The Machiguenga used large amounts of it in ayahuasca before they discovered **Psychotria**; it is said to produce 'visions of eyeballs'. The Kofan and Siona-Secoya use the plant to treat headaches. An extract was apparently active on 5-HT1a and 5-HT2a receptors (Russo undated). Fittonia spp. are common in horticulture (pers. obs.).

Geogenanthus sp. [Commelinaceae] – no longer used; produces patterned visions (Russo undated).

Gnetum leyboldii, G. nodiflorum [Gnetaceae] – possibly 'kúri kaxpi dá'. May perhaps represent an obscure source of 'yajé' [see **Banisteriopsis**], but this is doubtful (Trout ed. 1998).

Guettarda ferox [Rubiaceae] – 'garabata'. Contains cathenine, hetero-*yohimbine* alkaloids (McKenna et al. 1995); the related G. viburnoides is known as 'angico', a name which is also applied to **Anadenanthera** spp. in Brazil (Trout ed. 1998).

Heliconia sp. [Heliconiaceae] – 'winchu'. This unidentified species, possibly identical to H. stricta, is added to ayahuasca by the Shuar (Bennett 1992).

Herrania sp. [Sterculiaceae] – 'kushiniap'. The Shuar add fruit husks, bark and/or leaves to ayahuasca (Bennett 1992).

Himantanthus succuba [Apocynaceae] – 'bellaco caspi'. Requires special diet (Luna 1984); contains fulvoplumieron and flavonoids (McKenna et al. 1995).

Lomariopsis japurensis [Dryopteridaceae/Polypoidaceae] – 'shoka', 'dsuii teitseperi'. 3-4 branches added to the brew by the Sharanahua (Rivier & Lindgren 1972).

Malouetia tamaquarina [Apocynaceae] – 'guay-ee-ga-mo-yoo-ke-ree', 'cuchara caspi'. Leaves sometimes added for difficult diagnosis. Its fruits are eaten by the 'pajuil' bird [Nothocrax urumutum], rendering its bones toxic to dogs and others. Contains steroidal alkaloids (Ott 1993; Pinkley 1969; Schultes 1957, 1967, 1987; Schultes & Raffauf 1990).

Mandevilla scabra [Apocynaceae] – 'clavohuasca'. Considered a plant teacher (Luna 1984).

Mansoa alliacea [Bignoniaceae] – 'ajo sacha', 'sacha ajos'. May be used for good luck. Used alone under diet as a 'very strong' plant teacher to 'learn medicine' (Luna 1984; McKenna et al. 1995), as well as being disinfectant and used to repel evil spirits; the leaves are burned in the evening for this purpose (Luna & Amaringo 1991). Also antirheumatic (McKenna et al. 1995).

Montrichardia arborescens [Araceae] – 'raya balsa'. Juice of shoots is also taken alone [under special 6 month diet] to learn to travel to 'underwater realms' to gain healing knowledge (Luna 1984).

'Mukuyasku' [Malpighiaceae] – an unidentified vine cultivated by the Shuar; leaves are added to ayahuasca (Bennett 1992).

Phrygilanthus eugenoides, P. eugenoides var. robustus [Loranthaceae] – 'miya', 'ko-ho-bo'. A similar quantity of leaves to 'chacruna' [see **Psychotria**] is added, or the juice drunk with ayahuasca (Pinkley 1969; Rivier & Lindgren 1972; Schultes & Raffauf 1990).

Phtirusa pyrifolia [Loranthaceae] – 'suelda con suelda'. May also be taken alone under diet as a plant teacher (Luna 1984).

Pontederia cordata [Pontederiaceae] – 'amaron borrachero' ['intoxicant of the boa']. Suspected of being added to ayahuasca. Used to relieve facial paralysis; contains sterols and triterpenes (Schultes 1972; Schultes & Raffauf 1990).

Rinorea viridiflora [Violaceae] – 'ayahuasca'. A bioassay of a Shuar ayahuasca brew, containing this plant as the admixture to **Banisteriopsis** caapi, was active in a manner suggestive of the presence of *DMT*; the plant itself still needs chemical analysis (Trout ed. 1998). The Shuar add an unidentified plant which they call 'paraprа' to ayahuasca; it is thought to possibly be a Rinorea sp. (Bennett 1992).

Sabicea amazonensis [Rubiaceae] – 'koti-kana-ma'. Added to sweeten the taste (Trout ed. 1998). See *Endnotes* for more.

Sclerobium setiferum [Leguminosae] – 'palosanto' (McKenna et al. 1995).

Scoparia dulcis [Scrophulariaceae] – 'nuc-nuc pichana'. May be taken alone under diet as a plant teacher (Luna 1984); contains triterpenes, 6-MeO-benzoxazolilinone (McKenna et al. 1995). See *Endnotes*.

Stygmaphyllon fulgens [Malpighiaceae] – 'kai ria'. Leaves sometimes added in the Mitú region to make the drink stronger; contains saponins (Schultes & Raffauf 1990).

Tournefortia angustifolia [Boraginaceae] – 'hetu bisi'. Not actually added to the brew, but amongst the Siona sections of vine are split and infused overnight, the infusion being drunk the morning before an ayahuasca session as a purgative. Leaves of T. cuspidata are made into a tea to relieve trembling in the elderly. Some members of the genus contain pyrrolizidine alkaloids (Schultes & Raffauf 1990).

Tovomita sp. [Guttiferae] – 'chullachaqui caspi'. The jungle spirits known as chullachaqui [an encounter with which may make one ill or insane] are said to live where these trees are abundant (Luna & Amaringo 1991). Taken alone under diet, 2 handfuls of the rasped bark are infused in water overnight (Bear & Vasquez 2000). The diet last 30 days, and the plant reputedly strengthens the body. Taken with ayahuasca, 4 pieces of bark are added to the brew (McKenna et al. 1995).

Triplaris surinamensis, T. surinamensis var. chamissoana [Polygonaceae] – 'tangarana'. Shoots are added in place of **Psychotria**, when leaves of the latter are unavailable. May also be taken alone under diet as a plant teacher (Luna 1984; Trout ed. 1998).

Tynnanthus panurensis [Bignoniaceae] – 'clavohuasca'. Tentatively identified as an additive; considered a plant teacher (Luna 1984).

Vismia guineensis [Guttiferae] – used in ayahuasca made for dancing amongst the Hupda-Maku (Leite da Luz undated); bark and roots have been used both internally and externally to treat skin disorders. Roots have yielded β-sitosterol, anthraquinones and xanthones; the essential oil contains mostly α-*pinene* (Bilia et al. 2000a). In Liberia, the Mano have been reported to "rub the bud [...] between the hands and inhale the fumes for the relief of vertigo" (Watt 1967). Back in the Amazon, the related V. tomentosa is given as a tonic for elderly people who are physically degenerated and have "difficulty in understanding instructions" (Schultes 1993).

Vitex triflora [Verbenaceae] – 'tahuari', 'taruma' (Ott 1995c; Trout ed. 1998). Other Vitex spp. such as V. agnus-castus are used medicinally to treat rheumatism, pneumonia, headaches, respiratory troubles, menstrual problems and bacterial dysentery (Bremness 1994; Chevallier 1996). V. agnus-castus is sometimes used as 'jurema branca' [see **Mimosa**] in Brazil (Ott pers. comm.; Ott 1997/1998). See *Endnotes* for more.

Vouacapoua americana [Leguminosae] – 'huacapu'. Requires special 30-day diet, may be taken alone as a plant teacher (Luna 1984; McKenna et al. 1995); used in magic by the Tiriós (Trout ed. 1998).

The combination of plant chemistry that leads to what is now often referred to as the classic 'ayahuasca-effect' consists of appropriate amounts of harmala-type alkaloids [eg. *harmine*, *harmaline*, *leptaflorine*] with MAOI-activity, and *tryptamine*-alkaloids, particularly *DMT* – both of the broader indole alkaloid group. The harmala-alkaloid source is generally **Banisteriopsis** caapi, and though the harmala-alkaloids inhibit MAO at lower concentrations than their psychoactive levels, the vine is frequently used in larger amounts than necessary, and so the psychotropic and 'experience-modifying' effects of the vine and its alkaloids often also shine through [though also adding to nausea and vomiting]. *Harmine* inhibits MAO efficiently from about 1.5mg/kg; *harmaline* does so from about 1.2-1.32mg/kg [expect personal variations]. The *DMT* source is often **Psychotria** viridis or **Diplopterys** cabrerana. *DMT* needs to be present in the brew at about 1.5-2 times the amount used for smoking purposes – many people find perhaps 40-60mg to be quite sufficient, though some people seem to require much higher quantities [ie. greater than 100mg]. Based on a method tested and suggested by Jonathan Ott (Ott 1994), many people in the west prepare their ayahuasca [or 'ayahuasca analogues'] with a gentle 3-stage decoction [as described in the previous chapter], using a 30% lemon juice/70% water solution [just over enough to cover the plant matter]. The harmala-component and the *DMT*-component are also often prepared separately in non-indigenous preparations – it is recommended that the harmala-component undergoes a longer simmering time than the *DMT*-component [15-20 min. for the former, if done in one go]. The harmala-alkaloid brew should preferably be drunk first, and the *DMT*-brew drunk up to 10-15 minutes later, after giving time for MAO to be inhibited. Results will also be achieved if the extracts are prepared and consumed together, as is traditional, but some believe this may not be as efficient (Callaway et al. 1999; Ott 1994; Trout ed. 1998; pers. comms.). If using **Peganum** harmala seeds as an MAOI substitute for **Banisteriopsis**, efficient filtering of the brew is strongly advised, as small pieces of seed have a tendency to linger in the throat and nasal passages, if vomited back up [which is quite likely!]. These fragments have a particularly nasty taste, which adds an unpleasant dimension to the experience, that can be avoided (pers. obs.).

Although ayahuasca or ayahuasca analogues rich only in *DMT* and harmala alkaloids are generally very safe to consume, special caution is advised when any *5-MeO-DMT* is present. Some people have found this alkaloid, taken orally and combined with MAOI, to be unpredictable and to sometimes result in highly distressing experiences and loss of consciousness (pers. comms.). More disturbingly, there is one known case of a person found dead the morning after having consumed a herbal ayahuasca analogue that contained [based on post mortem blood analysis] harmala alkaloids typical of **Banisteriopsis**, as well as *DMT* and relatively very high levels of *5-MeO-DMT*. However, the actual cause of death was not determinable from the post mortem (Skleroy et al. 2005).

It should be noted that in Amazonia the ayahuasca beverage often uses only **Banisteriopsis**, and that the most common admixture plant is tobacco [see **Nicotiana**] rather than any *DMT*-containing plant. For this reason the so-called 'ayahuasca effect' discussed above is somewhat inappropriately named, and refers to a simplification of the brew most prevalent in non-traditional use.

Zombi potions

In rural Haiti, the zombi phenomenon has long been a part of life, and has only relatively recently been explored from an ethnopharmacological and ethnobotanical/zoological viewpoint. Evidence suggests that people may be made into zombis by members of Vodoun-related 'secret societies' if they have committed severe breaches of social protocol and subsequently deemed by the society as deserving of such a fate [which is believed to be one worse than death]. Zombis are 'created' due to the administration of plant/animal compounds in several phases, accompanied by magical ritual. Powerful sorcerers can reputedly create a zombi with the use of magic alone. The first phase consists of use of the 'poison' or 'trap', which is a powder prepared in various forms. The most widely noted method of applying the poison is to place it in the form of a cross on a doorway or other spot where the intended victim is to walk; however, this could not be expected to allow passage of the poison through the calloused sole of the foot [though the mere sight of it may cause the victim to fall into shock, now being aware of their approaching fate], and if magic alone is not effective then a more direct application may follow, such as blowing the powder into the face or rubbing it into the skin or freshly-made flesh wounds [some common ingredients are abrasive and/or irritating – see below]. Some such powders are intended to kill outright [these may be placed in food to be eaten by the victim]; others cause various kinds of illness; some are used to capture the soul of the victim. Indeed, the process of zombification [as seen by Haitians] essentially consists of capturing the soul of the victim, which is stored in a special jar by the sorcerer responsible, and is itself a kind of zombi – one which is considered to be of more value than a 'mere zombi of the flesh'.

The zombi powders which demand our interest are those which initially cause the victim to appear intoxicated or seriously sick, and later appear to be dead. Sometimes, if the poison was too strong, true death may result – or if not strong enough, the desired effect may not eventuate. Evidence suggests that in this mock-death the victim is still conscious, yet totally paralysed and can not respond to stimuli. Metabolism is lowered to the point where vital signs appear to be absent on cursory analysis. Shortly after a quick burial, the victim is dug up at night by the perpetrators and revived with magical rites and an 'antidote'. At this point, various methods are used to prevent the soul of the victim re-entering the body, and the soul is captured in the previously mentioned jar. Sometimes the revival does not work and the body is found to be truly dead upon exhumation. Different people have their own preferred recipes for the poison and antidote. Although there is no firm documentation on how the zombis are 'created' after this revival, anecdotal evidence suggests that victims are force-fed a paste containing **Datura** stramonium, teasingly known in Haiti as 'concombre zombi' or zombi cucumber. This may also be the actual 'antidote' referred to above, as the potions usually termed antidotes to the zombi poison are apparently only used as a protectant to coat exposed flesh during preparation of the poison. The delirium and amnesia resulting from **Datura** ingestion, coupled with the domineering magic of the sorcerer, the horrifying experience already undergone and cultural-religious conditioning, are believed to help create the final zombified state. However, it must be stated that in Haiti it is believed that powders and other drugs alone can not create a zombi – it is the magic involved which is the most important, and sometimes sole, element. New zombis are given new names and taken to remote localities; sometimes they may be used for slave labour. They must be re-fed the **Datura** paste at regular intervals. Folklore claims that exposure to even tiny amounts of salt may rouse a zombi from its state of amnesiac enslavement. Unfortunately, former-zombis are not accepted in Haitian society and are still regarded as dead and unwanted, even if they are seen in a seemingly recovered state and recognised years after burial.

Plants and creatures used in the powders vary from one practitioner to the next, or depending on the intended result. Ingredients reported to have been included are as follows:

Albizzia lebbeck [Leguminosae] – 'tcha-tcha' fruits. Contains toxic saponins that weaken vital functions; other Albizzia spp. treat epilepsy and nervous complaints [see *Endnotes* for more].
Ameiva chrysolaema [a lizard] – this is burned before being added.
Anacardium occidentale [Anacardiaceae] – 'pomme cajou' leaves. In parts of S. Africa, an intoxicating drink is made from the fruit; contains compounds that can cause severe contact inflammation and irritation. A. occidentale is the well-known 'cashew tree'.
Anolis coelestinus, A. cybotes ['anole lizards'] – see Ameiva chrysolaema.
Bufo marinus [Bufonidae] – 'buga' toad.
Comocladia glabra [Anacardiaceae] – 'bresillet'. A dangerous plant, the resin of which causes severe contact inflammation and dermatitis; it is considered to be evil and malicious.
Dalechampia scandens [Urticaceae] – 'mashasha'. Bears stinging hairs containing *acetylcholine*, *serotonin* and *histamine*.
Dieffenbachia sequine [Araceae] – 'calmador'. Its tissues contain calcium oxalate needles that cause irritation and swelling upon ingestion, causing throat and mouth constriction if absorbed orally. See also D. alba above.
Diodon holocanthus, D. hystrix ['porcupine fish'] – 'poisson fufu', 'bilan'. Contain tetrodotoxin, which is extremely toxic and causes neuromuscular paralysis, and even death [see *Endnotes*].
Epicrates striatus [a lizard] – see Ameiva chrysolaema.
Homo sapiens [human] – burnt grave remains are usually added to the powdered poison [for some discussion of human chemistry see *Neurochemistry*, *Influencing Endogenous Chemistry*].
Leiocephalus schreibersi [a lizard] – see Ameiva chrysolaema.
Mucuna pruriens [Leguminosae] – 'pois gratter' fruits.
Osteopilus dominicensis [a tree frog] – two varieties, 'crapaud brun' and 'crapaud blanc'. The skin is used in small amounts and has irritating glandular secretions [see also **Phyllomedusa** and *Endnotes* for other frogs].
Sphoeroides spengleri, S. testudineus ['sea toad', 'puffer' or 'blowfish'] – 'crapaud du mer'. See Diodon spp. above.
Trichilia hirta [Meliaceae] – 'consigne'. The leaves treat anaemia, asthma, bronchitis and pneumonia; may induce vomiting and sweating.
Urera baccifera [Urticaceae] – 'maman guepes'. See Dalechampia scandens.
Zanthoxylum martinicense [Rutaceae] – 'bwa pine'.

Some of the powders also contain small amounts of various tarantulas and centipedes [see *Endnotes*]. As well as the plants listed above which can irritate and/or blister the skin, ground glass is often added to help break the skin surface so the poison may be readily absorbed. The most important and consistent ingredients amongst the varied recipes noted are

the human remains, and the numerous species of tetrodotoxin-producing fish, which are considered most potent in summer. Tetrodotoxin [discussed further in *Endnotes*] is believed to be responsible for inducing the death-like state observed from administration of active samples of the poison; other ingredients are often not included in quantities that would be expected to be pharmacologically active, but let's not forget the possibility of synergy. In any case, the naturally varying toxicity of such fish is reflected in the varying potencies of zombi powders.

Ingredients reported for the various 'antidotes' include the following:

Aloe vera [Liliaceae] – a laxative and purgative; relieves itching and inflammation. See also Aloe spp. in *Endnotes*.

Amyris maritima [Rutaceae] – 'bois chandelle'.

Capparis cynophyllophora, C. spp. [Capparidaceae] – 'bois ca-ca' ['shit tree'], 'cadavre gate' ['spoiled corpse']. Foul-smelling plants that treat oedema and are believed to have magical properties; they are used to make magical charms. See also Capparis spp. in *Endnotes*.

Cedrela odorata [Meliaceae] – 'cedre'. A tonic that 'realigns various components of the soul', and treats rheumatism and malarial fever; contains c.3% essential oil.

Citrus limon [Rutaceae] – lemons, 'magically prepared'.

Guaiacum officinale [Zygophyllaceae] – 'gaiac franc'. An analgesic and laxative; contains saponins, and an aromatic resin. See *Endnotes*.

Ocimum basilicum [Labiatae] – 'basilic'.

Petiveria alliacea [Phytolaccaceae] – 'ave'. See *Endnotes*.

Prosopis juliflora [Leguminosae] – 'bayahond'.

As stated above, such 'antidotes' [which frequently also contain alcoholic spirits, perfumes and ammonia] are seemingly not used to revive zombis from their mock-death, but predominantly to coat exposed flesh as a protectant during preparation and application of the poison. These antidotes are believed to counteract the effects of the poison, yet due to the recorded ingredients Davis (1988a) stated that they must be pharmacologically inactive for this purpose. He did not, however, report having submitted samples of the antidotes to testing for antagonism of the poison samples collected. The **Datura** paste fed to the victim after removal from the grave may be the actual antidote which helps terminate the first phase and initiate the final phase of zombi creation (Davis 1988a, 1988b).

Sehoere

The Basuto of southern Africa have been reported to employ cast-off horns from their cattle as containers for a composite drug, 'sehoere', which is ritually consumed in conjunction with 'intoxicating feasts' [see **Acacia**, *Endnotes*]. The composition of the sehoere is said to differ, but one informant claimed that the following ingredients have been used:

Cyperus fastigiatus [Cyperaceae] – 'mothoto'

Ipomoea oblongata [Convolvulaceae] – 'mothokho'

Pentanisia variabilis [Rubiaceae] – 'setima mollo'

Phragmites australis root [Gramineae] – 'qoboi'

Phygelius capensis [Scrophulariaceae] – 'mafifi matso'

Polygonum sp. [Polygonaceae; see *Endnotes*] – 'morara o moholo'

Sagittarius serpentarius flesh [Sagitariidae] – 'leshokhoa', 'secretary bird'

Typha latifolia [Typhaceae; see *Endnotes*] – 'motsitla'

Xysmalobium undulatum [Asclepiadaceae] – 'leshokhoa'

Human flesh, derived from 'slain enemies', is also sometimes added. The ingredients are charred and mixed with fat before use. It was also reported that "One of these plants is slightly toxic, and sometimes the Basuto women take advantage of this property for making their beer [see above] more intoxicating. The beer is then called joala ba hiki" (Laydevant 1932). Unfortunately, it was not mentioned which plant was being referred to.

Utopian Bliss Balls

This is a contemporary preparation, which has been a popular psychedelic snack food for several decades.

- **Argyreia** nervosa – 5 seeds
- bee pollen – 1tsp
- **Turnera** diffusa powdered herb – 1 pinch
- dates [Phoenix dactylifera fruit] – 1 fruit
- **Panax** ginseng powdered root – 1 pinch
- **Centella** asiatica powdered herb – 1 pinch

The **Argyreia** seeds are crushed, and ground together with the herbs and bee pollen; this mixture is stuffed into the pitted date, and consumed by one person with tea [see **Camellia**] (Rätsch 1990).

Herbal 'ecstasy', smart drinks and energy drinks

At least a decade ago, a recipe was being freely circulated by word of mouth for a "herbal ecstasy" [referring, of course, to the synthetic MDMA (3,4-methylenedioxy-N-methyl-*amphetamine*), popularly called 'ecstasy']. It is very simple to prepare, as long as you can obtain a good source of *safrole*. All that is required [per person] is ½ a ripe avocado [fruit of Persea americana (Lauraceae) – see *Endnotes*], 2 tablespoons freshly ground nutmeg [see **Myristica**], and about 4 drops of **Sassafras** oil [now difficult to obtain]. The ingredients are mixed together into a paste, which is left to sit for about 10-30 minutes [during which it turns a greyish colour], and consumed – eg. spread on bread and eaten. Of course, nutmeg in quantity tastes foul on its own, and this concoction is only a little bit easier to get down – but once it's down, it stays down. Myself and three friends consumed a dose each one afternoon many years ago, and we all had different responses. One of us noticed effects about 1.5-2 hours after consumption, and was very intoxicated for the next 4-5 hours. Another did not notice anything until about 3 hours later, when he was driving at night, and it came on unexpectedly – his intoxication continued to subside and re-emerge for a few more hours, before rapidly returning to his original state. I had a mild but persistent effect [noticeable after about 2-3 hours] which was potentiated by smoking **Cannabis**. The experience was characterised by a moderate and pleasant CNS stimulation accompanied by positive mood enhancement, enhanced thought-processes and colour perception, and a general feeling of peace, goodwill and confidence. Despite my experiences with nutmeg on its own, none of us experienced any negative side-effects that night, or the next day. It is for this reason that I presume the avocado is present as a lipid-soluble buffer for the digestive system, as many essential oils [as present in this recipe] display liver toxicity and severe gastric upset after internal ingestion.

Many preparations have been available over the past few years claiming to be herbal substitutes for MDMA; some have virtue, others not, though it appears that some people are better able to appreciate the effects of some of these products than others. Common ingredients are **Ephedra** and **Paullinia** cupana; other ingredients which have been used include **Panax** ginseng, **Ginkgo**, **Centella** asiatica, **Cola** nuts, **Corynanthe** yohimbe, **Polygala** tenuifolia, **Glycyrrhiza**, green tea [see **Camellia**], **Maytenus** ebenifolia [mis-spelled as 'ehrifolia'], nutmeg [usually as 'rou gui', a "rare Chinese nutmeg"; see **Myristica**], **Ptychopetalum** spp. ['muira puama'], **Turbina** corymbosa seeds, **Ziziphus** jujuba, **Salvia** miltiorrhiza, **Sida** spp., **Syzygium** aromaticum, **Tribulus** terrestris, Angelica dahurica [Umbelliferae; see *Endnotes*], Carthamus tinctorius [Compositae], Epimedium grandiflorum [Berberideae; see *Endnotes*], Inula japonica [Compositae], Lepidium meyenii [Brassicaceae; see *Endnotes*], Paeonia veitchii [Ranunculaceae; see *Endnotes*], '**Citrus** extract' [actually synephrine] and 'geranium oil extract' [actually a synthetic chemical which is found naturally in small amounts in this oil; see Pelargonium in *Endnotes*] as well as vitamins and amino acids (pers. obs.; Rätsch 1998). Some of these ingredients, and others, are often found in the abundant varieties of 'smart drinks' and 'energy drinks' currently available. Listed ingredients have included **Paullinia** cupana, **Cola** nuts, **Centella** asiatica, **Ginkgo**, **Corynanthe** yohimbe, **Glycyrrhiza**, Tabebuia lapacho [Bignoniaceae; see *Endnotes*], ginger [see *Endnotes*], green tea [see **Camellia**], **Panax** ginseng, **Pueraria** lobata, **Ilex** paraguariensis, kava [see **Piper 2**], **Humulus**, **Theobroma** cacao, **Capsicum**, '**Citrus** extract' [see above], *caffeine*, *phenylalanine*, tyrosine, *taurine*, leucine, *methionine*, inosine, carnitine, proline, *pyroglutamic acid*, *glutamine*, *aspartic acid*, glucuronolactone, glucose, sucrose, fructose, folic acid, calcium, vitamin C [ascorbic acid] and B vitamins (pers. obs.).

I have in my possession a recipe for "Exstacy cake" [sic.], retrieved over a decade ago from an issue of Revelation magazine [based in Western Australia; unfortunately I only had access to the single page it was printed on, and can not give a proper reference for it]. Also, unfortunately, many of the measures/quantities for the ingredients were not given, presumably leaving it up to the intuition of the cook. I have never made one, but according to the creator it "looks like a tropical garden, tastes better than Amadeus' table and gives you pupils like black flying saucers"! The ingredients and method are as follows [with my additional comments]

- Flesh of 1 coconut [Cocos nucifera (Palmaceae)], grated
- juice of 2 limes, and grated skin of 1 [very fresh] [**Citrus**]
- 6-7 ripe peeled bananas [**Musa** spp.]
- 1 well-ground nutmeg [**Myristica** fragrans]
- 1 stick cinnamon [**Cinnamomum** zeylanicum]
- 'little-finger sized' turmeric root, grated [Curcuma longa (Zingiberaceae)] – contains antioxidants
- 20 red and pink Hibiscus spp. blooms [flowers must be fresh, all greenery removed] [see *Endnotes*]
- polenta [from Zea mays; see *Endnotes*]
- sultanas [from Vitis vinifera (Vitaceae)]
- ghee [clarified butter]
- poppy seeds [**Papaver** somniferum]
- cold chamomile tea [**Anthemis**/**Matricaria** sp.]
- rosewater [from Rosa spp. (Rosaceae)] – preferably Lebanese Red [Cortas 'Maward' brand]
- brown rice flour [Oryza sativa (Gramineae)]
- sugar or honey to taste
- 1 cup lecithin [pre-soaked in water]
- 4 drops bitter almond oil [**Prunus** spp.]
- coconut cream [from Cocos nucifera] and/or cold wattleseed coffee [**Acacia** spp.] and/or Japanese tea [**Camellia** sinensis]

Squeeze the lime juice over the bananas, add the nutmeg, turmeric, grated lime skin, grated coconut flesh, and ½ the cinnamon. Squeeze the mass together, and then mix in the hibiscus blooms. Bake this [in a glass

baking dish] in a moderately hot oven for 20 minutes.

To prepare the next layer of the cake, slowly boil up a small pot of polenta with the coconut cream and/or cold wattleseed coffee [and/or substitutes], plus the rest of the cinnamon, a few sultanas, and an extra touch of nutmeg. While the polenta cooks, melt some ghee, pour it into a bowl containing the poppy seeds, cold chamomile tea and rosewater. Mix together, and add enough brown rice flour to make a smooth mixture. When the polenta is cooked, add a bit of sugar or honey and the lecithin; the polenta will become slimy. Add a few more hibiscus petals, followed by the ghee mixture. Stir, and remove base mixture from oven.

Add 4 drops only of the bitter almond oil to the polenta/ghee mix. Spread over the base, slice some banana on top and squeeze over a little lime juice. Cover the baking dish with its lid [or a wet banana leaf, shiny side up, weighted down with empty coconut shells] and bake 15-20 minutes at c.200°C. Remove from oven and add 5 pale hibiscus flowers chopped finely and sprinkled over the top. Add rosewater, cut into small pieces, and serve hot.

A mixture I found effective on several nights as a euphoric inebriant [though not similar to MDMA] was produced by bringing the following ingredients slowly to a boil, simmering for several minutes on lowest heat, and cooling before drinking [with honey added]. Weights are approximate.

- **Alpinia** galanga dried root, 10g
- **Areca** catechu dried nut, 10g
- **Cinnamomum** zeylanicum dried bark, 5g
- **Foeniculum** vulgare dried seed, 4g
- **Glycyrrhiza** glabra dried rhizome, 4g
- **Illicium** verum dried fruit and seed, 4g
- Lycium chinense [Solanaceae; 'Chinese wolfberry'] dried fruit, 5g [see *Endnotes*]
- **Myristica** fragrans dried nut, 2g [1 whole nutmeg]
- **Papaver** somniferum dried leaves, 4g
- **Pimenta** dioica dried fruit, 2g
- Silybum marianum [Compositae; 'milk thistle'] extract equivalent to 7g dry fruit – protects liver from toxicity [see *Endnotes*]
- **Syzygium** aromaticum, a pinch
- and lecithin.

The effects manifested within about 1 hour following consumption [it didn't taste nice], and consisted of CNS stimulation, euphoria and mild sensory distortions, accompanied by mental introspection, lasting about 6 hours.

IF POISONING SHOULD OCCUR

This book can not, unfortunately, provide a thorough guide to the treatment of poisoning, due to the great variety of compounds featured, and their wildly varied natural combinations. I can not over-state the importance of looking before you leap! Ingesting unknown substances can be a highly risky business, as there are many quite toxic and even deadly chemical compounds distributed amongst the natural world. Many of the plants discussed in this book are perfectly safe if used properly. However, others are more toxic, and are accompanied by warnings in the text regarding the potential for death and other, less final, physiological effects. Take note of these warnings, and take care to learn to recognise common plants that can be dangerous. Some of these can closely resemble a less toxic but psychoactive plant to the unwitting plant collector.

It is definitely encouraged to go to your local university library and do your own research. Find out all you can about updates of plant chemistry, explore the toxicity of compounds contained in the plant, and most importantly, find out all you can about the treatment of poisoning. Required action may differ in small but significant ways, depending on which chemical or combination of them has been consumed; while it may be recommended to induce vomiting in one case, such an approach may provoke further disaster in another.

If you think you have been seriously poisoned, take any appropriate immediate action to relieve the poisoning [having done your research beforehand] and have someone get you medical help as soon as possible. This is one reason why it's always good to have someone around when you experiment. It is also a good idea to have, near your telephone, a number to call for poisoning advice. In the case of the classic natural psychedelics, such as **Lophophora**, **Psilocybe**, **Cannabis** etc., if it is all getting too much and you are so paranoid or uncomfortable that you think you have been poisoned, a visit to the emergency ward is exactly what you don't need. Doctors in such places often pump the stomachs of people having 'bad trips' [even though they know such a method will not be effective] just to "teach them a lesson" [in malice?]. Those of the medical profession, generally, do not understand anything about the psychedelic experience, and they will not give you a sympathetic come-down. These natural psychedelic agents just mentioned are relatively non-toxic, and the practical chance of overdose to the point of physical concern with them is so remote as to be almost non-existent.

Still...

Be careful, and good travelling!

PART TWO

The Plants, Fungi and Animals – Entries by Genus

ACACIA

(Leguminosae/Mimosaceae)

Acacia abyssinica *Hochst. ex Benth.* – ol giloriti, ol kiloriti

Acacia acuminata *Benth.* **ssp. acuminata (A. acuminata var. ciliata** *C.F.W. Meissn.***)** - jam wattle, raspberry jam wattle

Acacia acuminata ssp. burkittii *(F. Muell. ex Benth.) Kodela et Tindale* **(A. burkittii** *F. Muell. ex Benth.***; A. randelliana** *W. Fitzg.***)** - fine leaf jam wattle, Burkitt's wattle, sandhill wattle, pin bush, gunderbluey

Acacia albida *Delile.* **(A. gyrocarpa** *Hochst.***; A. saccharata** *Benth.***; Prosopis kirkii** *Oliv.***)** – apple ring acacia, white acacia, white thorn, winter thorn, anaboom

Acacia angustissima *(Mill.) O. Kuntze* **(A. angustifolia** *(Mill.) Kuntze***; A. filiciana** *Willd.***)** – eastern prairie acacia, fern acacia, palo de pulqué, ocpatl

Acacia auriculiformis *A. Cunn. ex Benth.* **(Racosperma auriculiforme** *(A. Cunn. ex Benth.) Pedley***)** – northern black wattle, Darwin black wattle, pale-barked wattle, ear pod wattle, ear-leaf acacia, marra

Acacia bahiensis *Benth.* **(A. tavaresorum** *Rizz.***)** – jurema branca, calumbi difuso, coraco de mulata, espinheiro, pau de ferro, unha de gato [see also **Uncaria** tomentosa]

Acacia baileyana *F. Muell.* **(Racospermum baileyanum** *(F. Muell.) Pedley***)** – Cootamundra wattle, golden mimosa

Acacia berlandieri *Benth.* **(A. tephroloba** *A. Gray***)** – huajillo, guajillo, matorral, membre

Acacia caesia *(L.) Willd.* **(A. intsia** *Willd.***; A. torta** *(Roxb.) Craib.***)** – aila, chilar, karanta, kandam janam

Acacia complanata *Cunn. ex Benth.* **(A. anceps** *Hook., non DC.***; Racosperma complanatum** *(Cunn. ex Benth.) Pedley***)** – long-pod wattle, flat-stemmed wattle

Acacia concinna *(Willd.) DC.* **(A. sinuata** *(Lour.) Merr.***)**

Acacia confusa *Merr.* **(A. richei** *A. Gray***)** – hai hung tou ['red bean from the sea'], hai yuk ['sea medicine'], 'thoughtful tree'

Acacia cornigera *(L.) Willd.* **(A. spadicigera** *Cham. et Schlechtend***)**

Acacia courtii *Tindale et Herscovitch*

Acacia cultriformis *A. Cunn. ex G. Don* **(A. glaucifolia** *A. et N. Baumann ex Meisn.***; A. glaucophylla** *F. Cels***; A. papuliformis** *G. Don***; A. scapuliformis** *A. Cunn. ex G. Don***; Racosperma cultriforme** *(Cunn. ex G. Don) Pedley***)** – knife-leaf wattle, dog-tooth wattle, half moon wattle, golden glow wattle

Acacia difformis *R.T. Baker* – drooping wattle, wyalong wattle, mystery wattle

Acacia farnesiana *(L.) Willd.* **(A. lenticellata** *F. Muell.***; Mimosa farnesiana** *L.***; Popanax farnesiana** *(L.) Raf.***; Vachellia farnesiana** *(L.) Wight et Arn.***)** – jurema branca, sweet acacia, mimosa bush, huisache, stinking bean, cassie, alwek, irlakwe, putunarri, yintiringirningi

Acacia floribunda *(Vent.) Willd.* **(A. floribunda var. latifolia** *Benth.***; A. intermedia** *A. Cunn. ex Hook.***; A. longifolia f. floribunda** *(Vent.) Siebert et Voss***; A. longifolia var. floribunda** *(Vent.) Benth.***; A. retinodes var. floribunda** *(Vent.) H. Vilm.***; Mimosa floribunda** *Vent.***; Racosperma floribundum** *(Vent.) Pedley***)** - gossamer wattle, white sallow wattle, sally wattle

Acacia leucophloea *(Roxb.) Willd.* – hivar, rijua, arjiya, reon, babula-bhed

Acacia longifolia *(Andrews) Willd.* **ssp. longifolia (A. longifolia var. latifolia** *Sweet***; Mimosa longifolia** *Andrews***)** – sallow wattle, Sydney golden wattle, long-leafed acacia

Acacia longifolia ssp. sophorae *(Labill.) Court* **(A. longifolia var. sophorae** *(Labill.) Benth.***; A. longifolia fo. sophorae** *(Labill.) Siebert et Voss***; A. sophorae** *(Labill.) R. Br.***; Mimosa sophorae** *Labill.***; Racosperma sophorae** *(Labill.) Martius***)** – coast wattle

Acacia longissima *Hort. ex H.L. Wendl.* **(A. linearis** *Sims, non. Desv. ex Ham.***; A. linearis var. longissima** *(Hort. ex H.L. Wendl.) DC.***; Racosperma longissimum** *(Hort. ex H.L. Wendl.) Pedley***)** – narrow-leaf wattle

Acacia maidenii *F. Muell.* **(Racosperma maidenii** *(F. Muell.) Pedley***)** – Maiden's wattle

Acacia mellifera *(Vahl) Benth.*

Acacia mucronata *Willd. ex H.L. Wendl.* **(A. longifolia var. mucronata** *(Willd. ex H.L. Wendl.) Benth.***)** – narrow-leaf wattle, variable sallow wattle

Acacia neurophylla *W. Fitzg.*

Acacia nilotica *(L.) Willd. ex Delile* **(A. adansonii** *Guill. et Perr.***; A. arabica** *(Lam.) Willd.***; A. scorpioides** *Wight***; A. vera** *Willd.***)** – scorpion mimosa, Egyptian thorn, sunt, kaarad, gaudi, babul, Indian gum-arabic tree, ol giloriti, ol kiloriti

Acacia nilotica ssp. subalata *(Vatke) Brenan* – ol giloriti, ol kiloriti

Acacia nubica *Benth.* **(A. orfota** *Schweinf.***; A. pterygocarpa** *Hochst. ex Benth.***)** – pelil, wanga, oldepe, gomur

Acacia obtusifolia *A. Cunn.* **(A. intertexta** *Sieber ex DC.***; A. longifolia fo. elongata** *Benth.***; A. longifolia fo. latifolia** *Benth.***; A. longifolia var. obtusifolia** *(A. Cunn.) Benth. ex Seem.***; Racosperma obtusifolium** *(A. Cunn.) Pedley***)** – stiff-leaf wattle, blunt-leaf wattle

Acacia orites *Pedley* **(Racosperma orites** *(Pedley) Pedley***)** – mountain wattle

Acacia phlebophylla *H.B. Will.* **(A. longifolia var. phlebophylla** *F. Muell. ex Benth.***; A. sophorae var. montana** *F. Muell.***)** – Buffalo sallow wattle

Acacia piauhiensis *Benth.* – jurema branca, calumbi branco

Acacia polyacantha *Willd.* **ssp. camplyacantha** *(Hochst. ex A. Rich.) Bren.* **(A. caffra** *(Thunb.)* **var. camplyacantha** *(Hochst ex A. Rich.) Aubrev***; A. camplyacantha** *Hochst ex A. Rich.***; A. catechu** *Oliv. non Willd.***)** – fárcèn karnata ['falcon's claw'], kamboorin shááhòò ['hawk's claw']

Acacia pycnantha *Benth.* **(A. falcinella** *Meisn., non I.F. Tausch***; A. petiolaris** *Lehm.***; A. westonii** *Maiden***)** – golden wattle, broad-leaved wattle

Acacia retinodes *Schltdl.* – swamp wattle, silver wattle, ever-blooming wattle, wirilda

Acacia rigidula *Benth.* – blackbrush

Acacia senegal *(L.) Willd.* **(A. dudgeoni** *Craib ex Holl.***; A. verek** *Guill. et Perr.***; Mimosa senegal** *L.***)** – Egyptian thorn, gum arabic tree, Sudan gum arabic, Somali gum, arabic cape gum, baval, goradia, kher, kumta, mgwara, ol gitende, ol kerdidi, ol derkesi, ol terikesi

Acacia seyal *Del.* – white-galled Acacia, white whistling thorn, buffalo thorn, thirsty thorn, suakim gum arabic, ol jorai, ol jerai, sadra bed, bulbi, ndom, erehi

Acacia seyal *Del.* **var. fistula** *(Schweinf.) Oliv.* – ol jorai, ol jerai

Acacia simplicifolia *(L. f.) Druce et MacBride* **(A. simplex** *(Sparrman) Pedley***)** – tatagia

Acacia victoriae *Benth.* **(A. coronalis** *J.M. Black***; A. decora var. spinescens** *Benth.***; A. hanniana** *Domin.***; A. sentis** *F. Muell.***; Racosperma victoriae** *(Benth.) Pedley***)** – elegant acacia, elegant wattle, bramble acacia, bramble wattle, prickly wattle, arlep, tuperle, urlepe, pulkuru, narran, ngatunpa, aliti, kanaparlku, yalupu, yarlirti, gundabluie

Acacia spp. – wattles [many of the African Acacia spp. have a huge array of colloquial names, and only a small selection is listed here]

Note: although the 'leaves' of non-bipinnate Acacia spp. are technically referred to as phyllodes, for overall simplicity they will be called leaves below, as they look like leaves and serve the same functions. The species with phyllodes, rather than pinnules [Acacia subgenus Phyllodineae], have been reclassified into a separate ge-

nus, Racosperma. Some of these (from Butcher et al. 2001 and Pedley 1987) are listed above. However, the proposal doesn't seem to have taken hold with the majority of wattle-lovers and other botanists, who continue to refer to them all as Acacia.

The wattles are a large group of trees and shrubs found mostly in Australia and Africa, where they flourish due to their tolerance of dry conditions and ability to restore fertility to the soil. Many African wattles, with their high, flat canopies are a familiar sight on the savannahs, and are much loved by elephants and giraffes as food.

The wattle with the most extensive cultural history is A. senegal – its wood was used in building the Jewish tabernacle [possibly A. seyal instead] (Duke 1983), and its branch in flower was used to symbolise the sacred word of the Hebrews. A sprig placed in the turban is said to ward off evil, and the wood is burned in sacred fires in India. The tree has been associated with several deities – Ishtar [goddess of love and war], Diana [or Artemis – goddess of fertility, nature and the moon], Ra [sun god and guide of the worlds], and Osiris [god of fertility and resurrection] (Cunningham 1994; Jordan 1992). In Nigeria and Senegal, a mistletoe [see *Endnotes*] growing parasitically on A. senegal is infused and taken as a body-wash or in other ways, to give "quick, clear vision" as a magical hunting aid (Burkill 1985-1997). It is well known that mistletoes often absorb the phytochemicals of the host plant [see also **Duboisia**]. The resin from the tree, known as 'Gum Arabic' [a.k.a. 'white sennar gum', 'kordofan gum'], is used in sweets, inks, fabric printing, to add shine to silk, and as a thickener for artist's paints. It has been used to treat burns, inflammations, dysentery, gonorrhea and other complaints, also acting as a demulcent and emulsifier. It was once also extracted from A. nilotica [as A. arabica], and similar gums have been extracted from A. laeta and A. seyal ['suakim gum arabic']. A. catechu is the source of 'catechu' or 'cutch' [see also **Uncaria**], a disinfectant and antiinflammatory gum sometimes chewed with betel nuts [see **Areca**, *Methods of Ingestion*] (Bremness 1994; Gowda 1951; Morton 1977), and used medicinally for its astringent properties. It is extracted from the inner bark by water decoction, which is then concentrated, and poured into moulds to dry (Felter & Lloyd 1898).

A. tortilis was said by the Bedouins to be the original 'tree of knowledge' (Shulgin & Shulgin 1997). A. polyacantha ssp. camplyacantha is regarded as an aphrodisiac in the Belgian Congo. In Senegal the root bark is macerated in water for a day and drunk to combat fatigue, lumbago and rib-pains. Also in Senegal, the powdered root of A. seyal is taken with the dried ventral portion of a fat hedgehog as an aphrodisiac; the gum and bark are also believed to be aphrodisiac (Burkill 1985-1997; Duke 1983; Watt & Breyer-Brandwijk 1962).

In Africa, A. ataxacantha root is macerated in water with **Securidaca** longepedunculata and Capparis tomentosa, and taken to treat hernia, sores and wounds. The leaf is analgesic, and contains an alkaloid. A. nilotica has been used in Sudan for many medical ailments, such as colds, bronchitis, diarrhoea, haemorrhage, dysentery and syphilitic lesions. The fruit has antibacterial actions. Also, the Masai take a decoction of the stem bark and root to acquire courage – it acts as a nerve stimulant, aphrodisiac and 'intoxicant'. The Masai make such use of a variety of plants [see also *Endnotes*] to make them aggressive and strong, characters for which Masai warriors are renowned. These same plants may also be used as stimulants for dancing. The plants may be taken in a number of ways, but one method regularly observed has been the consumption of a water infusion of barks and roots, along with meat that had been cooked with an extract of the same or similar plants. Milk is not to be consumed on the same day, as dysentery may apparently result. Depending on the need [a more demanding battle or raid requiring greater preparation], such stimulant-feasts may continue for up to a month or more. Acacia spp. included have been A. abyssinica [roots], A. nilotica, A. nilotica ssp. subalata, A. senegal, A. seyal [bark], and A. seyal var. fistula. One researcher [S.L. Hinde] reported in 1901 that "when the warriors are preparing to go on the war-path, or even in their war-dances, many of them chew the bark of the mimosa tree [probably an Acacia sp. – Ed.], the properties of which are supposed to endow the partaker with strength and courage. Some of the men become raving mad from the effects of the bark, and others fall into a comatose condition". Used under similar circumstances these Acacia spp. have also been said [by D. Storrs-Fox] to "produce a fierce and unbalanced state of mind" (Burkill 1985-1997; El Nabi et al. 1992; Lehmann & Mihalyi 1982). Bark decoctions of A. nilotica ssp. subalata have been reported to have intoxicating and aphrodisiac effects, and the root is used to treat impotence. In Tanganyika, A. mellifera has also been reportedly cooked with meat and eaten as a stimulant. A. mellifera var. detinens is believed to affect the weather, by the Tlhaping, who say that it attracts lightning, and that cutting one of the trees down after the first rains have fallen will result in bad weather. The hooked thorns of the stems are believed to "have the power of enticing and detaining the 'weather spirit'" (Watt & Breyer-Brandwijk 1962).

Some Australian aboriginal tribes use selected Acacia spp. [such as A. aneura, A. beauverdiana, A. calcicola, A. coriacea, A. estrophiliata, A. hakeoides, A. homalophylla, A. kempeana, A. ligulata, A. pruinocarpa, A. salicina and A. saligna] to produce a fine, alkaline ash for chewing with tobacco [see **Nicotiana**] or pituri/pitcheri [see **Duboisia**], to aid in alkaloid release. The part used is usually either the leaf, bark or twigs, varying from species to species. In the Lake Eyre district, A. salicina used for ash production is often itself called 'pitcheri'. Here, the young branch tips [up to 23cm long] were cleaned of damaged and diseased growth. To make the ash, the tips "were tied in bundles, ignited over the fire and then allowed to burn out while held over a wooden bowl" (Aiston 1937; Bindon 1996; Johnston & Cleland 1933; Latz 1995; Low 1990; Peterson 1979).

A. aneura wood is sometimes made into spear-heads; it is said to contain toxic compounds, and thus causes dangerous wounds. The roasted, ground seeds are an important and nutritious food. Mature seeds of A. murrayana were roasted and used as a coffee substitute [see **Coffea**] by early European settlers. Bark of A. falcata, as well as bark and leaves of A. penninervis, have been used to stun fish, as have the bark and twigs of A. melanoxylon [in the Lismore region of NSW]. The latter species has been suspected of poisoning stock, and the wood is thought to cause dermatitis. In the Fitzroy River region of Queensland, A. salicina bark is used as a fish poison. Branches of A. holosericea have also been so used. A. pulchella and A. verniciflua have also been used as fish poisons, but the parts used were not reported (Hurst 1942; Latz 1995; Low 1990).

The boiled young leaves, shoots and seeds of many wattles are edible [wattle seed is often made into a nutritious bread], and the roots can be tapped for water; they are also used to treat a variety of ailments (Bindon 1996; Latz 1995; Maslin et al. 1998). Root shavings of A. georginae have been used as a tea substitute [see **Camellia**] (Latz 1995). In n. Australia, the Ngarinyman heat leaves and branches of A. lysiphloia on hot coals, and apply them to sore muscles or joints as an analgesic (Smith et al. 1993). An infusion of the leaves and pods of A. auriculiformis is used as an analgesic wash, to relieve body pains (Low 1990). In Groote Eylandt, a species which is probably A. pellita is used for the same purpose. Its heated leaves are also applied to the forehead for headaches. Excited and uncontrollable children are sometimes held head-down in smoke from the burning young leaves, to quieten them (Bindon 1996; Levitt 1981).

Aboriginal use of wattles in sacred contexts is common in many parts of Australia. A. peuce is often featured in mythology from central Australian indigenous groups. A. dorotoxylon [A. ammobia] is an important plant in the mythology of the Pitjantjatjara, who use its seed as food. The leaves of A. aneura, another food-provider, have been used as a mat on which sacred objects are placed. In central Australia, secret male rituals are conducted to ensure the proliferation of A. murrayana seed, which is an important food. A. ligulata is of ritual and spiritual importance to Warlpiri women, and the leaves are used in smoking ceremonies to treat a wide variety of illnesses. In northern Australia, crushed leaves of A. estrophiliata are smouldered in smoking ceremonies, to drive away evil spirits. A. dictyophleba, A. pruinocarpa and A. lysiphloia leaves are used as 'smoking medicines' in northern Australia, for newborn babies and their mothers. A. ligulata is also used for 'smoking medicine' (Aboriginal Communities 1988; Bindon 1996; Hurst 1942; Latz 1995; Low 1990).

A. cornigera is sometimes used in the preparation of 'balché' [see **Lonchocarpus**, *Methods of Ingestion*] by traditional Mayans, and the Maya of San Antonio, Belize, drink a tea of the root as an aphrodisiac. A. angustissima and A. albicans roots were probably once added to Aztec 'pulqué' brews [alcoholic beverages prepared from Agave spp. – see *Methods of Ingestion*], presumably to enhance the effects. In Brazil, A. bahiensis, A. farnesiana and A. piauhiensis are known as 'jurema branca' [see **Mimosa**, **Pithecellobium**], though it is unknown whether they are actually used ritually as the name would suggest (Ott 1995b, 1997/1998, pers. comm.; Queiroz 2000; Rätsch 1998).

In India, the gum of A. nilotica is fried in ghee [clarified butter] and taken as an aphrodisiac (Nadkarni 1976). The seeds have also been fermented with dates to make a beverage (Usher 1974). The tree is considered sacred and holy in India, and is thought to be the home of the spirit of a Mohammedan saint. No one is allowed to cut them down, and offerings are made to them for good luck (Trout ed. 1997b, citing Majupuria 1988. Religious and Useful Plants of Nepal and India. Publ. M. Gupta, India). Also in India, A. farnesiana is used to treat insanity, delirium, epilepsy, convulsions, cholera, carbuncles and rabies; in Algeria it is used as an aphrodisiac and insecticide. A flower infusion is known to be stimulant, aphrodisiac and antispasmodic; essential oil from the pods is sedative, aphrodisiac, muscle-relaxant and cardiac-sedative. The essential oil from the flowers, 'cassie oil', is a popular scent, particularly in France (Nadkarni 1976; Trout ed. 1997b; West & Brown 1920). In Fiji, a bark decoction of A. simplicifolia is used as a purgative, and a cold leaf drink treats stomach ache (Cambie & Ash 1994).

Wattles are becoming better known now for their alkaloid contents. Traditionally used for their tannin content in tanning leather [from species such as A. pycnantha] in Australia, many species have been shown to yield alkaloids of the *tryptamine*, *phenethylamine*, imidazole and pyrrolidine classes. However, perhaps due to the finding of *DMT* in some species, alkaloid analyses of Australian Acacia spp. have not been published in any recent years. Despite this, independent researchers have since succeeded in discovering new visionary species that have not undergone formal analysis for alkaloids. These discoveries have in some cases result-

ed from misidentification, and in some cases from intuitive exploration. Some species also contain cyanogenic glycosides and have poisoned stock animals, so much care should be taken with chemically unknown species. Australian species known to be cyanogenic include A. bineura, A. cheelii, A. deanei, A. dorotoxylon, A. farnesiana, A. glaucescens, A. longifolia and A. oswaldii; others include A. giraffae, A. lasiopetala, A. robusta, A. stolonifera and A. tortilis ssp. heteracantha. Flowers, but not leaves, of A. borrowi produced hydrocyanic acid [HCN]. A. roemeriana and A. berlandieri have been reported to be cyanogenic from a field test, though subsequent work was not able to find any HCN. The cyanogenic glycoside usually present in S. African Acacia spp. is acacipetalin; in Australian species, it is usually sambunigrin. Many Acacia spp. are also regarded as toxic due to their content of tannins, acids such as fluoroacetic acid, and neurotoxic amino acids such as djenkolic acid [in seeds] (Conn 1973; Conn et al. 1989; Culvenor 1970; Hungerford 1990; Watt & Breyer-Brandwijk 1962). Acacia spp. also contain a variety of flavonoids in their heartwoods, which have proven useful indicators in chemotaxonomy (Clarke-Lewis & Dainis 1964; Clarke-Lewis & Porter 1972; Tindale & Roux 1969, 1974), as have the free amino acids present in the seeds (Evans et al. 1977).

Australian Acacia spp. known to have edible seeds [ie. those that have been used as such by native peoples] include A. acuminata, A. aneura, A. ayersiana, A. baileyana, A. beauverdiana, A. burkittii, A. brachystachya, A. confluens, A. coriacea ssp. sericophylla, A. craspedocarpa, A. cuthbertsonii, A. dictyophleba, A. dorotoxylon, A. estrophiolata, A. farnesiana, A. holosericea, A. inaequilatera, A. jennerae, A. kempeana, A. ligulata, A. linophylla, A. macdonnelliensis, A. maitlandii, A. microbotrya, A. murrayana, A. notabilis, A. olgana, A. omalophylla, A. oswaldii, A. pachyacra, A. palustris, A. pruinocarpa, A. pycnantha, A. ramulosa, A. retinodes, A. rivalis, A. salicina, A. saligna, A. sclerosperma, A. stenophylla, A. tetragonophylla, A. tysonii, A. victoriae and A. xiphophylla. Seeds from some species are simply eaten raw, whilst others are cooked before consumption. Sometimes the unripe pods are steamed and eaten whole. Although seeds of A. cowleana are sometimes eaten raw [after grinding to a paste with water], damper made from them has the reputation of causing headache (Bindon 1996; Maslin et al. 1998).

When identifying Acacia spp., it is worth noting that closely related species have been known to interbreed, which may complicate both matters of chemistry and positive identification. Also, apparently many Australian Acacia spp. have yet to be identified (New 1984). Results of analyses below reported by White (1944a, 1944c, 1951, 1954, 1957) were all performed on plants growing in New Zealand. White (1944a) noted that high concentrations of *phenethylamine* tended to be found only in species with uninerved leaves, and flowers in racemes [an exception to this is A. acinacea]. Species rich in this alkaloid also tended to contain it in moderate quantity in the ripe seed pods (White 1951).

A. acinacea stems and leaves yielded 0.04-0.07% alkaloids in Feb., 0.79-0.82% in Dec.; ripe seed pods yielded 0.08% alkaloids; seeds contained 0-traces of alkaloids. The alkaloid mixture consisted largely of *phenethylamine* (White 1951).

A. acuminata ssp. acuminata yielded 0.72% alkaloids from stems and leaves, and ssp. burkittii yielded 1.5% [both harv. Oct.]; this appeared to consist mostly of *tryptamine*, as well as smaller amounts of an unidentified *phenethylamine*-like base, and another unidentifed non-volatile base (White 1957). In an alkaloid screening, leaves of a plant from a nursery in Geelong, Vic. [Australia] gave strong positive results (CSIRO 1990). Recent TLC/GCMS analysis found ssp. acuminata leaves to contain 0.6-0.8% *DMT*, and up to 1.6% in bark; young leaves contained almost entirely *tryptamine*. On the other hand, ssp. burkittii was very variable in content, with bark of wild plants yielding 0.2-1.2% *DMT*, and leaves yielding under 0.1% alkaloids, mostly *NMT* (Jeremy 2007).

A. adunca [A. accola] stems, leaves, and flowers [harv. Aug.] yielded 3.2% alkaloids, which appeared to consist of c.70% N-methyl-*phenethylamine*, with smaller amounts of *phenethylamine* (White 1957); leaves from Qld. [Australia] yielded 2.4% N-methyl-*phenethylamine* (Fitzgerald 1964a).

A. albida leaf has been stated to yield *DMT* (Shulgin & Shulgin 1997), but this is in error. Traces of *5-methoxy-DMT* [*5-MeO-DMT*] were tentatively identified in twigs [harv. Oct.], as well as possibly *N-methyltryptamine* [*NMT*] (Trout ed. 1997d). Seeds contain large amounts of albizziine, with lesser amounts of α-amino-β-acetylaminopropionic acid, α-amino-β-oxalylaminopropionic acid, αβ-diaminopropionic acid, djenkolic acid, pipecolic acid [homoproline; 2-piperidinecarboxylic acid] and 4-OH-pipecolic acid (Evans et al. 1977).

A. angustissima leaves have yielded 0.028% N-methyl-*phenethylamine* (Camp & Norvell 1966); roots tested tentatively positive for *DMT* and *5-MeO-DMT* [harv. Mar.], though a second test was negative. Traces of *5-MeO-DMT* were also tentatively detected in seeds. There exists one report of the use of roots [presumably in an ayahuasca analogue] giving some psychoactivity; others consuming the same material did not report any effects (Trout ed. 1997d). The whole shrub also yielded 7,3',4'-trihydroxyflavonol (Clarke-Lewis & Dainis 1967).

A. argentea [A. leptostachya] leaves have yielded 0.03-0.6% N-cinnamoyl-*histamine* (Fitzgerald 1964b).

A. auriculiformis leaves have tested positive for alkaloids (Aboriginal Communities 1988); others have tentatively identified *5-MeO-DMT* in stem bark [harv. Apr.] (Trout ed. 1997b). Bark also contains a mixture of polyphenols which are mostly polymeric leuco-cyanidins and leuco-delphinidins, which turn red on exposure to light. Heartwood yielded 10% (-)-teracacidin, and lesser amounts of other flavonoids (Drewes & Roux 1966). Aerial parts have yielded α-spinasterol and 0.01% auriculoside [a flavan glycoside with mild CNS-depressant activity] (Sahai et al. 1980); funicles have yielded triterpenoid saponins called acaciasides A & B, with antifilarial activity (Ghosh et al. 1993). Fruit pericarps have yielded triterpenoid saponins with spermicidal activity, including acaciaside, proacaciaside-I, proacaciaside-II and acaciamine (Garai & Mahato 1997). Seeds contain large amounts of albizziine, with lesser amounts of S-carboxyethylcysteine, S-carboxyethylcysteine sulphoxide and α-amino-β-acetylaminopropionic acid (Evans et al. 1977).

A. baileyana [from Australia], growing in California [foothills of Santa Cruz Mts, Woodside], yielded [from the leaves] 0.02% alkaloids in late March [80% *tetrahydroharman*, 20% *tryptamine*], and 0.028% in early Oct. [*tryptamine* only]; July collections yielded no alkaloids (Repke et al. 1973). Stems, leaves, flowers and seeds from plants growing in New Zealand [harv. Mar., Aug.] were shown to contain small amounts of alkaloids (White 1944a). Bark and heartwood contain flavonoids (Tindale & Roux 1969). Seeds contain large amounts of albizziine and S-carboxyethylcysteine, with lesser amounts of S-carboxyethylcysteine sulphoxide, S-carboxyisopropylcysteine, 4-OH-pipecolic acid, 5-OH-pipecolic acid, pipecolic acid, djenkolic acid, djenkolic acid sulphoxide and α-amino-β-acetylaminopropionic acid (Evans et al. 1977); others have found in the seeds what was tentatively identified as *DMT* and 2 other indoles in small amounts (Trout ed. 1997b). Ripe and unripe pods have yielded c.0.02% unidentified alkaloids, with ripe and unripe seeds showing only traces (White 1951).

A. berlandieri has been responsible for stock intoxications, called 'guajillo wobbles' or 'limberleg', in Texas, which has been said to be due to the main alkaloid, N-methyl-*phenethylamine* (Camp & Norvell 1966; Keeler 1975; Kingsbury 1964). In one study, leaves yielded 0.28-0.66% of this alkaloid, with highest levels in May, and lowest in September (Camp & Moore 1960). Others found *tyramine*, N-methyl-*tyramine*, and *hordenine* to also be major alkaloids in the leaves (Adams & Camp 1966). In a more recent analysis, fresh leaves, petioles and tender stems were shown to have highest alkaloid concentrations [including a greater number of methylated analogues] in late autumn. Material yielded a large number of alkaloids, including some never before found in plants [ie. *amphetamine*s]. Constituents identified were [% given as early spring; late autumn] – N-methyl-*phenethylamine* [0.17; 0.374], N,N-dimethyl-*phenethylamine* [0.0099; 0.06], *phenethylamine* [0.099; 0.139], 3,4-dimethoxy-5-OH-*phenethylamine* [0.001; 0.0041], β-MeO-3,4-dihydroxy-5-MeO-*phenethylamine* [-; 0.003], *amphetamine* [0.0003; 0.001], *methamphetamine* [0.002; 0.001], N,N-dimethyl-*amphetamine* [0.0046; 0.023], p-OH-*amphetamine* [0.0008; 0.0007], p-MeO-*amphetamine* [4-MA – see *anethole*] [-; 0.0036], 3,4-dimethoxy-5-OH-*amphetamine* [0.0002; 0.0047], *tyramine* [0.037; 0.13], N-methyl-*tyramine* [0.0188; 0.0746], 3-MeO-*tyramine* [0.0003; 0.0015], 3,5-dimethoxy-*tyramine* [0.0003; 0.0034], *hordenine* [0.0009; 0.033], candicine [-; c.0.0035], *dopamine* [0.0004; 0.0025], N-methyl-*dopamine* [0.0002; 0.0011], *mescaline* [0.0005; 0.0036], trichocereine [-; 0.0028], anhalamine [0.0005; 0.004], anhalidine [0.0003; 0.0041], peyophorine [0.0003; 0.0047], *nicotine* [0.004; 0.011], *nornicotine* [0.002; 0.0072], mimosine methyl ester [0.0011; 0.0024], nortryptiline [0.002; 0.0071], 3-α-cumyl-1,3,4-oxadiazolidine-2,5-dione [0.031; 0.042] and musk ambrette [0.0027; 0.0027] (Clement et al. 1997). However, the validity of this research data is currently under question. Some of the compounds claimed to have been identified with comparison to reference standards had never been reported as having been synthesised before and have never before been found in nature, and the authors have made themselves unavailable for comment. These doubts also apply to the results published by the same authors regarding A. rigidula, discussed below (Shulgin pers. comm.; Trout pers. comm.).

A. buxifolia stems and leaves [harv. Dec.], from a variety slightly different than the norm, yielded 0.65% alkaloids; seeds yielded 0.09% alkaloids; pods yielded 0.58% alkaloids. The alkaloid mixture appeared to consist largely of *phenethylamine* (White 1951).

A. caesia bark has yielded *tryptamine* and *DMT*-N-oxide (Ghosal 1972; Ghosal et al. 1970b). An ethanol-extract of the aerial parts was hypothermic, and had unspecified actions on the CNS, and respiratory and cardiovascular systems (Trout ed. 1997b, citing Bhakuni et al. 1973. Indian J. Experimental Biol. 11:43-54).

A. cardiophylla stems, leaves, and flowers [harv. Oct.] yielded 0.03% alkaloids; stems and leaves yielded 0.02-0.06% alkaloids [highest in Mar.]. The alkaloid mixture appeared to contain *tryptamine* and *phenethylamine* (White 1957). In an alkaloid screening, leaves and stems from Mitcham, Vic. [Australia] gave negative results (CSIRO 1990).

A. catechu bark extract may contain c.60% tannins, including catechutannic acid, catechuic acid, and catechin; the gum contains sugars such as d-galactose, d-rhamnose, l-arabinose, and l-glycuronic acid (Nadkarni

1976; Watt & Breyer-Brandwijk 1962). The plant has also yielded taxifolin, a flavonoid with antiinflammatory, antioxidant, antihepatotoxic, antibacterial, antiviral, antifungal (Harborne & Baxter ed. 1993), analgesic and anti-oedema properties (Cechinel-Filho et al. 2000). The gum has been claimed to contain *mitraphylline*, roxburghine D, and gambirine (Huang 1993). However, I could not locate a primary reference for these alkaloids occurring in Acacia, and this was most likely in confusion with 'pale catechu' [derived from **Uncaria** gambir or U. rhynchophylla].

A. complanata dried leaves and stems from s. Queensland [Australia] yielded 0.3% N-methyl-*tetrahydroharman*, and traces of *tetrahydroharman* (Johns et al. 1966b). Alkaloid screening detected 0.22% alkaloids in leaf and stem (CSIRO 1990).

A. concinna leaf has yielded 2.1% *nicotine* [w/w] and 1.2% calycotomine [d/w] (Gupta & Nigam 1971).

A. confusa is said to be poisonous, but is widely used in Chinese medicine. It is an introduced species in Hong Kong, where it is used as a muscle relaxant, and to treat blood disorders. Dried stems yielded 0.074% alkaloids, c.20% being *DMT*, with 80% *NMT*; 0.017% β-sitosterol was also obtained (Arthur et al. 1967); trunk bark yielded *NMT*, as well as an unidentified *tryptamine* alkaloid that did not appear to be *DMT* (Lou et al. 1965). Root bark yielded 2.85% alkaloids [44.75% *DMT*, 55.25% *NMT*] (Liu et al. 1977). Unspecified parts [probably mixed aerial parts] yielded 0.005% *DMT*, 0.009% *DMT* N-oxide, 0.006% *NMT* and 0.007% N-chloromethyl-*DMT*, a new alkaloid which is probably an artefact of extraction (Buchanan et al. 2007). Dried leaves yielded 0.014% taraxerol, 0.027% lupeol (Arthur et al. 1967), and the flavonoids myricetin 3-O-(2"-O-galloyl)-α-rhamnopyranoside, myricetin 3-O-(3"-O-galloyl)-α-rhamnopyranoside 7-methyl ether, and myricetin 3-O-(2",3"-di-O-galloyl)-α-rhamnopyranoside (Lee, T.-H. et al. 2000). Bark and heartwood extracts have shown antioxidant free radical-scavenging activity, probably due to phenolic compounds (Chang et al. 2001). Seeds have been shown to contain large amounts of albizziine, with lesser amounts of S-carboxyethylcysteine, S-carboxyisopropylcysteine, α-amino-β-acetylaminopropionic acid, α-amino-β-oxalylaminopropionic acid, djenkolic acid, 4-OH-pipecolic acid, and 2,4-cis-4,5-trans-dihydroxypipecolic acid (Evans et al. 1977).

A. constricta leaves yielded 0.02% alkaloids, including what was tentatively identified as N-methyl-*phenethylamine* (Camp & Norvell 1966).

A. courtii, closely related to A. orites [see below], has been found by TLC/GCMS to contain up to 2% alkaloids in the bark, mostly or entirely *DMT*, and up to 1.2% in leaves, again mostly or entirely *DMT*. As this species is relatively rare with a restricted range, efforts at cultivation should be made rather than harvesting from wild plants (Jeremy 2007).

A. cultriformis leaf and stem yielded 0.07% alkaloids in Feb., 0.06% in Apr.; an August assay found 0.02% alkaloids in stems, 0.02% in leaves and 0.04% in seeds. The alkaloids appeared to include *phenethylamine* (White 1944a). Stems and leaves from two separate plants [harv. Dec.] yielded traces and 0.02% alkaloids, respectively, and unripe seed pods yielded 0.04% alkaloids; this appeared to consist mainly of *tryptamine* (White 1951). Stems and leaves [harv. Jul.] yielded 0.02% alkaloids, consisting partly of *tryptamine*, and a *phenethylamine*-like base (White 1957). Independent TLC analysis showed tentative presence of *5-MeO-DMT* in leaves, twigs and flowers (Trout ed. 1997b, pers. comm.).

A. cunninghamii [A. trinervata] gave positive tests for HCN (Hurst 1942). Leaf harvested in June [from Miles, Qld] tested positive for alkaloids, as did bark harvested in November [Warwick, Qld]. Other assays produced inconclusive results (Webb 1949). The plant has been the subject of some interesting bioassays. "The extract of one unripe pod of A. cunninghamii injected hypodermically into the arm of a person caused great pain, swelling and redness of the injected spot, as well as nausea and shivering; the extract of two pods caused headache, skin irritation, paralysis of the accomodation of the eye and mydriasis. It is beyond doubt that the juice of six wattle pods, hypodermically injected, will kill a man. Injected into the leg of a frog it caused total loss of sensibility and paralysis of muscles." The unripe pods have yielded 3% of a saponin which causes irritation and local anaesthesia, and acts as a "strong poison for the muscles and nerves". The saponin was found in smaller amounts in other green plant parts (Hurst 1942). The oral toxicity of the saponin is not known, though saponins are, in general, known to have irritant and/or caustic properties.

A. delibrata [from Australia] also contains a saponin in its pods, with similar properties to that from A. cunninghamii (Hurst 1942).

A. difformis leaves tested tentatively positive for presence of traces of *DMT*, and roots for *5-MeO-DMT* [2 year old plants]; roots from the next year did not contain any detectable *5-MeO-DMT*, though stems did [tentatively identified] (Trout pers. comm.).

A. farnesiana stem bark has yielded *tryptamine* (Ghosal 1972); others have found no alkaloids in leaf, stem bark, root bark, seed or flower (CSIRO 1990; Fong et al. 1972; Trout ed. 1997b). The green fruit has tentatively been shown to contain small amounts of *5-MeO-DMT* and an unidentified β-carboline (Trout ed. 1997b). The flower essence has yielded up to 30.9% methylsalicylic ester, as well as many other compounds, including *eugenol* [some found none], *methyleugenol*, butyric acid, geraniol, benzyl alcohol, benzaldehyde, anisaldehyde, p-cresol and OH-*acetophenone* (Schimmel & Co. 1904; Trout ed. 1997b, citing Duke 1981. Handbook of Legumes of World Economic Importance. Plenum Press, NY).

A. floribunda tops [harv. Apr.] yielded 0.18% alkaloids, consisting mostly of *tryptamine*, with traces of *phenethylamine*; flowers [harv. Sep.] yielded 1.18% alkaloids [0.82% from an undated harvest], consisting of +- equal quantities of *tryptamine* and *phenethylamine* (White 1944c); flowers [harv. Oct.] yielded 0.15-0.98% alkaloids; leaves yielded 0.07-0.08% alkaloids; stems yielded 0.04-0.19% alkaloids; stems and leaves combined yielded 0.06-0.16% alkaloids (White 1944a); bark has yielded traces of an alkaloid that was not identified (White 1951). It may be that the techniques used by White were not good for identifying *DMT*, as this commonly cultivated species has recently been found to be a good source of that alkaloid. Using TLC/GCMS, leaves were found to contain mostly *DMT* [usually less than 0.1%]; bark yielded up to c.1% alkaloids, with 0.3-0.5% *DMT*, slightly less *NMT*, and small amounts of *tryptamine*, *harman* and *norharman* (Jeremy 2007).

A. greggii leaves yielded 0.016% alkaloids, including what was tentatively identified as N-methyl-*phenethylamine* and *tyramine* (Camp & Norvell 1966).

A. hakeoides was reported to contain *phenethylamine* (White 1944a), but the plants analysed were later determined to have been A. praetervisa [see below, as A. prominens] (White 1951).

A. harpophylla leaves from Queensland [Australia] yielded 0.1-0.6% alkaloids [*phenethylamine* and *hordenine* in a 2:3 ratio], with 0.3% alkaloids in bark (CSIRO 1990; Fitzgerald 1964a). Bark from branchlets [harv. Jun.] tested strongly positive for alkaloids, though bark of the stems tested negative (Webb 1949).

A. holosericea bark [harv. near Mackay, Qld] has yielded 1.2% *hordenine* (Fitzgerald 1964a); plants from Lotus Creek, Qld yielded 1.22% alkaloids from the bark, and leaves and stems gave weak positive reactions for presence of alkaloids (CSIRO 1990). In another screening, leaves, bark and root of A. holosericea tested negative for alkaloids (Aboriginal Communities 1988).

A. implexa roots were tentatively reported to contain *5-MeO-DMT* (Trout ed. 1997b), but this was in error (Trout pers. comm.). Leaf material harvested in November [from Mt. Lindsay and Warwick, Qld] tested moderately to strongly positive for alkaloids, whilst bark tested negative. Immature fruits were also alkaloid-positive. December-harvested leaf [from Mt. Glorious, Qld] gave mostly negative results (Webb 1949). In a later screening, leaves gave only weak-positive reactions (Rovelli 1967). The unripe seed pods have been implicated in stock deaths and illness (Hurst 1942).

A. kettlewelliae leaves and stems yielded 1.3% alkaloids in Apr. and 1.88% in Oct., which appeared to consist of more than 92% *phenethylamine*, with no *tryptamine* (White 1957); leaves from Creswick, Vic. [Australia] yielded 0.9% N-methyl-*phenethylamine* (Fitzgerald 1964a).

A. laeta has been stated to contain *DMT* in the leaves (Shulgin & Shulgin 1997), but this is in error (Trout ed. 1997d).

A. leucophloea root bark has yielded *tryptamine* (Ghosal 1972), as well as the diterpenoids leocoxol, leucophleol and leucophleoxol (Rojas et al. 2001). The bark is aphrodisiac and demulcent; an alcohol-extract of aerial parts was CNS-depressant and hypotensive. The plant is known to be cyanogenic (Trout ed. 1997b, citing Indian J. Exp. Biol. 9:91 [1971], Indian Vet. J. 54:748 [1977] and J. Res. Indian Med. 8:67 [1973]).

A. linifolia stems and leaves were reported to contain *phenethylamine* (White 1944a), but the plants analysed were later found to have been A. prominens. Stems, leaves, and flowers [harv. Apr., Sydney (Australia)] yielded 0.03% of an alkaloid that was not identified (White 1951). Stems and leaves from Sydney plants contained "insignificant concentrations of alkaloid" in Oct. (White 1957).

A. longifolia ssp. longifolia growing naturalised in California has yielded the *histamine*-amides N-(2-imidazol-4-yl-ethyl)-trans-cinnamamide and N-(2-imidazol-4-yl-ethyl)-deca-trans-2,cis-4-dienamide. Respectively, leaves [harv. late Jan.] yielded 0.0038-0.004%/0.0225-0.024%, leaves [harvested Mar.] yielded 0.0067%/0.027%, bark [harv. late Jan.] yielded 0.015%/0.0175%, and pods [harv. at maturity in Jul.] yielded 0.09-0.17%/0.06-0.112%. Seeds [harv. Jul.] and flower spikes [harv. in Mar., fresh] contained traces of these two compounds (Repke 1975). Tops from plants growing in New Zealand [harv. Nov.] yielded 0.12% alkaloids [c.1% was obtained from tops (I suspect this assay may have actually been on flowers) with an unspecified harvest time]; flowers [harv. Sep.] yielded 0.186% alkaloids. In both, *phenethylamine* was identified as a minor constituent, and though *tryptamine*-like bases seemed to be present, *tryptamine* itself was not detected (White 1944c), except in some samples of flower spikes (White 1951). Tops and flowers combined have yielded up to 0.01% *phenethylamine*; in one sample, it only comprised 9.2% of the total alkaloids. Stems and leaves collected at various times in New Zealand yielded 0.02-0.29% alkaloids; there was no clear correlation between yield and month of harvest. From an Oct. harvest, stems yielded 0.15% alkaloids, leaves 0.06%, and flowers 0.14-0.29% (White 1944a). Bark [harv. Apr.] yielded 0.03% alkaloids; seeds yielded 0.01%

alkaloids (White 1951). Material from Victoria [Australia] was reported to contain N-methyl-*tyramine*, *hordenine*, *NMT*, N-formyl-*NMT*, N-methyl-*tetrahydroharman*, 2-methyl-THβC, N-cinnamoyl-*histamine*, 3-OH-dec-2-enoyl-*histamine*, and other *histamine*-amides (Nichols 1983). However, this data was referenced to Rovelli (1967), which only reported finding *histamine*-derivatives in the leaves [from 0.2% total crude alkaloids] of Australian-grown plants [location not specified]; no indoles were reported from this species (Rovelli 1967). This species has been reported to yield *DMT* (Harborne et al. ed. 1971), possibly confused with A. phlebophylla [as A. longifolia var. phlebophylla]. However, independent psychonauts have verified that at least some examples of this species can be useful as an entheogen. Up to 0.2% *DMT* [as well as what may be *tryptamine*] has reportedly been obtained from unspecified parts, with highest yields in winter (E 1996; E pers. comm.). Also, in 1995, a friend succeeded in obtaining what seemed to be *DMT* from the bark of A. longifolia ssp. longifolia from Eltham, Vic. [Australia]. This was successfully smoked by six people (pers. comm.). A. longifolia ssp. longifolia bark has also yielded up to 18.9% tannin, the leaf yielding smaller amounts. Leaves have also yielded hydrocyanic acid (Hurst 1942; Watt & Breyer-Brandwijk 1962); naringenin [5,7,4'-trihydroxyflavonol] has also been found in flowers [0.12%] and leaves (Clarke-Lewis & Dainis 1967; White 1957). Seeds contain large amounts of albizziine, with lesser amounts of S-carboxyethylcysteine, S-carboxyisopropylcysteine, S-carboxyethylcysteine sulphoxide, djenkolic acid, djenkolic acid sulphoxide, γ-glutamyldjenkolic acid, pipecolic acid, 4-OH-pipecolic acid, 5-OH-pipecolic acid, and α-amino-β-acetylaminopropionic acid (Evans et al. 1977). Found in SA, NSW, and Victoria [Australia].

A. longifolia ssp. sophorae growing in California has been claimed to have yielded *DMT*, *5-MeO-DMT*, *bufotenine*, *gramine* and cinnamoylhistamine [as well as other *histamine*-derivatives] at levels of 0.6% in bark, and 0.15% in leaves, in an elusive unpublished analysis (E 1996; E pers. comm.); *DMT* was apparently a minor alkaloid in both bark and leaf in these assays (Trout pers. comm. quoting D. Siebert). A. longifolia ssp. sophorae from Victoria [Australia] was reported to contain N-methyl-*phenethylamine*, *tyramine*, N-methyl-*tyramine*, *NMT*, *DMT*, *tetrahydroharman*, N-methyl-*tetrahydroharman*, 2-methyl-THβC, N-cinnamoyl-*histamine*, N-decadienoyl-*histamine*, 3-OH-dec-2-enoyl-*histamine*, other *histamine*-amides, and *nicotine* (Nichols 1983). However this was referenced to Rovelli (1967), who only reported finding *histamine*-derivatives in leaves from plants growing at Mentone, Vic. [0.1% crude bases in May, 0.03% in Jan.] (Rovelli 1967). A form of A. longifolia close to ssp. sophorae yielded 0.15% crude alkaloids from unripe pods, 0.07% from stems and leaves [harv. May], and none from seeds (White 1944a). Alkaloid screening in Australia revealed strong presence of alkaloids in the leaf (CSIRO 1990). Found in eastern Australia [SA, NSW, Vic. and Tas.].

A. longissima has yielded useful tryptamine alkaloids in some assays (E pers. comm.). Plants from Springbrook, Queensland, yielded 0.25% alkaloids from leaves, and 0.02% from bark; the identity of the alkaloid/s was not reported (CSIRO 1990). Less than 0.01% alkaloids were detected in stems and leaves [harv. Jul., Oct.], and seeds (White 1944a).

A. maidenii is a variable species, which has sometimes been confused with A. obtusifolia in the wild (E pers. comm.; Mulga pers. comm.). Bark yielded 0.36% *DMT*, and 0.24% *NMT* (Fitzgerald & Sioumis 1965), though a later screening found a slightly higher yield of 0.71% total alkaloids. Bark extracted for pharmacological testing yielded 0.13% alkaloids, consisting of *DMT* and *NMT*. Given orally to rats, the extract was active from 100mg/kg; 250mg/kg produced convulsions. In mice, presence of convulsions was not noted even at 500mg/kg [oral]. In cats, 10mg/kg [oral or i.p.] caused "acute bewilderment and a marked fear complex when approached." In anaesthetised cats, 0.5mg/kg [route of administration not noted] showed respiratory depressant and cardiotoxic activity; in anaesthetised dogs, 0.1-0.5mg/kg [i.v.] was cardiotoxic (CSIRO 1990). Younger trees are said to give best yields (E 1996). Others have had little success with obtaining *DMT* from this plant, due to quite variable yields. The common form with broader, more falcate phyllodes appears to be +-deficient in alkaloids. The leaves of useful varieties are said to sometimes contain greater levels of alkaloids (pers. comms.; Mulga undated); in an early alkaloid screening, the phyllodes gave a strong-positive reaction (Rovelli 1967). Leaf and bark harvested from Tamborine, Qld [Australia] in June tested strongly positive for alkaloids (Webb 1949). Roots have tested strongly positive for *NMT* [major constituent] and *DMT*; wood tested weakly positive for *5-MeO-DMT*; and twigs tested positive for *5-MeO-DMT* [all tentative identifications] (Trout ed. 1997b). Heartwood yielded the flavonoids teracacidin and 7,8,4'-trihydroxyflavonol, as well as (+)-pinitol, L-pipecolic acid, trans-4-OH-L-pipecolic acid, L-proline and 4-OH-L-proline (Clarke-Lewis & Dainis 1967). It is found in Qld, NSW and isolated areas of Vic., Australia.

A. mellifera leaves have been stated to contain *DMT* (Shulgin & Shulgin 1997), but this is in error (Trout ed. 1997d).

A. mucronata var. longifolia leaf appears to contain *DMT* and probably other alkaloids (E pers. comm.); in a formal alkaloid screening, alkaloids were detected in the leaf of A. mucronata var. dissitiflora, and also of an unspecified variety of the species [which gave a slightly stronger reaction] (CSIRO 1990; Rovelli 1967).

A. myrtifolia leaf and stem yielded 0.76% crude bases, including (-)-acacine [a new spermidine alkaloid], and traces of unidentified alkaloids (Nichols 1983). Alkaloid yield did not vary seasonally, in plants from the Dandenong Ranges [Vic., Australia] (Rovelli 1967). Stems and leaves from Sydney, Australia [harv. Apr.] did not yield any alkaloids (White 1951).

A. neurophylla hybridises with A. acuminata, and is represented by two subspecies - ssp. neurophylla and ssp. erugata. The former is very variable, and some specimens may represent new species or subspecies. Plants from the A. neurophylla complex were found [by TLC/GCMS] to contain mostly *DMT* in the bark, with leaves containing mostly *harman* and *norharman*, with traces or no *DMT* (Jeremy 2007).

A. nilotica has been said to contain *DMT* in the leaves (Ott 1993; Shulgin & Shulgin 1997), though this may have been in error as Ott (1994) later retracted the statement. Leaves, stem bark, roots and seeds have all tested negative for alkaloids (Odebiyi & Sofowora 1978). Others have stated that the leaf has yielded *tryptamine* and *leptaflorine* (Oliver-Bever 1986), yet this is suspect. Stems, roots, and leaves have tentatively tested positive for the presence of traces of *5-MeO-DMT*. Seeds have tentatively tested positive for the presence of *DMT*, *NMT* and *5-MeO-DMT*, though later tests did not confirm this (Heffter 1996; Trout ed. 1997b, pers. comm.). Immature fruits of plants growing in Queensland [as A. arabica; harv. Dec.] tested positive for alkaloids (Webb 1949). The seeds contain large amounts of N-acetyldjenkolic acid, with lesser amounts of djenkolic acid, djenkolic acid sulphoxide, N-acetyldjenkolic acid sulphoxide, pipecolic acid and 4-OH-pipecolic acid (Evans et al. 1977). An aqueous extract of the seeds showed spasmogenic, vasoconstrictive, and hypertensive effects in animal studies (Amos et al. 1999); a methanol extract of the pods showed antispasmodic and antihypertensive effects in animals (Gilania et al. 1999), and a water extract was antimicrobial (El Nabi et al. 1992). A. nilotica is found in Sudan, Egypt, India and Australia [NT, SA and Qld]; A. nilotica ssp. indica is also found in Australia (International... 1994; Parsons & Cuthbertson 1992).

A. nubica dried leaves [harv. in Sudan, late Nov.] yielded 0.0016% *DMT* (Khalil & Elkheir 1975).

A. obtusifolia is a variable Australian species which has sometimes been confused with A. maidenii, A. longifolia ssp. longifolia and A. orites in the field (pers. comms.). Bark has yielded 0.15% alkaloids, though their identities were not reported (CSIRO 1990); in n.e. NSW, 0.15-0.2% has typically been isolated (E pers. comm.), though others have achieved higher yields of 0.4-0.5%. Fresh young leaves yielded c.0.07% alkaloids (Mulga undated); dried leaves from different locations have yielded 0.15-0.3% alkaloids. Bark has been used in ayahuasca analogues, and extracted for freebase alkaloids. Preliminary TLC analysis of one bark extract revealed the presence of at least 5 alkaloids, including what was very tentatively identified as *DMT*, *5-MeO-DMT*, and *bufotenine*. At some times of year, plants from the same patch yielded an extract seemingly comprised of *DMT* and a larger quantity of *NMT*. A great deal of variation in alkaloid composition has been observed [based on subjective experiences and limited TLC analysis], seemingly influenced by a complex range of factors including time of harvest, rainfall, soil composition, and possible hybridisation. Definite correlations betwen alkaloidal composition and these factors have not yet been determined (E pers. comm.). In one array of extracts, a summer extract was orange in colour, whereas a winter extract was dark brown, although there was further variation between colour and season that suggests it's not that simple. Initial analysis found the orange summer extract to contain traces of *bufotenine* and the dark winter extract to contain more, though a second analysis found none (Trout 2005). A recent, more accurate analysis of stem bark extract by HPLC/MS found *DMT* as the major alkaloid by far, with traces of *tryptamine*, possibly *NMT*, and unidentified β-carbolines; no *5-MeO-DMT* or *bufotenine* was observed (Mulga 2005). Another analysis [TLC/GCMS] using plants from various sources also found no *5-MeO-DMT* or *bufotenine*. In general, bark contained up to 1.4% alkaloids - mostly *DMT*, with lesser amounts of *NMT*, *tryptamine*, *harman* and *norharman*; leaves contained mostly *NMT*, with lesser amounts of *DMT* (Jeremy 2007). Heartwood has yielded the flavonoids melacacidin, isomelacacidin, teracacidin, isoteracacidin, and 7,8,4'-trihydroxyflavonol, as well as (+)-pinitol and an unidentified leuco-anthocyanidin (Clarke-Lewis & Dainis 1967).

A. orites has on occasion been confused with A. obtusifolia and A. longissima [see above], and is suspected of being useful for shamanic purposes (pers. comms.; pers. obs.). Some underground researchers have reported obtaining alkaloids that might be β-carbolines (E pers. comm.).

A. phlebophylla leaves [harv. May] gave a strongly positive result in alkaloid screening; "leaves and tops" harvested later, in August, yielded 0.3% *DMT* as apparently the sole alkaloid [or at least the major alkaloid by far] (Rovelli 1967; Rovelli & Vaughan 1967). A recent TLC/GCMS analysis found leaves to contain up to 0.6% *DMT*, though youngest growth was much less potent; bark contained up to 1% *DMT*, though bark harvesting of this species is not sustainable (Jeremy 2007). Others have reported yields of 0.1-1% *DMT* from leaves (Julian pers. comm.). Most of the natural population has been heavily and adversely affected by

galling caused primarily by a rust fungus, Uromycladium sp. (Heinze et al. 1998), though a recent extensive bushfire at Mt. Buffalo appears to have destroyed the infected material, and the species is currently regenerating well. This Victorian species is also rare and may be considered threatened, and successful cultivation is often difficult. Wild specimens should preferably be left unmolested, particularly given the poor health of most of the current population of mature trees. Careless wandering throughout its natural range might also possibly aid in spreading the galling fungus to areas previously unaffected. In the past, however [at least in my case, when I was not aware of these factors apart from that of the limited range of the species], myself and others have successfully used this plant in ayahuasca analogues, with c.20g dried leaves and stems [harv. late Jan.] being a moderate [but still very strong] dose, accompanied with c.3g **Peganum** harmala seeds (pers. obs.; see also Ott 1994). Interestingly, the closely related A. alpina, which looks somewhat like a dwarf A. phlebophylla and grows in the same area but at higher altitude, gave a negative result in alkaloid screening of the leaves (Rovelli 1967).

A. podalyriaefolia bark from Ipswich, Qld [Australia] yielded 0.12% alkaloids; stems and leaves yielded 0.28% alkaloids (CSIRO 1990); stems and leaves [harv. Feb.] yielded 0.11% alkaloids, which appeared to contain *phenethylamine* (White 1944a); stems and leaves [harv. Nov.] yielded 0.29% alkaloids, which appeared to consist mainly of *tryptamine*, with smaller amounts of *phenethylamine* (White 1957); stems and leaves collected after flowering yielded 0.11% alkaloids, consisting mostly of *tryptamine*, with no *phenethylamine* (White 1951); seeds and pods yielded 0.11% alkaloids, also consisting mainly of *tryptamine*, with smaller amounts of *phenethylamine* (White 1957).

A. polyacantha ssp. camplyacantha dried leaves [harv. in Sudan, late Nov.] yielded 0.004% *DMT* (Khalil & Elkheir 1975). Leaves also contain the flavonoids rutin and vicenin 2 (International... 1994).

A. polystachya bark yielded 0.35% N-cinnamoyl-*histamine* (Fitzgerald 1964b).

A. pravissima stems [harv. Aug.] yielded 0.13% alkaloids; leaves [harv. Aug.] yielded 0.31% alkaloids; stems and leaves combined [harv. Mar.] yielded 0.44% alkaloids. This appeared to consist largely of *phenethylamine* (White 1944a). Tops [harv. Jan.] yielded 0.69% crude alkaloids, consisting mostly of *phenethylamine* (White 1954).

A. prominens [A. praetervisa] stems and leaves yielded 0.2-0.65% alkaloids [highest found in Aug. and Dec.]; stems and leaves separately [harv. Aug.] yielded 0.17% alkaloids each; seeds yielded 0.04% alkaloids. *Phenethylamine* appeared to be the major alkaloid (White 1944a, 1951). Stems and leaves from both a small and a large tree yielded 0.23% and 0.25% alkaloids, respectively [harv. Aug.]; this consisted of c.50% *phenethylamine* and c.20% N-methyl-*phenethylamine* (White 1957). Flowering tops of a horticultural variety yielded 1.8% alkaloids, consisting mostly of what was tentatively identified as *phenethylamine* and N-methyl-*phenethylamine*. Other samples of tops yielded 1.11-2.38% crude alkaloids. Both types varied in which alkaloid was predominant at different times, though no definite correlations could be determined (White 1954).

A. pruinosa tops have yielded 0.04% alkaloids, consisting mostly of *tryptamine*, with small amounts of *phenethylamine* (White 1944c); stems and leaves [harv. Feb.] yielded 0.03% alkaloids; stems and leaves [harv. May] yielded 0.09% alkaloids; stems and leaves [harv. Oct.] yielded 0.02% alkaloids (White 1944a); stems, leaves and flowers [harv. Aug.] yielded 0.02% alkaloids (White 1957); stems and leaves [harv. Dec.] yielded 0.02% alkaloids; no alkaloids were found in seeds or unripe pods (White 1951).

A. pycnantha is Australia's national floral emblem. A crude alkaloid extract was obtained in very small yield from the dried leaves. The extract smelled like *DMT*, and although the small quantity was not sufficient to determine its identity, it was psychoactive when smoked. The effect was similar to that of a sub-threshold dose of *DMT*. This has not yet been followed up with further extractions (pers. obs.). Less than 0.01% alkaloids were detected in leaves and stems [harv. Apr.], and stems, leaves and flowers [harv. Sep.] (White 1944a). An alkaloid screening did not reveal the presence of alkaloids in the leaf of the 'weeping variety'. A tannin, butein, has been found in the plant (Rovelli 1967).

A. retinodes has reportedly yielded *nicotine* (Nichols 1983 refers to Fikenscher 1960. Pharmaceutisch Weekblad 95:233-235, which I have been unable to locate; the Chemical Abstracts citation [see Bibliography] does not name the species analysed). Leaves of plants from Berwick, Melbourne [Vic., Australia] gave a small yield of a single major alkaloid which did not correspond with *nicotine*; also, leaves of plants from Cape Schanck, Mornington Peninsula [Vic., Australia] gave a very low yield of an alkaloid that could not be identified in comparison to the reference standards [which were *phenethylamine*, *hordenine*, *NMT*, *DMT*, *tetrahydroharman* and N-methyl-*tetrahydroharman*] (Rovelli 1967). Stems and leaves [harv. Apr.] and seeds were found to contain <0.01% alkaloids (White 1944a); in another assay, stems, leaves, bark, ripe and unripe seeds, and unripe pods contained no alkaloids (White 1951).

A. rigidula leaves in early tests yielded 0.025% alkaloids, consisting of a mixture of what was tentatively identified as N-methyl-*tyramine* and N-methyl-*phenethylamine* (Camp & Norvell 1966); more exhaustive study of fresh leaves, petioles, and tender stems revealed [% given as early spring; late autumn] *DMT* [0.032; 0.057], *NMT* [0.0005; 0.0055], *tryptamine* [0.00008; 0.0021], *phenethylamine* [0.087; 0.11], N-methyl-*phenethylamine* [0.23; 0.53], N,N-dimethyl-*phenethylamine* [0.012; 0.072], 3-OH-4-MeO-*phenethylamine* [0.0016; 0.016], N-methyl-3-OH-4-MeO-*phenethylamine* [0.0019; 0.018], *DMPEA* [0.0001; 0.0006], N-methyl-*DMPEA* [0.0008; 0.0028], 3,4,5-trihydroxy-*phenethylamine* [0.0002; 0.0013], N-methyl-3,4,5-trihydroxy-*phenethylamine* [0.00003; 0.0002], 3,4-dimethoxy-5-OH-*phenethylamine* [0.0016; 0.0057], β-MeO-3,4-dihydroxy-5-MeO-*phenethylamine* [0.0005; 0.0022], *tyramine* [0.046; 0.17], N-methyl-*tyramine* [0.024; 0.17], 3-MeO-*tyramine* [0.0002; 0.0013], N-methyl-3-MeO-*tyramine* [0.0003; 0.0028], *dopamine* [0.0009; 0.0036], N-methyl-*dopamine* [0.00005; 0.0008], N,N-dimethyl-*dopamine* [0.0011; 0.0045], *mescaline* [0.0003; 0.0027], N-methyl-*mescaline* [0.0002; 0.0035], trichocereine [0.00002; 0.0014], *hordenine* [0.0006; 0.053], *amphetamine* [0.0007; 0.0012], *methamphetamine* [-; 0.0012], N,N-dimethyl-*amphetamine* [0.0058; 0.039], p-OH-*amphetamine* [0.0002; 0.0007], p-MeO-*amphetamine* [4-MA – see *anethole*] [-; 0.0016], 3,4-dimethoxy-5-OH-*amphetamine* [0.0005; 0.006], anhalamine [0.001; 0.0049], anhalidine [0.0006; 0.005], *anhalonidine* [0.0002; 0.0016], peyophorine [0.0004; 0.004], *nicotine* [0.0046; 0.015], *nornicotine* [0.0023; 0.0084], pipecolamide [0.087; 0.098], p-OH-pipecolamide [0.024; 0.035], 1,4-benzenediamine [0.01; 0.013], 4-methyl-2-pyridinamine [0.034; 0.057], 2-cyclohexylethylamine [0.00008; 0.0035] and N-2-cyclohexylethyl-N-methylamine [0.0001; 0.0047] (Clement et al. 1998). See A. berlandieri above for comments on the doubtful validity of this data.

A. roemeriana leaves yielded 0.036% alkaloids, including what was tentatively identified as N-methyl-*phenethylamine*, *tyramine*, and N-methyl-*tyramine* (Camp & Norvell 1966).

A. schottii leaves contained an alkaloid tentatively identified as N-methyl-*phenethylamine* (Camp & Norvell 1966).

A. senegal leaves [harv. Sudan, late Nov.] yielded 0.003% *DMT* (Khalil & Elkheir 1975); an ethanol-extract of the stem bark showed spasmolytic and anti-inflammatory properties (Trout ed. 1997b, citing Indian J. Exp. Biol. 15:208 [1977]). Gum from the branches contains mainly salts of arabic acid [arabin], as well as an oxidising enzyme (Morton 1977).

A. seyal and A. sieberiana have been stated to contain *DMT* in their leaves (Shulgin & Shulgin 1997), though this is in error (Trout ed. 1997d); the latter species contains the cyanogenic glycosides heterodendrin, proacaciberin and proacacipetalin in leaves and pods, as well as 1-O-(2-methylbutyryl)vicianose, a 1-O-(2-methylbutyryl)disaccharide, and its isomer (Brimer et al. 1980).

A. simplicifolia stem bark and leaf yielded 3.6% alkaloids, consisting of 22.5% *DMT*, 40% *NMT*, 12.7% 2-methyl-THβC and small amounts of N-formyl-*NMT* (Poupat et al. 1976). It is found on some Pacific Islands, as well as in Argentina (International... 1994).

A. spectabilis leaves and stems yielded 0.21-0.35% alkaloids, consisting of 60-72% *phenethylamine*, with traces of a non-volatile base, and no *tryptamine*; leaves and bark [harv. Jun.] were rich in alkaloids (White 1957).

A. spirorbis [from New Caledonia] fresh root bark [harv. Mar.] yielded 0.15% alkaloids, including N-cinnamoyl-*histamine* [0.024%]; fresh trunk bark [harv. Mar.] yielded 0.06% alkaloids, including N-cinnamoyl-*histamine* [0.025%] and *hordenine* [0.007%]; leaves yielded 0.02% alkaloids, including N-cinnamoyl-*histamine* [0.019%]. A maceration of the trunk and/or root bark is used to treat rheumatism, and leaves are used to treat malaria (Poupat & Sévenet 1975).

A. suaveolens stems and leaves yielded 0.7-0.89% alkaloids; stems [harv. Sep.] yielded 0.07% alkaloids, leaves 0.69%, seeds 0.01%, and unripe seed pods 0.05-0.17%. Stems, leaves, and flowers [harv. Apr., Sydney (Australia)] yielded 0.97% alkaloids. The alkaloid mixture in all cases appeared to consist mainly of *phenethylamine* (White 1944a, 1951). Tops [harv. Nov.] yielded 1.1% crude alkaloids, consisting mostly of *phenethylamine* (White 1954).

A. texensis leaves yielded 0.008% alkaloids, including what was tentatively identified as N-methyl-*phenethylamine* and *tyramine* (Camp & Norvell 1966).

A. tortilis has been stated to contain *DMT* (Ott 1993), though this is in error (Trout ed. 1997b), and Ott (1994) later retracted the statement.

A. ulicifolia whole plant yielded 0.0166% ether-soluble tertiary alkaloids, which may be phenolic amines. In mice, 500mg/kg [oral] and 100mg/kg [i.p.] caused CNS-depression, with no observable effect at lower doses – double these doses were fatal (CSIRO 1990).

A. vestita stems and leaves gave different alkaloid yields at different times – 0.03-0.04% [Jan.], 0.28% [May], 0.08% [Jul.-Aug.], and 0.12% [Oct.]; this consisted of up to 83% *tryptamine*, with traces of a non-volatile base (White 1957).

A. victoriae has tentatively tested positive for *DMT* in aerial parts, and *5-MeO-DMT* in roots (Trout ed. 1997b). Alkaloid screening of leaf and stem was negative in spot tests (CSIRO 1990), though Rovelli (1967) obtained a weak-positive reaction with the leaves (Rovelli 1967). Aerial parts and seed pods contain triterpenoid saponins called avicins, which have

antioxidant and anticancer activities (Hanausek et al. 2001; Haridas et al. 2001).

In broad alkaloid screenings, a number of other Australian Acacia spp. were found to contain alkaloids which were not identified – A. amblygona [leaf and stem; only detected in some tests], A. aneura [0.009% in leaf], A. angusta [0.08% in leaf and stem], A. aulacocarpa [leaf harv. Jul., weak-positive; none in Jan. harvest], A. bakeri [leaf and stem], A. beauverdiana [leaf and stem], A. conferta [leaf harv. Jul., weak-positive], A. cowleana [leaf], A. dealbata [<0.01% in leaf and stem harv. Nov., seeds; weak-positive in leaf harv. Jun.], A. deanei [leaf and stem], A. decora [leaf harv. Jun.; traces in stem and leaf harv. Mar., Apr. & Oct.], A. decurrens [<0.01% in stem and leaf harv. May; 0.02% in stem and leaf harv. Feb.; none in stem and leaf harv. Dec.; weak-positive in leaf. harv. Jun.], A. doratoxylon [0.06% in leaf and stem], A. drumondii [<0.01% in leaf and stem harv. Feb., none in leaf and stem harv. Aug., or in flowers], A. elata [<0.01% in stem and leaf harv. Mar. & Nov., seeds; traces in unripe pods, none in bark or unripe seeds], A. estrophiliata [leaves], A. excelsa [leaf and stem], A. falcata [<0.01% in leaf and stem harv. May; traces in leaf and stem harv. Apr. & Dec., stem leaf and flower harv. Jul., and ripe seeds and pods; another assay of leaf in Jul. gave no alkaloids], A. fimbriata [leaf and bark, harv. Mar.], A. flexifolia [traces in stem, leaf, and flower harv. Jul.], A. gilbertii [leaf], A. gonophylla [leaf], A. howittii [reported incorrectly as A. vestita; <0.01% in stem and leaf harv. Feb.-May; no alkaloid in other assays of stem, leaf, ripe seeds, and pods], A. ixiophylla [leaf, harv. Jun.], A. juncifolia [0.008% in leaf], A. juniperina [leaf and stem harv. Nov., strong-positive], A. kybeanensis [leaf], A. latipes [leaf], A. leichhardtii [0.007% in leaf and stem], A. leiocalyx [leaf and stem], A. leiophylla [leaf], A. leprosa [<0.01% in stem and leaf harv. Feb., stem leaf and flower harv. Sep.], A. leptocarpa [0.09% in leaf; some tests negative], A. linearis [leaf], A. lunata [leaf harv. Jun., strong-positive], A. lysiphloia [leaf], A. maitlandii [leaf], A. mangium [leaf and bark], what may have been A. mearnsii [as A. decurrens var. mollis; <0.01% in seeds, 0.02% in stem, leaf and flower harv. Oct., none in galls], A. melanoxylon [young leaf; samples of mature leaf from other locations were negative; <0.01% in stem and leaf harv. Apr. & Aug.; 0.03% in ripe pods, none in bark or seeds], A. neriifolia [1.3% in leaf, 1.2% in bark], A. nervosa [leaf], A. oxycedrus [0.16% in leaf and stem], A. paradoxa [0.01% in tops; as A. armata, plants in New Zealand gave no alkaloid from stem and leaf harv. Mar., or stem, leaf and flowers harv. Oct., though ripe pods contained traces], A. pendula [leaf, not in bark in some tests], A. penninervis [leaf and bark harv. Jun., leaves gave stronger reaction], A. rhodoxylon [leaf and stem], A. rupicola [traces in stem, leaf and flower harv. Jul.], A. salicina [leaf harv. Jun., weak-positive; has also given negative results], A. saligna [<0.01% in stem and leaf harv. Feb.; traces in stem and leaf harv. Apr., as A. cyanophylla], A. semilunata [leaf], A. shirleyi [identity uncertain; leaf harv. Jun.], A. simsii [0.03% in leaf], A. stenoptera [leaf], A. stricta [<0.01% in stem and leaf harv. Feb. & Aug., also in seeds; another assay found none in stem, leaf, flowers, ripe seeds, or pods], A. terminalis [as A. discolor; 0.03% in stem, leaf and flower harv. Feb.; traces in stem and leaf harv. Apr.-May, traces in flower spikes], A. tetragonophylla [root bark; leaf was negative], A. torulosa [leaf, not in bark], A. triptera [leaf and branches harv. Jun.], A. umbellata [0.013% in leaf], A. urophylla [leaf], A. verniciflua [traces in stem and leaf harv. Feb.; another Feb. harv. gave no alkaloids], A. verticillata [<0.01% in flowers, leaf and stem harv. Sep.; none detected in bark], and A. viscidula [leaf and stem harv. Nov.] (Aboriginal Communities 1988; CSIRO 1990; Rovelli 1967; Webb 1949; White 1944a, 1951, 1957).

Acacia obtusifolia is an erect, glabrous shrub to small tree, 1-5m tall; branches rigid; branchlets +- angular, becoming terete, striate, reddish. Phyllodes dark green, rather thick and leathery, glabrous, 8-20cm x 7-25mm, narrow oblong-elliptic, flat and coriaceous, straight, margins uneven, often minutely glandular-resinous, reddish, apex obtuse, (1-)2(-3) prominent longitudinal nerves, secondary nerves finely branching [anastomosing] between, becoming raised when dry; pulvinus 2-3mm long; gland small, 5-10mm above the pulvinus; young phyllodes reddish. Inflorescence of pale to creamy yellow flowers scattered on 1-several spikes 3-7cm long in the axils; peduncles 5-7mm long, glabrous; flowers 4-merous; sepals partly united, lobes triangular and often ciliate; petals partly united, glabrous, apex keeled; ovary pubescent. Seed pod a legume, linear, 5-9(-15)cm x 4-7mm, thick-walled, subcylindrical, straight or slightly curved, not becoming twisted, attenuate at both ends. Seeds longitudinal in pod, funicle folded several times into a large aril. Fl. late Nov.-Feb.

Common in coastal forest and tablelands of NSW, extending to c.w. slopes and to n.e. Vic. and s.e. Qld.; in Eucalyptus spp. forests and woodlands, in higher rainfall areas of coastal mountains (Costermans 1992; Tame 1992).

Rarely fruits, self-propagates mainly from suckers (Entwistle et al. 1996); however, others dispute this and have observed this species to fruit readily (E pers. comm.). Germinate seeds by scarification, followed by soaking in water for a few hours; plant in well-drained, moist germination medium. Enjoys an open, sunny, well-drained position; fertilise with granite or rock dust. Hardy once established, cold-tolerant (Floyd pers. comm.).

A. longifolia ssp. longifolia and A. longifolia ssp. sophorae, once considered separate but closely related species, can sometimes be very difficult to tell apart, as they intergrade imperceptibly in some populations, and can also interbreed. They can usually [but not always] be distinguished from each other by a number of features. Proportions of leaf length to width on main stems are the easiest differences to observe in the field. In one examination, A. longifolia ssp. longifolia ranged from [5-]9.4-12[-20] x [0.5-]1.2-1.5[-1.9]cm; A. longifolia ssp. sophorae ranged from [5-]5.7-8.6[-12] x [1-]1.25-2.9[-3]cm. Leaves of A. longifolia ssp. longifolia are usually widest near or below the middle, narrowing gradually to the apex; leaves of A. longifolia ssp. sophorae are usually widest near or above the middle, narrowing abruptly towards the apex. Seed pods of A. longifolia ssp. sophorae are more contorted than those of A. longifolia ssp. longifolia [which are +- straight], and the seeds are larger and heavier [as well as being more numerous per-pod, on average]. Pods of A. longifolia ssp. sophorae are dark reddish-brown, whilst those of A. longifolia ssp. longifolia are brown. Chemically, A. longifolia ssp. sophorae leaf has a more complex flavonoid composition than A. longifolia ssp. longifolia (Butcher et al. 2001; Murray et al. 1978).

A. obtusifolia is readily distinguished from A. longifolia ssp. longifolia by the thicker, more rigid phyllodes, with resinous margins, of the former. A. maidenii and A. obtusifolia can also appear very similar in some instances, due to their wide variation and frequent co-habitation in the wild. Despite this, there are important differences which easily separate them. Leaves of A. maidenii are relatively light and flexible compared to those of A. obtusifolia, which are thick and leathery, and often have irregular, reddish margins, and reddish new growth. The nervation on A. maidenii is very fine and sparsely anastomosing, whilst A. obtusifolia nervation is more distanced and prominent. Flowers of A. obtusifolia are a light creamy yellow, whilst those of A. maidenii are golden yellow. Fruit of A. obtusifolia is straight, and fruit of A. maidenii is usually highly contorted (Entwistle et al. 1996; Mulga pers. comm.; pers. obs.). A. obtusifolia [as A. intertexta] was once confused with the similar A. orites (Clarke-Lewis & Dainis 1964), which has since been recognised as a separate species (Pedley 1964).

Exploitation for drug content has lead to much destructive harvesting of several Acacia spp. in Australia, causing noticeable damage in National Parks. This has particularly been a problem with A. phlebophylla [which has a very small population and is difficult to cultivate] and A. obtusifolia (E 1996; pers. comms.).

People outside of Australia may have difficulty in cultivating Australian Acacia spp., as the roots of the plants grow in symbiosis with soil-dwelling rhizobium bacteria. Rhizobium innoculants for various groups of Leguminous plants can be obtained from some horticultural suppliers. A. phlebophylla seed should be germinated as for A. obtusifolia, but may take up to a month to germinate; keep slightly moist in this time. In practice the seeds seem to have a low viability. Enjoys a sunny position, and a coarse, well-drained soil with elements of sand, gravel and granite; fertilise with granite or rock dust. Water only moderately; fungus-sensitive. Hardy, cold-tolerant (Floyd pers. comm.).

ACANTHURUS, KYPHOSUS, MUGIL, NEOMYXUS, MULLOIDICHTHYS, UPENEUS, ABUDEFDUF, EPINEPHELUS, SARPA and SIGANUS

(Acanthuridae)

Acanthurus triostegus *L.* **ssp. sandvicensis** *Streets* – convict surgeonfish, tang, convict tang, manini

(Kyphosidae)

Kyphosus bigibbus *Lacepède* **(K. fuscus** *Lacepède***)** – brown chub, grey seachub, grey drummer, insular rudderfish, isuzumi, nenue, karamami pakavai, minami-isuzumi, petit wiwa, umuleo, renigiiy

Kyphosus cinerascens *Forsskål* **(Pimelepterus cinerascens** *Forssk.***; Sciaena cinerascens** *Forssk.***)** – seachub, blue seachub, snubnose chub, highfin chub, chub, rudderfish, highfin rudderfish, bluefish, Ashen drummer, topsail drummer, isuzumi, tenjikuisaki, kibawo, kuwa, nenue, manaloa, achlat karang, beras-beras, renigiiy, sirisiriwai

Kyphosus vaigiensis *(Quoy et Gaimard)* **(K. bleekeri** *Fowler***; K. gibsoni** *Ogelby***; K. lembus** *(Cuvier)***; Pimelepterus vaigiensis** *Quoy et Gaimard***; Segutilum gibsoni** *Ogelby***)** – sea chub, lowfin chub, blue seachub, brassy chub, brass bream, drummer, Waigeu drummer, large-tailed drummer, low-finned drummer, lowfin rudderfish, isuzumi, nenue, saborre, renigiiy, lupak, yaaji

(Mugilidae)

Mugil cephalus *L.* **(M. strongylocephalus** *Richardson***)** – common grey mullet, flathead mullet, longarm mullet, black mullet, bright mullet, hardgut mullet, striped mullet, springer, ama ama, pua ama, haarder, kahaha, wu tau tze

Neomyxus chaptalii *(Eydoux et Souleyet)* **(Chaenomugil nauticus** *Bryan et Herre***; Mugil chaptalii** *Eydoux et Souleyet***)** – silvery mullet, Chaptall's mullet, eatar, uoauoa

(Mullidae)

Mulloidichthys flavolineatus *Lacepède* **(M. samoensis** *(Günther)***; Mulloides samoensis** *Günther***; Mullus flavolineatus** *Lacepède***)** – goatfish, gold-striped goatfish, golden goatfish, yellowstripe goatfish, Samoan goatfish, pallid goatfish, bait goatfish, surmullet, weke, weke'a'ā ['staring weke'], weke 'ula ['scarlet weke', 'ghost weke'], weke ke'oke'o ['white weke'], sand weke, baybayo, kawe, oama, tubac, tuyo, afolu i'a sina

Upeneus arge *Jordan et Evermann* – goatfish, gold-striped goatfish, band-tailed goatfish, surmullet, weke, weke pueo ['owl weke'], weke nono ['red weke'], weke pahulu ['nightmare weke'], jome, rouget, tebaweina, te maebo, tubac, tuyo, afolu i'a sina

(Pomacentridae)

Abudefduf septemfasciatus *(Cuvier)* **(A. multifasciatus** *Seale***; A. paee** *Curtiss***; Chaetodon rotundus** *L.***; Glyphisodon septemfasciatus** *Cuvier***)** – sergeant major, seven-banded sergeant major, banded sergeant, sevenbar damsel, damselfish, maomao, ulavapua, alala saga, mutu, bakej, tebukibuki, palata, shichisen-suzumedai

(Serranidae)

Epinephelus corallicola *(Valenciennes)* **(Seranus altivelioides** *Bleeker***; S. corallicola** *Valenciennes***)** – grouper, coral grouper, coral rock cod, gatala, rero, baraka, kugtung, vieille, hiregurohata, bulang, lapu-lapu, kusele, kerapu belosoh

(Siganidae)

Siganus argenteus *(Quoy et Gaimard)* **(S. rostratus** *(Valenciennes)***; Amphacanthus argenteus** *Quoy et Gaimard***; A. rostratus** *Valenciennes***; Teuthis argentea** *(Quoy et Gaimard)***; T. rostrata** *Valenciennes***)** – rabbitfish, silver rabbitfish, forktail rabbitfish, streamlined rabbitfoot, streaked spinefoot, rabbitface spinefoot, Roman-nose spinefoot, spinefoot, baliwis, malava, palit, cordonnier, hana-aigo, shimofuri aigo

Siganus canaliculatus *(Park)* **(S. oramin** *(Bloch et Schneider)***; Amphacanthus dorsalis** *Valenciennes***; Chaetodon canaliculatus** *Park***; Teuthis oramin** *(Bloch et Schneider)***)** – rabbitfish, seagrass rabbitfish, spiny rabbitfish, slimy rabbitfish, white-spotted rabbitfish, white-spotted spinefoot, pearly spinefoot, pearl-spotted spinefoot, gold-lined spinefoot, ellok, mole, lopauulu, baliwis, palit, shimofuri-aigo

Siganus corallinus *(Valenciennes)* **(Amphacanthus corralinus** *Valenciennes***; Teuthis corallina** *(Valenciennes)***)** – blue-spotted spinefoot, orange spinefoot, ocellated orange spinefoot, coral spinefoot, coral rabbitfish, spotted rabbitfish, cordonnier brisant, sango-aigo, sigano coral, kelang, lambai, belaris, igesheosheo

Siganus luridus *Rüppell* – dusky spinefoot, mouwasit

Siganus rivulatus *Forssk.* **(Amphacanthus rivulata** *(Forssk.)***; A. sigan** *Klunzinger***; Scarus rivulatus** *(Forssk.)***; Teuthis rivulatus** *(Forssk.)***)** – rabbitfish, rivulated rabbitfish, marbled spinefoot, baliwis, palit, cordonnier

Siganus spinus *L.* – little spinefoot, black spinefoot, scribbled spinefoot, bluntnosed spinefish, spiny rabbitfish, scribbled rabbitfish, black trevally, blue-spotted trevally, batwayi, safi, seeseege, epong

(Sparidae)

Sarpa salpa *(L.) Smith* **(Boops goreensis** *Valenciennes***; B. salpa** *L.***; Box goreensis** *Valenciennes***; Box salpa** *L.***; Eusalpa salpa** *L.***; Sparus salpa** *L.***)** – sea bream, goldline, salpa, saupe, salema, salema porgy, strepie

These fish, all colloquially referred to as 'weke' or 'dreamfish', have been implicated in a condition known to medics as 'ichthyoallyeinotoxism', or more simply, 'hallucinatory mullet poisoning'. This phenomenon has occasionally been noted from some areas of Hawaii and Norfolk Island [near Australia], as well as the Indian Ocean, and the Mediterranean for Sarpa spp. Around Hawaii [Kauai and Moloka'i] the fish are said to only be toxic from certain localities, and then only from June to August. Some locals say the toxic mullet and goatfish species often have red blotches on the surfaces of the lips and sides of the head. However, these features are not a fail-safe method of distinguishing between toxic and nontoxic specimens. The toxicity seems to be more or less random in populations of these fish. Different people also seem to display very different tolerances to the fish. Eating from the same catch, some people may become intoxicated, while others do not (Halstead 1988; Helfrich & Banner 1960). An unidentified fish found off the coast of Trujillo [Peru] is known as 'borracho', and its flesh is reported to be "highly hallucinogenic" (Kennedy 1982). In Mascareignes [Reunion Island], Siganus spinus is known as "the fish that inebriates". Sarpa salpa is said to have been used "for recreational purposes in the Mediterranean during the Roman Empire", and some Arabs know it as "the fish that makes dreams". Recently it has caused some 'hallucinogenic' poisonings that have been confused with ciguatera [see below]. It is sometimes sold in fish markets in the Mediterranean despite being known by local fishmongers to occasionally have these effects, though in Italy and Spain it is not regarded as edible (De Haro & Pommier 2006). Smith & Heemstra (1986) commented that "the flesh is tasty when quite fresh, but soon softens and is not much esteemed".

The Hawaiian term 'weke' translates roughly to 'opening a crack, or door'. Weke fish were once valued in sorcery, and much-used as offerings to the gods (Pukui & Elbert 1971), though their use today does not appear to have any ritual significance. Pukui & Elbert (1971) also mention a connection with the deity Pahulu ['nightmare'], who ruled over a horde of ghosts on his island home of Lana'i [adjacent to Moloka'i – see above]. Pahulu's soul influenced certain fish in the area so that they would bring about nightmares in anyone who consumed them. It is still believed locally that the resultant nightmares are worse from fish caught closest to Lana'i (Pukui & Elbert 1971).

The flesh of the whole fish may be eaten, but the head and brain are considered the most potent parts; not gutting the fish immediately after catching is also reputed to give more powerful effects. It reportedly makes no difference whether the fish is cooked or not. The symptoms of eating the 'toxic' fish consist of an itching or burning in the throat immediately after eating, in some people; some may experience muscular weakness and loss of coordination; some complain of a tight constriction of the chest. Gastric distress is sometimes reported. From 10 minutes to 2 hours after ingestion, CNS effects manifest, including hallucinations, mental depression, dizziness and loss of equilibrium. These effects last for 3-24(-36) hours, before complete recovery. If the consumer goes to sleep just before the effects begin, nightmares or unusual and vivid dreams may be experienced (De Haro & Pommier 2006; Halstead 1988; Helfrich & Banner 1960).

The existence of the dreamfish phenomenon was first revealed to the western public through an article in National Geographic (Roughley 1960), which included some interesting descriptions of the effects of the fish caught off Norfolk Island [Kyphosus fuscus – see below]. A local islander told Roughley "The small ones don't affect me, but once I had a big one for supper. I spent that night on an operating table, with the surgeon doing one operation after another – always cutting through a new and expensive suit I had just purchased." The photographer for the article, Joe Roberts ["who usually doesn't dream at all"], consumed a single broiled specimen, and reported the next morning, "It was pure science fiction. I saw a new kind of car, steered with a stick like a plane. And then I was taking pictures of a monument to mark man's first trip into space." Finally, Roughley ate a specimen himself for supper. In his own words – "I found it tasty, but strong flavoured, like mackerel. I told myself not to dream. But no. I dreamed I was at a party where everybody was nude and the band played 'Yes, we have no pajamas'" (Roughley 1960)!

The compounds responsible for causing the symptoms of hallucinatory mullet poisoning have not yet been identified, and there is still much room for speculation. It is interesting to note that some of these 'hallucinogenic' species are also important commercial fish, which are widely eaten without any resultant psychoactivity [most of the time!].

The dreamfish Kyphosus fuscus, sometimes eaten at Norfolk Island (Roughley 1960), has been claimed to contain *5-methoxy-DMT*, but there does not seem to be any chemical literature to support this (Ott 1993; Stafford 1992). K. fuscus is now considered a synonym for immature specimens of K. bigibbus (http://www.fishbase.org/). The presence of visionary tryptamines would not be entirely unlikely, however, due to their known presence in mammalian brains (eg. Corbett et al. 1978; Relkin 1983a), and the presence of tryptamines in other marine life (Shulgin & Shulgin 1997; see also *Endnotes*). Given that even common commercial fish - raw or cooked - contain β-carbolines [see *Influencing Endogenous Chemistry*], it is tempting to explain the chemical mechanism of hallucinatory fish poisoning as an ayahuasca effect [see *Methods of Ingestion*] or, in this case, 'fishuasca' (pers. obs.)!

There is a strong possibility that 'toxic' specimens of these fish accumulate psychoactive compounds, or precursors to psychoactive compounds, from their diet. Hawaiian fishermen sometimes attribute the toxicity to the blue-green alga Lyngyba majuscula, known as 'stinging lumu'. This has been refuted for a number of reasons. Firstly, the toxic fish are not known to feed on L. majuscula. Secondly, there is a lack of meaningful correlation between the occurrence of hallucinatory mullet poisoning and the distribution of L. majuscula (Helfrich & Banner 1960). L. majuscula has also been suggested as a source of 'ciguatera poisoning' [see below], which has different symptoms than the hallucinatory poisonings (Halstead 1988). However, this does not rule out algae altogether. Many

of these fish do feed on a variety of algae [some closely related to L. majuscula] and diatoms, and Siganus fuscescens, a close relative of some of the 'hallucinogenic' fish, does feed on L. majuscula. Seasonal and other variations in the toxicity might also relate to fluctuations in the ability of the fish to metabolise certain chemicals from their diet, leading either to their accumulation or their absence. Algae [and other marine organisms] can also be very variable in their chemical content, leading to further uncertainties (theobromus pers. comm. 2001).

Some blue-green algal blooms [cyanobacteria] produce powerful toxins – Anabaena flosaquae and Aphanizomenon flosaquae both produce anatoxin-a [up to c.1%], a potent *cocaine*-analogue [agonist of nicotinic *acetylcholine* receptors (3-50 times more potent than *nicotine* at neuronal receptors), stimulating catecholamine release, also with anticholinesterase properties; highly toxic, can cause death by respiratory paralysis]. Toxin production is increased with age, and at temperatures in the low 20's [°C]. Whilst these species also exist in non-toxic strains, there are also anatoxin-a producing strains of Cylindospermum spp. and Oscillatoria spp. (Buckingham et al. ed. 1994; Hunter 1992; Molloy et al. 1995; Rapala et al. 1993). Aphanizomenon flosaquae has been used in a controversial blue-green alga health product, which was claimed to boost energy levels; some users did report feelings of stimulation and increased energy, others did not (pers. comms. 1998).

Some of these fish, and their relatives, have also been implicated in 'ciguatera' poisoning. The polyether ciguatoxin [which is responsible for this poisoning] is thought to originate from the dinoflagellates Gambierdiscus toxicus [contains maitotoxin], Prorocentrum lima [contains okadaic acid] and other algae, which are eaten by some warm-water fish; G. toxicus often grows adhering to Turbinaria spp. fronds.These fish include Acanthurus triostegus, Mugil cephalus, Mulloidichthys flavolineatus, Upeneus arge, and Abudefduf septemfasciatus (Halstead 1988). In these cases, where the same species [or a sub-species, in the case of Acanthurus triostegus] is also implicated in hallucinatory mullet poisoning, there may be either confusion of symptoms by physicians, or a more complex variation in toxicity of these fish not yet understood (pers. obs.). Indeed, "ciguatera has become a general term used to describe fish poisoning caused by the consumption of tropical and subtropical finfish that can be differentiated from those related to *histamine* or tetrodotoxin" [see *Endnotes*] (Iwaoka et al. 1992), and by these criteria hallucinatory poisoning would be included under the broad umbrella of 'ciguatera' (pers. obs.). Symptoms may appear almost immediately, or up to 30 hours following consumption, and may vary between cases. Initial symptoms include abdominal pain, nausea, vomiting, watery diarrhoea, and sometimes tingling sensations and numbness of the mouth and throat. Other symptoms may include headache, blurred vision, photophobia, temporary blindness, mydriasis, malaise, anxiety, dizziness, motor incoordination, insomnia, exhaustion, weakness, pallor, ataxia, prostration, chills, fever, sweating, itching, cyanosis and rapid, weak pulse. Sometimes extensive skin disorders develop, and hair and/or nails may be lost. Severe poisonings may involve a continuing decline in motor coordination, diminished reflexes, difficulty in speaking, 'pins and needles', muscular paralysis, muscular twitches, tremors, convulsions, coma, and finally death from respiratory paralysis. Severe poisonings which are survived may take a long time to fully recover from, with some symptoms recurring many years later. Ciguatera poisoning involves a very large number of fish species, many of which are also considered good to eat under other circumstances (Halstead 1988).

Acanthurus triostegus from waters off the west coasts of Oahu and Hawaii was assayed for toxicity; ciguatoxin and/or related compounds were tentatively found in only 4% of fish analysed, although toxicity to mice extended randomly across much of the sample, indicating the presence of unrecognised toxins different to ciguatoxin. There was high variability in toxicity of different specimens caught from the same area and at the same time of day. The most lethal toxicity was found in methanol extracts, followed by hexane extracts; water extracts were largely survived with complete recovery from symptoms after 6hrs. Human skin contact with the water extract brought about a localised tingling sensation taking effect within 10min. and lasting 30min. (Iwaoka et al. 1992).

Kyphosus vaigiensis grows to 58cm; silvery-grey to bluish, darker to olive-brown above, with a close-set series of bright golden ribbons running head to tail; usually a patch of yellow-orange or silvery-white below the eye. Pectoral fin bright yellow, all others grey; 14-15 spines and rays in dorsal fin, soft dorsal rays very slightly shorter than dorsal spines; 12-13 spines and rays in anal fin. Jaws with single row of compressed incisors.

On rocky outcrops along northern coastline of Australia – shoals often seen in shallow waters of coral reef lagoons on the Great Barrier Reef, extending down into the Capricorn/Bunker Group area; Indo-Pacific.

Mugil cephalus grows to 76cm, weighing up to 8kg; olive-green above with silvery sides when in ocean, darker and browner from rivers and estuaries; small black spot at base of pectoral fin; body moderately elongate and compressed; head bluntly rounded and broad; eye almost obscured by a prominent adipose lid, a narrow slit over the pupil being uncovered; lower lip very thin with double symphysial knob. Jaws with row of setiform teeth on each, easily-shed. Anal fin with 8 rays, as with dorsal fin; pectoral rays 16-17. 1st and 2nd dorsal origins respectively opposite the 12th and 24th scales; anal origin slightly before the 2nd dorsal; pectoral reaches the 10th scale, with a distinct axillary scale.

Found in coastal and estuarine waters, entering fresh water; Indo-Pacific. Most important commercial fish in Queensland [Australia] (Grant 1982).

Acanthurus triostegus ssp. sandvicensis is found in Hawaiian waters; A. triostegus is more widely distributed.

Abudefduf septemfasciatus is found in the Indo-Pacific, in lagoons and outer reefs.

Siganus oramin is found in the Indo-Pacific, and near east Africa and Saudi Arabia (Halstead 1988). S. argenteus and S. corallinus have caused poisonings in Mauritius, S. luridus in Israel, S. rivulatus in Mauritius and possibly Israel, and S. spinus in Reunion (De Haro & Pommier 2006).

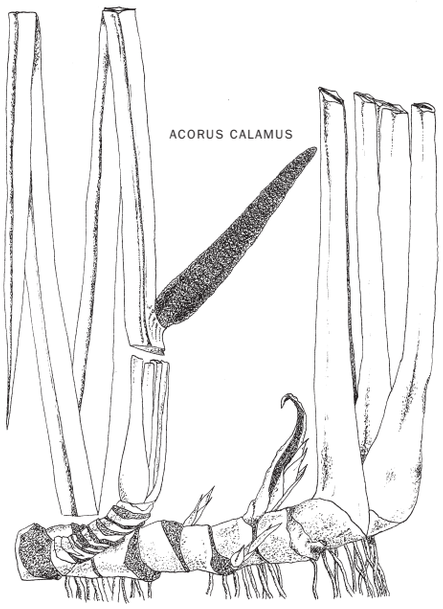
Sarpa salpa occurs in the Mediterranean, and e. Atlantic around S. Africa to s. Mozambique (Smith & Heemstra ed. 1986); it has caused poisonings in France, Tunisia and Israel (De Haro & Pommier 2006).

Other listed species are all found in the Indo-Pacific region (Halstead 1988).

Note – as some of the colour-related colloquial names of these fish seem to contradict each other, it should be mentioned that some fish change colour depending on maturity, what they are doing, and whether or not they are in the water.

ACORUS

(Araceae)



Acorus calamus *L.* **(A. aromaticus** *Gilib.***; A. odoratus** *Lam.***)** – sweet flag, sweet sedge, sweet calamus, ratroot, myrtle flag, rush, calamus, ugragandha, wasa, che ts'ang p'ou, pai ch'ang, chang pu

Acorus calamus var. americanus *(Raf.) Wulff* **(A. americanus** *(Raf.) Raf.***)** – makatek, makakerekerep, wee-kees

Acorus calamus var. angustifolius (A. angustifolius *Schott***; A. calamus var. angustatus** *Bess.***)** – shui chang pu

Acorus calamus var. calamus (A. asiaticus *Nakai***; A. calamus var. vulgaris** *L.***)**

Acorus gramineus *Aiton* **(A. pusillus** *Siebold***)** – shih chang pu, ch'ang p'u, akha

Used in medicine since the time of Hippocrates, sweet flag was an important ingredient in various preparations wherever it grew. The Sumerians used it in their sacred incenses, as did the ancient Egyptians, who also used the rhizome as an aphrodisiac. The Romans and Arabs also knew of its aphrodisiac properties. It has long been used in Ayurvedic medicine to treat diarrhoea and insanity, and the Chinese use it [A. calamus var. angustifolius and A. gramineus] to treat epilepsy, stroke, asthma, insomnia and arthritis. It is also said to 'replenish intelligence', and treat amnesia and 'excessive dreaming', and acts as a CNS-depressant sedative. In China it has been used in a potion consumed to 'see spirits', containing also Podophyllum pleianthum [see **Mandragora**] and **Cannabis** fruit [see **Cannabis** for further discussion of this potion]. In France, A. calamus has been added to beers, and in Holland, children chew the rhizome. Sometimes, the powdered rhizome is used to protect clothes from insect damage, and to kill fleas. The leaves may be scattered on the floor to deter pests and improve the odour of a room (Bremness 1994; Chopra et al. 1965; Hsu et al. 1986; Li 1978; Motley 1994; Nadkarni 1976; Rätsch

1992; Samorini & Festi 1995). Also, European witches may have used A. calamus var. calamus in some of their flying ointments (Ott 1993). Nowadays, the plants are used in perfumery, and in some countries the rhizome is sold as a crystallised sweet, like glazed ginger [see *Endnotes*].

The Cherokee use A. calamus var. americanus as a stimulant, antispasmodic and diuretic, and to treat digestive disorders, flatulence, intestinal worms, colds and headache. Many Native American tribal groups have similar uses for the herb, and chew, snuff, smoke or decoct it as a daily stimulant tonic and antifatigue agent. Many tribes also attribute mystical powers to the plant. Dakota warriors chewed it to a paste and rubbed it on their faces before battle, to make them calm and fearless. The Saulteau smoke it with tobacco [see **Nicotiana**] to relieve headache, as well as using it as a poultice for wounds and pains. The Cree, who know it as 'wee-kees' ['musk-rat root'], use it as a stimulant and aphrodisiac, chewing a small piece of the root [2.5-5cm length] while walking or hunting [or loving!]. The Cheyenne tie a piece of the rhizome to their children's night clothes to keep 'night spirits' away, and the Sioux also use it to keep away ghosts or evil spirits. The rhizome has also been used by the Omaha and Sioux, in the form of a snuff and an infusion, respectively, as a horse stimulant (Hamel & Chiltoskey 1975; Kindscher 1992; Morgan 1980, 1981; Motley 1994; Plowman 1969; Rätsch 1992).

In the Western Highlands of Papua New Guinea, the Raiapu Enga give A. calamus rhizome to their dogs as a hunting stimulant; it is prepared by chewing, and administered by spitting it into the noses of the dogs (Thomas 2001a). A. calamus is widely used for ritual magic in Papua New Guinea. It has been used "to make young men grow tall and strong, to promote success in hunting, to attract wealth and to prevent face paint from running during ceremonial dancing". It is also used in love magic (Paijmans ed. 1976).

Two westerners living with the Cree in the 1960's experimented on 5 occasions with large doses [c.25cm length] of the rhizome [reported as A. calamus – presumably it was A. calamus var. americanus], and reported 'LSD-like' experiences (Morgan 1980). Some modern-day experimenters have experienced no effect, or only sickness, from chewing the rhizome. Many others experience strong CNS-stimulation and mild sensory alterations from both American and Eurasian varieties, as well as with A. gramineus (pers. comms.). A self-experiment by Giorgio Samorini with 20g A. calamus rhizome produced a psychedelic state of moderate intensity, lasting 4-6 hours (Samorini & Festi 1995). I have experimented with an alcohol extract [inactive, possibly due to age] and chewed dry rhizome pieces [c.24g] of what was believed to have been A. calamus var. calamus. In the latter experiment, the rhizome pieces were swallowed when exhausted of flavour. The dose was chewed over the course of several hours, experiencing after this time a pleasant CNS-stimulation, not unlike the initial sensations of a *mescaline* experience. The effects developed no further, but the stimulation persisted for at least another 5-6 hours. On another occasion I ingested, in a similar fashion, rhizome slices of A. gramineus [estimated c.25cm length of rhizome c.1cm thick – this is really a wild guess]. The same CNS-stimulation was experienced, but after several hours mild delirium and nausea set in, followed quickly by sweating, stomach pain and severe vomiting, leaving a horrible after-taste throughout my nose, mouth and throat; I vomited twice more in the next 10 hours. Sweet flag rhizomes taste spicy, pungent and slightly sweet, with a bitter after-taste that gets nastier the longer the rhizome is chewed (pers. obs.).

There has been controversy about the true nature of sweet flag's psychoactive properties. This may be partially explained by the fact that the three varieties of A. calamus have been confused as one, and each has a different chemical and genetic profile. A. calamus var. americanus is found in N. America and Siberia; A. calamus var. angustifolius is found in India; and A. calamus var. calamus is found in Europe and n. India, and is sterile (Bruneton 1995; Darke ed. 1994). Populations of A. calamus var. calamus have also been found naturalised in Canada and the US (Packer & Ringius 1984). In animal experiments, Indian A. calamus [probably var. angustifolius] has generally shown sedative, tranquillising, analgesic, anticonvulsant, antiarrhythmic, antiadrenergic, and MAOI effects (Opdyke 1977). Rhizomes of most varieties yield 1.5-9% essential oil, and fresh aerial parts have yielded 0.12% (Bruneton 1995; Chopra et al. 1965; Nadkarni 1976).

Here the confusion spreads – β-*asarone*, frequently the major component of the essential oils [see below], acts as a sedative on its own, but the liver is potentially capable of aminating this chemical into the potent psychedelic TMA-2 (Shulgin 1976; Shulgin et al. 1967). Asian sweet flags, high in *asarones*, are often used as sedatives, with no greater level of psychotropic activity noted amongst these cultures [except for aphrodisiac effects] (eg. see Perry & Metzger 1980), doses possibly being too small [usually 1.5-7.5g]. A. calamus essential oil is generally said to have tranquillising properties. However, A. calamus var. americanus is used widely as a stimulant, and claimed to be psychedelic in higher doses, but contains little or no *asarone*. Could there be other active agents responsible, or is there even wider chemical variation than is now thought?

A. calamus var. americanus is devoid of β-*asarone*, which has been believed to be the 'active principle' in sweet flags. The rhizome essential oil [1.7% yield] is rich in sesquiterpene ketones, including shyobunone, isoshyobunone, 2,6-di-epi-shyobunone, acorenone, isoacorone and preisocalamendiol (Keller & Stahl 1983).

A. calamus var. angustifolius is dominant [up to 96% of the essential oil] in β-*asarone* (Motley 1994).

A. calamus var. calamus essential oil contains usually not more than 10% phenylpropanoids, mostly β-*asarone*, *methyleugenol* and *eugenol*, as well as sometimes calamol [an isomer of *asarone*]; also found are sesquiterpenoids such as acorenone [8%], β-gurjunene [6.7%], shyobunone [2.6%], isoshyobunone [6.2%], calamendiol [3.8%], α-selinine [3.8%], α-calacorene [3.5%], calamusenone [3.2%], camphene [3.2%], p-cymene [analgesic], γ-cadinene, linalol [sedative, fungistatic, antiseptic], α-terpineol, and α-cadinol (Battaglia 1995; Bruneton 1995; Chopra et al. 1965; Hall 1973; Harborne & Baxter ed. 1993).

A. gramineus has yielded 0.5-0.9% essential oil, mostly consisting of *asarone* (Hsu et al. 1986). In cultured rat neurons, a methanol extract of the rhizome showed a neuroprotective action against neurotoxicity mediated by *glycine* binding-sites of NMDA receptors (Choa et al. 2000).

Acorus calamus is a perennial wetland herb with a creeping and branching horizontal aromatic rhizome, tinted pink. Leaves equitant, basally sheathing, 1.7-3.8cm x 0.9-1.8m, rather rigid, bright green, acute, nerves parallel, midrib distinct; in emerging leaves, sporadic zones of lateral wrinkling and puckering. Spathe and peduncle barely distinguishable; peduncle narrower than leaves, strongly 2-3-ridged; spathe 15-75cm long; pedicel 3.2-3.8cm broad; spadix sessile, borne at or above midpoint of spathe/peduncle and held at 45°, cylindric, obtuse, slightly curved, yellow, becoming green, 5-10 x 1.2-3cm, densely crowded with bisexual flowers; sepals 5, orbicular, concave, incurved, as long as ovary, scarious; stamens 6, filaments linear-flat; anthers yellow, reniform. Ovary conical, 2-3-celled; stigma minute; ovules many, pendulous from the top of each cell. Fruit turbinate, prismatic, top pyramidal, few-seeded; seeds oblong, micropyle often fimbriate.

Throughout northern hemisphere, generally in marshes and at edges of waterways (Chopra et al. 1965; Darke ed. 1994); prefers rich, loamy soil in a sunny position, kept permanently moist. Propagate from very fresh seed, or by root division in spring and autumn (pers. comms.).

ACRAEA

(Nymphalidae, subfamily Heliconiinae/Acraeinae)

Acraea andromacha *Fab.* **(A. entoria** *Godart***; A. theodote** *Wallengren***; Papilio andromacha** *Fab.***)** – glasswing butterfly

This rather inconspicuous looking butterfly, the only Australian representative of the subfamily Acraeinae, is of interest because of a chemical curiosity. The eggs of the butterfly are laid on species of wild passionfruit [Adenia heterophylla, A. populifolia and **Passiflora** spp.], some of which produce β-carboline alkaloids and cyanogenic compounds. These chemicals are passed on to the larvae and the adult butterfly, as part of a chemical defence system against predators (Burns & Rotherham 1977; Fisher 1995; Watson & Whalley 1975). The **Passiflora** spp. utilised are P. alba, P. suberosa [both native to Australia], P. mollissima, P. edulis and P. ligularis, though the larvae do not thrive on these latter two species (Herbison-Evans & Crossley 2000).

Adult butterflies, which fed as larvae on β-carboline-containing plant material [species not noted], were shown to contain small amounts of *norharman* [β-carboline], *harman* [major alkaloid] and *harmine*. Along with **Heliconius** spp., butterfly samples also contained [as confirmed by TLC] 6-MeO-*harman* and *harmaline* (Cavin & Rodriguez 1988), though it is not made clear whether this applied to all species analysed.

Acraea andromacha eggs are pale yellow, slightly higher than wide, vertically ribbed, and laid in clusters on Adenia and **Passiflora** spp.; larvae yellow-brown to brownish-black, with numerous long black branched spines in longitudinal rows, arising from blue-black areas at the base, c.6 spines to each segment, upper part of head yellow, black below; pupa slender and elongate, creamy-yellow to brown, with irregular black lines on wing cases and orange spots edged with black on abdomen, attached by its tail to a pad of silk spun on a sheltered object near the food plant. Adult butterfly slow-flying, +- polymorphic, sexes similar in size and colouration, 50-60mm long, average wingspan 5.4-5.7cm, forewings almost transparent, underside almost the same as upperside, but hindwings with larger creamy spots in the blackish margins; beneath the tip of the abdomen, females have a shiny plate or pouch on which a brown mass called a sphragis is deposited by the male after copulation to prevent another fertilisation.

New Caledonia, New Georgia, Indonesia, Sulawesi [Celebes], New Guinea, Samoa, Fiji, Australia [n. WA, NT and Qld to Sydney (NSW) all year – occasionally s. to Vic. and Adelaide (SA) in late summer and autumn, when unusually humid] (Burns & Rotherham 1977; Watson & Whalley 1975).

ACTINIDIA

(Actinidiaceae)

Actinidia arguta *(Siebold et Zucc.) Planch. ex Miq.* **(Trochostigma arguta** *Siebold et Zucc.***)**
Actinidia kolomikta *(Maxim. et Rupr.) Maxim.* **(A. gagnepainii** *Nakai***; A. kolomikta var. gagnepainii** *(Nakai) H.L. Li***; Prunus kolomikta** *Maxim. et Rupr.***)** – miyama-matatabi
Actinidia polygama *(Siebold et Zucc.) Maxim.* **(A. lecomtei** *Nakai***; A. polygama** *Miq.***; A. polygama var. lecomtei** *(Nakai) H.L. Li***; A. repanda** *Honda***; A. volubilis** *Franch. et Sav.***; Trochostigma polygama** *Siebold et Zucc.***)** – silver vine, Chinese cat powder, ch'ang-chu, mu tian liao, matatabi

In China, plants of the genus Actinidia are called 'yang-tao', and have been cultivated there since at least 770AD. A. deliciosa [A. chinensis] is the common 'kiwi fruit', or 'Chinese gooseberry'. A. arguta sap is used by the Ainu of Siberia as an expectorant. A. polygama is used in TCM in rice wine, as a sedative to depress the limbic system. A decoction of the stem is used as a sedative in Russia and Ukraine. The plant is also sometimes used in zoos to tranquillise and inebriate large cats. A. kolomikta is also useful in this regard. When smoked, A. polygama has a similar effect to 'catnip' [see **Nepeta**] (Emboden 1979a; Ott 1993).

The chemicals responsible for the cat-attracting/inebriating effects of these plants are primarily *actinidine* [a monoterpenoid pyridine alkaloid], matatabilactone [a mixture of iridomyrmecin and isoiridomyrmecin], and other similar lactones, such as are found in **Nepeta** (Sakan et al. 1959a, 1959b, 1965; Tucker & Tucker 1988). See *Endnotes* for the occurrence of these compounds in insects.

A. arguta has yielded *actinidine* (Gross et al. 1972).

A. chinensis fruit contains actinidin, an acidic protein which is not the same as *actinidine* (Harborne & Baxter ed. 1993).

A. polygama leaves and galls have yielded *actinidine*, matatabilactone (Sakan et al. 1959a), dihydro-*nepetalactone*, isodihydro-*nepetalactone*, neo-*nepetalactone* (Sakan et al. 1965), actinidiolide, dihydroactinidiolide, and β-phenylethyl alcohol [induces salivation] (Tucker & Tucker 1988); the iridoid enol glucosides iridodialo-β-D-gentiobioside and dehydroiridodialo-β-D-gentiobioside have also been isolated from the plant (Murai & Tagawa 1979).

Actinidia polygama is a twining vine to 5m; branchlets glabrous, filled with white, solid pith. Leaves alternate, simple, dentate, 7-12 x 5-8cm, ovate or ovate-oblong, apex acuminate, base acute or rounded to subcordate, serrulate, glabrous above, usually bristly on veins, bronzed when young, silvery-white to creamy-yellow throughout or above only, in patches or flecks. Flowers in axillary cymes, solitary or in clusters of 2-3, to 3cm, white, fragrant, cup-shaped; sepals and petals usually 5, rounded; stamens numerous; anthers purple or yellow. Fruit a many-seeded berry to 2.5cm diam., ovoid-globose, apex somewhat beaked, yellow, translucent, sour. Fl. summer.

Temperate east Asia.

A. polygama var. lecomtei is different from the above in that its leaves are glabrous beneath, and the anthers are brown. Found in w. China.

Plant in deep and well-drained loamy soil, rich in organic matter with neutral pH; grows well in part shade; will withstand temperatures as low as -17°C; shelter from wind, which will easily snap and bruise young growth (Burras ed. 1994).

ACTINOPYGA, AFROCUCUMIS, CUCUMARIA, EUAPTA, HOLOTHURIA, PENTACTA and STICHOPUS

(Echinodermataceae/Holothuroideae)

Actinopyga agassizi *Selenka*
Actinopyga lecanora *Jaeger* **(Holothuria lecanora)** – stone fish
Afrocucumis africana *Semper* **(Pseudocucumis africana)**
Cucumaria echinata *Von Marenzeller*
Euapta lappa *Müller*
Holothuria argus *Jaeger* **(Bohadschia argus** *Jaeger***)** – Polynesian sea cucumber, spotted sea cucumber, ocellated sea cucumber, sand-sifting sea cucumber, sand-eating cuke, leopard fish sea cucumber, tiger fish
Pentacta australis *Ludwig*
Stichopus chloronotus *Brandt* – green fish
Stichopus variegatus *Semper* – Australian sea cucumber, curry fish, gamat

Collectively also known as – sea cucumber, sea slug, trepang, holothurie, beche de mer, fieuse de coton, hai shen ['sea ginseng'], warripa

For centuries, Macassans from Celebes harvested sea cucumbers from waters off the coast of Arnhem Land [n. Australia], bringing them to China, to be sold as 'sea ginseng' to the wealthy [see **Panax**]. They had a repuation as a nervous stimulant and aphrodisiac. Some of the aphrodisiac reputation may come from the phallic shape of the creature's bodies, as well as the fact that they eject liquid when excited or irritated. As 'trepang', sea cucumbers are a popular food in the Indo-Pacific region, where they are boiled, dried, and sometimes smoked to leach out toxins, in order to render them safe to eat [deaths have been reported from sea cucumber ingestion]. Trepang is often added to soups and stews, to help bring out the flavour of the foods it is cooked with (De Monfreid 1935; Halstead 1988). Today, trepang is harvested from all over the world to supply the demand for it as food.

Due to the extended cooking required for safe consumption, indigenous Australians of the northern coasts did not make much use of sea cucumbers as food. The Warramirri, however, know of other properties – they say that the sea cucumber has a special sexual energy which it can impart on the consumer, and it is associated with their 'trickster deity' Marryalyan. Other indigenous elders from northern Australia have stated that eating them uncooked causes vomiting and diarrhoea, followed by a period in which the mind is affected strangely, and one feels "un-real and delirious" (Cawte 1996). The juice of sea cucumbers such as H. argus and H. atra has been used in Guam to catch fish, by poisoning coral reef pools with it (Nigrelli & Jakowska 1960).

Sea cucumbers have been shown to contain steroidal glycosides called holothurins [most concentrated in the 'organs of Cuvier' (see below) and the body wall], which have anticholinergic, haemolytic, antimetabolic and some antitumour properties. They also direct muscle-contraction, and may be 'irreversible' neurotoxins. The neurotoxic potency of holothurin A is similar to that of *cocaine*. Fortunately, holothurins are much less toxic to mammals orally than i.p., and they are largely hydrolysed by gastric acids into nontoxic products. Other compounds found include aglycones [such as griseogenin, koellikerigenin and holotoxinogenin], saponins [such as cucumarioside and stichoposide] and quaternary ammonium bases [homarine]. Contact with sea cucumber toxins may result in burning pain, redness and violent inflammation, and even blindness, if brought into contact with the eyes (Baslow 1977; Corbett 1971; Elyakov et al. 1973; Halstead 1988; Hashimoto 1979; Nigrelli & Jakowska 1960).

Sea cucumbers have an elongated body, with a series of tentacles around the mouth (at the bottom of the body); some also have tube-feet attached to the body. Skeleton a series of irregular plates embedded in the skin. Organs of Cuvier are a series of tubules attached to the stem of the respiratory tree; may be emitted from the anus (whereupon they swell and stretch on contact with the water, becoming sticky) to entangle predators. Habit is vertical on the sea floor, in a wide range of habitats and depths, sometimes camouflaged with debris; they attach themselves using their tube-feet, and move with rhythmic body contractions; they feed on fine bottom materials and organisms, shovelled into the mouth with the tentacles (Halstead 1988).

AESCULUS

(Hippocastanaceae)

Aesculus californica *(Spach.) Nutt.* – California buckeye
Aesculus glabra *Willd.* – Ohio buckeye, smooth buckeye, foetid buckeye
Aesculus hippocastanum *L.* **(Hippocastanum vulgare** *Gaertn.***)** – buckeye, horsechestnut, conker tree, monkey chestnut, suo huo zi
Aesculus pavia *L.* – red buckeye
Aesculus spp. – buckeyes

Aesculus spp. are of interest due to their obscure narcotic properties. Seeds of A. pavia and other Aesculus spp. have been used by natives of southern and eastern US to stun fish. A. glabra and other Aesculus spp. were used in N. America in the 19th century as an opium substitute [see **Papaver**]. A Dr McDowell from this time claimed that 0.65g of the powdered seed-coat was equal in potency to 0.2g of opium. In 1877, Prof. E.M. Hale wrote that A. glabra causes "confusion of the mind, vertigo, stupefaction and coma", as well as gastro-intestinal complaints. Buckeye seeds have also been described as "an irritant of the cerebro-spinal system". Medicinally, they have also been used to relieve some forms of asthma. In overdose, coma and death may result. A. hippocastanum is regarded as having weaker effects than other species such as A. glabra (Emboden 1979a; Felter & Lloyd 1898; Pammel 1911). Most buckeyes are toxic to stock animals, the young growth and mature fruits being considered the most toxic parts. A. pavia has been recorded as causing incoordination, sluggishness, excitability and twitching in cattle and horses. The flowers of A. californica are toxic to bees, and honey made by them has also caused poisoning in humans who have ingested it (Kingsbury 1964).

The Cherokee use A. octandra seeds as a poultice for swellings, sprains, infections and tumors; an infusion is taken to prevent fainting, and small pieces of the seed may be chewed and swallowed for colic. A bark infusion is used to aid childbirth, and stop post-partum bleeding (Hamel & Chiltoskey 1975).

During food-shortages, the treated mashed fruit of A. hippocastanum

has been used as animal-fodder; the protein-rich seeds have been ground and made into flour or a coffee substitute [see **Coffea**], after washing and boiling to remove toxins. The plant has been implicated in the deaths of children who ate the nuts. They have been reported to cause inflammation of mucous membranes, burning sensations in the stomach, nausea, and vomiting (Bremness 1994; Pammel 1911). In medicine, compounds from the seed are used as an astringent, antiinflammatory, and to tone and strengthen vein walls (Bruneton 1995; Chevallier 1996; Mabey et al. ed. 1990). The hardened nuts have long been popular with European schoolchildren in the game of 'conkers'.

A. hippocastanum seed contains up to 10% saponins, collectively called aescin [inhibits chemically-induced tumours], which is made up of derivatives of protoaescigenin and barringtogenol; proanthocyanidins [epicatechol-derivatives], flavonol glycosides, 6-8% lipids [including phytosterol, linoleic acid, palmitic acid, stearic acid], tannins, pectin, 40-50% starch, calcium and phosphorous. Bark also contains aescin, tannins and 2-3% coumarins, including aesculoside (Bruneton 1995; Chiej 1984; Harborne & Baxter ed. 1993), aesculetin, aesculin, scopolin, *scopoletin*, fraxin and fraxetin. Aesculin and aesculetin were the major coumarins, and maximum yields were obtained from bark of young branches [1.06% coumarins], compared to wood and leaves (Reppel 1956). The plant has also yielded butyrospermol, dicaffeoylspermidine, N,N-dicoumarylspermidine, isoescigenin, fungitetraose, and plastoquinones 4 & 8 (Buckingham et al. ed. 1994).

Aescin is also found in other Aesculus spp. In subtoxic doses, it acts as a respiratory stimulant, cardiac stimulant and hypotensive; it is also antiinflammatory, and increases corticosterol and *adrenocorticotropin* levels (Huang 1993; Rastogi & Mehrotra ed. 1990-1993).

Aesculus glabra is a tree to 10m tall; bark grey, much furrowed and broken into scaly plates. Leaves deciduous, compound; leaflets usually 5(-7), elliptic to obovate, +- abruptly acuminate, narrowed at base, 7.5-13cm long, finely toothed, pinnately straight-veined; petioles 10-15cm long. Flowers in branched clusters 10-15cm long, showy, to c.3cm long, pale greenish-yellow; pedicels jointed; calyx campanulate to tubular, irregularly 5-lobed, c.6mm long, often oblique or gibbous at base; petals (4-)5, nearly equal in length, villous-ciliolate, clawed, nearly hypogynous; stamens (5-)7(-8), exserted to almost twice corolla length; filaments long, slender, often unequal in length; anthers elliptical, glandular-apiculate, 2-celled, opening longitudinally. Ovary 3-celled; style 1; pistils mostly imperfect and sterile. Fruit a capsule to 5cm diam., prickly, with 1-2 seeds; seeds to 35mm wide, with thick coat and a large round pale scar. Fl. Mar.-May.

In woodlands and bottomlands in n.e. Texas, primarily in the Ohio and Mississippi Valleys (Correll & Johnston 1970).

'Texas buckeye' or 'Mexican buckeye', Ungnadia speciosa, is an unrelated plant from the Sapindaceae [see **Sophora**].

AGROCYBE

(Agaricaceae/Bolbitiaceae)

Agrocybe farinacea *Hongo*

Agrocybe semiorbicularis *(Bull. ex St. Amans) Fayod* **(A. arenaria** *(Peck) Singer***; A. arenicola** *(Berk.) Singer***; A. pediades** *(Rf.) Fayod***; A. semiorbicularis** *(Bull. ex Fr.) Fayod***; A. subpediades** *(Murr.) Watling***; Agaricus semiorbicularis** *Bull.***; Naucoria semiorbicularis** *(Bull.) Quél.***; N. vervacti** *(Fr.) Kumm.***)**

Agrocybe sp.

In studies of Oaxacan 'narcotic puffballs' [see **Lycoperdon**, **Scleroderma**], A. semiorbicularis was identified by an indigenous informant as causing similar effects. Its supposed similarity in appearance to **Psilocybe** mexicana was thought to have possibly caused confusion (Ott 1993), though I assume the native people would know their fungi sufficiently well not to make such an error in identification. Curiously, though the researchers ingested the puffballs identified by their informant, they did not bioassay the Agrocybe sp.

A. farinacea, a beautiful species from Japan, has yielded 0.2-0.4% *psilocybin*. None could be detected in Japanese A. semiorbicularis (Koike et al. 1981).

An unidentified Agrocybe sp. from Finland has also yielded 0.003% *psilocybin* (Ohenoja et al. 1987).

Agrocybe semiorbicularis is a small mushroom; cap 1-3cm diam., yellow or whitish-greasy, ochraceous, drying to almost white, hemispherical or slightly expanded, smooth, greasy, flesh white, firm and thin; stem pallid yellow or whitish, smooth, +- equal, ring absent, flesh whitish, becoming tinged brown in stem-base, fibrous and full; gills cream at first, turning coffee-brown at maturity, adnate or slightly decurrent, crowded; spores rust-brown, smooth, ellipsoid, germ pore indistinct, 10-14 x 8-11µm; basidia 4-spored; gill-edge cystidia flask-shaped; gill-face cystidia rarely seen; odour not distinctive; taste not distinctive. Fr. summer-autumn.

Solitary, scattered, or in loose trooping groups, on soil or in grass; common in UK (Jordan 1995), widely distributed in N. America (Phillips 1991), and also reported from Australia (May & Wood 1997).

ALCHORNEA

(Euphorbiaceae)

Alchornea castaneifolia *(Humb. et Bonpl. ex Willd.) A. Juss.* **(A. castaneifolia** *Baill.***; A. castaneifolia** *Benth.***; Hermesia castaneifolia** *Humb. et Bonpl. ex Willd.***)** – hiporuru

Alchornea cordifolia *(Schum. et Thonn.) Müll.-Arg.* **(A. cordata** *(A. Juss.) Müll.-Arg.***; Schousboea cordifolia** *Schum. et Thonn.***)** – Christmas bush, tekei, agyama, mbom, diangba [many other names]

Alchornea floribunda *Müll.-Arg.* – alan, elando, eando, niando, delande, dilandu, mulolongu, kai, sumara fida

Alchornea hirtella *Benth.* – bwujanka, be tira, tibi, tukingi, tolokenge, kuliwuri, tola-tamis ['spider's web kola']

Alchornea laxiflora *(Benth.) Pax et K. Hoffm.* **(Lepidoturus laxiflorus** *Benth.***)** – uwenuwen, ububo, ijan, ijan funfun, ijandu, pepe, longoso, urievwu

Alchornea rugosa *(Lour.) Müll.-Arg.* **(A. hainanensis** *Pax et K. Hoffm.***; A. javensis** *Müll.-Arg.***; Cladodes rugosa** *Lour.***)**

People of the Byeri cult of the Fang of Gabon [an older precursor to today's Bwiti – see **Tabernanthe**] used to consume large amounts of 'alan' root [A. floribunda, though one author identified alan as Hylodendron gabonense (Leguminosae)] as an initiatory entheogen. They say the effects are weaker and shorter-acting compared to 'iboga' [**Tabernanthe**]. During the initiation proceedings, with the initiate strongly affected by the alan root, s/he was shown the skulls of their ancestors in order to be able to communicate with spirits of the dead. It is still sometimes used today as an occasional iboga-additive, or as an aphrodisiac, for which purpose the root cortex is macerated in palm-wine [see *Methods of Ingestion*] for several days. It is said to produce an intense excitement, and 'indescribable bliss' with later depression, vertigo and collapse, during which the spirit is believed to journey to the land of the ancestors. Occasionally the intoxication leads to overdose and death. The sun-dried root bark may also sometimes be taken powdered, mixed with salt and food, and consumed previous to battle or tribal ritual for strength (De Smet 1996, 1998; Emboden 1979a; Pope 1969; Rätsch 1990, 1992; Samorini 1993, 1995a, 1997a). The leaves are sometimes eaten in the Congo as an antidote to poison, and leaf or root sap may be applied to skin afflictions or wounds (Burkill 1985-1997).

In Ivory Coast, the purgative leaves of A. cordifolia are taken in decoction and as a bath, as a sedative antispasmodic. The plant has a great variety of medicinal and practical uses, and twigs are used as chewsticks. A. hirtella root or leaf sap is taken as a sedative analgesic in w. Africa; the root is taken by decoction, and the sap is applied topically or to scarifications. A. laxiflora is used by the Yoruba of Nigeria in incantations to deflect malevolent sorcery back to the sender (Burkill 1985-1997). A. castaneifolia has been used in Peru as an ayahuasca-additive [see **Banisteriopsis**], and is widely employed as a rheumatism treatment (Luna 1984; McKenna et al. 1995; Ott 1994).

A. castaneifolia has yielded alchorneine, imidazole and corynantheine type indole alkaloids [see also **Corynanthe**] (McKenna et al. 1995).

A. cordifolia roots and stems have yielded 0.04-0.26% alkaloids, including possibly *yohimbine* (Paris & Coutarel 1958). Leaves and bark contain saponins and tannins, as well as a bitter principle, alchorin (Burkill 1985-1997).

A. floribunda roots and stems yielded 0.56-1.21% alkaloids, of which *yohimbine* was tentatively identified from the root extract (Paris & Coutarel 1958). The presence of *yohimbine* here and in other Alchornea spp. is thought to be in error, possibly in confusion with the alchorneine-type indole alkaloids, which were then poorly known (Burkill 1985-1997; De Smet 1996; Samorini 1993; pers. obs.). In a later analysis, trunk bark yielded 0.013% alkaloids, c.66% of which was alchorneine; root bark yielded 0.186% alkaloids, mostly alchorneine with smaller amounts of isoalchorneine; leaves yielded 0.483% alkaloids, including isoalchorneine and alchorneinone (Khuong-Huu et al. 1972). Given to anaesthetised dogs, a decoction of the powdered root was found to increase the sensitivity of the sympathetic nervous system to *epinephrine* (De Smet 1996).

A. hirtella yielded 0.06-0.74% alkaloids from bark and roots, believed to include *yohimbine* [see above] (Paris & Coutarel 1958); the trunk bark later yielded 0.016% alkaloids, including alchorneine (Khuong-Huu et al. 1972).

A. latifolia has yielded *GABA* (Durand et al. 1962).

A. rugosa leaves yielded 0.386% alkaloids, consisting of alchorneine, alchornidine, and isopentenylguanidine alkaloids, including N1,N1-diisopentenylguanidine (CSIRO 1990).

Alchornea floribunda is a leaning shrub or small tree, sometimes subscandent, to 10m tall, mostly without milky sap; branchlets, petioles and undersides of leaves minutely puberulous. Leaves alternate, simple, elongate-obovate-oblanceolate, long-attenuate at base, shortly acuminate

at apex, repand-denticulate margin, 14-31 x 6-12cm, lateral nerves in 12-19 pairs with sessile glands at base; bracts up to 1mm long, inconspicuous; petioles 0.5-3cm long. Flowers dioecious, much reduced, pale green. Male flowers in panicles of 10-25cm long spikes, terminal, axillary, and on old wood; calyx closed in bud, enveloping the stamens, calyx lobes valvate; petals absent; stamens 7-8, 1-2-seriate, the outer alternate with sepals, or all +- central; interstaminal glands absent; filaments unbranched, usually free; anthers 2-celled, opening lengthwise, anther cells pendulous, not long-cylindrical; rudimentary ovary sometimes present. Female flowers terminal, simple or branched, up to 11-40cm long; interstaminal glands absent; ovary 3-celled, ovary cells 1-ovuled; ovules pendulous; styles 3, simple, 5-15mm long, free or united at base; indumentum not stellate. Fruit a 3-celled capsule or drupe, c.8-11mm broad, smooth, pubescent; seeds often with conspicuous caruncle, endosperm copious, fleshy, embryo straight.

In forest undergrowth; Mali, Liberia, s. Nigeria, Cameroun, Guinea, Gabon, Zaïre, Uganda, Sudan (Hutchinson & Dalziel 1955-1972).

ALSTONIA

(Apocynaceae)

Alstonia constricta *F. Muell.* **(A. mollis** *Benth.***)** – bitterbark, quinine bark, fever bark, Australian fever bark, Peruvian bark, whitewood, lacambie

Alstonia scholaris *(L.) R. Br.* **(A. cuneata** *Wall.***; Echites scholaris** *L.***; Pala scholaris** *(L.) Roberty***)** – dita, dita bark, bitterbark, devil tree, milky pine, white cheesewood, white pine, whitewood, pale mara, chhatim, birrba, koorool, zopang, katung

Alstonia venenata *R. Br.* **(A. venenatus** *Brown***)** – dita, addasarpa, rajaadana, pazhamunnipala

These trees, notable for their array of indole alkaloids, have varied medicinal uses. Bark of A. scholaris rolls off in layers, and has long been used to make parchments. It is used in treating a number of ailments in India – such as menstrual cramps, stomach ache, chronic ulcers, dysentery, diarrhoea, teeth caries, catarrh, leprosy, asthma, heart diseases, blood diseases, tumours and general pain. Mixed with oil and milk, it is used for earache. The bark may also be taken as a general tonic after sickness (Kirtikar & Basu 1980; Nadkarni 1976). It is used by some indigenous peoples of n. Queensland, Australia for fever, dysentery and abdominal pain, and the latex used to treat neuralgia and toothache. The tender leaves may also be roasted and powdered to use as a poultice for skin ulcers (Forster & Williams 1996; Lassak & McCarthy 1990). In TCM, the dried leaves ['deng tai ye'] are used as an expectorant and antiphlogistic (Huang 1993). The seeds have been taken as an aphrodisiac by practitioners of tantric yoga, to prolong and intensify erection, and stimulate the sensory nerves. They are prepared by crushing and soaking in water over night, straining and drinking the water the next day; for stronger effects, the seeds may be boiled. A starting dose for experimentation is 2g (Miller 1985; Rätsch 1990, 1992).

In India, ripe fruit of A. venenata is used to treat insanity, epilepsy and syphilis; the bark has also been shown to act in a similar fashion (Bhattacharya et al. 1975; Kirtikar & Basu 1980; Nadkarni 1976). In some parts of the west Pacific, A. acuminata root bark is added to palm wine to give a bitter flavour (Usher 1974), most likely due to alkaloid content. During the early periods of Australia's colonisation, A. constricta bark was used as a 'bitters'. The decocted bark was also once used by beer brewers in England as a bitter hops substitute [see **Humulus**] (Cribb & Cribb 1981). In eastern Australia, A. constricta stem bark is used as a tonic and febrifuge; it is also reported to act as a cerebrospinal stimulant and antiperiodic. The latex has also been applied to sores. Bees have been observed to become intoxicated from the flower nectar – "they would drop to the ground in a comatose state and stay there for quite a long time. Then...they would waddle up to the plant and climb laboriously up and get stuck into these flowers again...and down they would come...absolute drunkards they became" (Lassak & McCarthy 1990). The plant is considered toxic to livestock (Forster & Williams 1996).

A. actinophylla [A. verticillosa] leaf and bark from Chillagoe, Queensland [Australia], harvested in June, gave positive tests for alkaloids, the bark more strongly so (Webb 1949).

A. brassii yielded 0.65% bases from bark; in mice, 500mg/kg [oral] of the bases produced sedation, ledge unsteadiness, dilated pupils, increased sensitivity to touch and sound, rapid breathing and intermittent clonic seizures (CSIRO 1990).

A. constricta stem bark has yielded alstonine ['chlorogenine', see below; inhibits cancer cell replication (Beljanski & Beljanski 1982), has antipsychotic-like effects in animals (Costa-Campos et al. 1998)], alstonidine, alstonilidine, vincamedine, porphyrosine, quebrachidine, O-3,4,5-trimethoxybenzoylquebrachidine, 14-ketoalstonidine and 1-carbomethoxy-β-carboline (Allam et al. 1987); root bark has yielded *reserpine*, alstonidine, alstonilidine, vincamajine and O-3,4,5-trimethoxycinnamoylamajine (Lassak & McCarthy 1990). Leaf of A. constricta var. mollis from Miles, Queensland [harv. Jun.] tested strongly positive for alkaloids (Webb 1949).

A. macrophylla bark has yielded alstophylline, villalstonine, macralstonine, macralstonidine, macrophylline and 'alkaloid M' (Kishi et al. 1965).

A. quaternata bark has yielded 0.2% alkaloids, including [as % of total alkaloids] 10% quaternatine, 0.3% cathafoline, 0.2% quaternine, 0.2% *yohimbine*, 0.2% pseudoyohimbine, and 0.2% tubotaiwine; leaves and twigs yielded 0.055% alkaloids, including 25% *yohimbine*, 10% pseudoyohimbine, 1.5% quaternine, 1.3% tubotaiwine, 1.2% cathafoline, 1.2% vincamajine, 0.5% quaternoxine, 0.3% quaternidine, and <0.1% quaternoline (Mamatas-Kalamaras et al. 1975).

A. scholaris bark has yielded ditamine, echitamine [ditaine], echitamidine, echitenine, echitine, echiteine, echicerine, echiretine, alstonine, venoterpine glucoside, β-amyrin acetate and lupeol acetate; root bark has yielded 0.21% echitamine, 0.001% echitamidine, 0.002% N-demethylechitamine, 0.0004% pseudoakuammigine, 0.0004% akuammicine N-oxide, 0.00035% akuammicine N-methiodide, <0.0001% akuammicine, 19,20-OH-dihydroakuammicine, 0.00045% tubotaiwine, stigmasterol and α-sitosterol; leaves have yielded 0.2% alkaloids consisting of strictamine [MAOI and antidepressant], picrinine, picralinal, pseudoakuammigine, 12-MeO-echitamidine [scholarine], and lochneridine, as well as betulin, ursolic acid and β-sitosterol (Boonchuay & Court 1976; Hartley et al. 1973; Kirtikar & Basu 1980; Lassak & McCarthy 1990; Rastogi & Mehrotra ed. 1990-1993). Bark from plants growing in Innisfail, Queensland [harv. May] tested strongly positive for alkaloids (Webb 1949). Flowers have yielded 0.01% picrinine [CNS-depressant], 0.004% strictamine, 0.0003% tetrahydroalstonine, and an unidentified indole alkaloid [0.00008%] (Dutta et al. 1976).

Seeds have been reported to contain alstovenine, 'chlorogenine', *reserpine*, and venenatine (Rätsch 1992), though I have been unable to locate any primary reference to support this. Chlorogenine was, at one point, considered synonymous with alstonine (Henry 1939), though chlorogenine is no longer recognised as an alkaloid name, due to confusion in early literature about the correct identity of the substance when extracted from plant material (Buckingham et al. ed. 1994). The chlorogenine first isolated by Hesse is synonymous with alstonine; the chlorogenine first isolated by Schunck is synonymous with the glucoside rubichloric acid, isolated by Rochleder. Miller (1985) claimed that "the seed contains a powerful alkaloid, chlorogenine, now considered the principal agent that acts as an aphrodisiac", though he appears to equate chlorogenine with *chlorogenic acid*, which is a different substance entirely. It should be noted that another unrelated substance is now known as 'chlorogenin' [(3β,5α,6α,25R)-spirostane-3,6-diol], which might cause further confusion.

A. spectabilis bark has yielded alstonamine, echitamine, echitenine, ditamine, quebrachidine, pleiocarpamine, villalstonine and macralstonidine (CSIRO 1990).

A. venenata stem bark has yielded alstovenine [MAOI], venenatine [*reserpine*-like action], echitovenidine [MAOI], echitovenine, 3-dehydroalstovenine, venalstonine, venalstonidine, anhydroalstonatine and trimethylgallamide; root bark has yielded alstovenine, venenatine, *reserpine* and 3-dehydro-*yohimbine* [3-dehydroalstovenine]; leaves have yielded echitovenaldine; and fruits have yielded echitoserpidine, echitoserpine, venoterpine, ursolic acid, β-amyrin and β-amyrin acetate; the plant has also yielded minovincinine and kopsinine (Bhattacharya et al. 1975; Farnsworth & Cordell 1976; Ganzinger & Hesse 1976; Rastogi & Mehrotra ed. 1990-1993).

A. villosa bark from plants growing in Cairns, Queensland [harv. Sep.] tested strongly positive for alkaloids (Webb 1949).

Alstonia venenata is a shrub usually 1.8-2.4(-6)m tall, glabrous. Leaves in whorls of 3-6, membranous, 10-20 x 2-4.5cm, oblong-lanceolate, very finely acuminate, base much-tapered, main nerves numerous, very close, parallel, slender, uniting in an intramarginal nerve, midrib strong; petiole 1.3-2cm long. Flowers white, inodorous, in terminal subumbellate pedunculate cymes, flowers often racemose on branches; calyx 5-lobed, without glands inside, 2.5mm long, lobes 1.6mm long, triangular-ovate, acute, ciliate; corolla hypocrateriform, tube slender, cylindric, swollen at tip over stamens, 13-22mm long, throat naked or +- enclosed by a ring of reflexed hairs, throat hairy at and below the insertion of stamens, lobes 8mm long, oblong, subacute, glabrous, overlapping; stamens near the top of the tube, included; anthers free, subacute; disc of 2 ligulate glands alternating with the carpels, annular or sometimes obscure, sometimes truncate or lobed. Carpels 2, distinct; ovules numerous in each carpel, many-seriate; style filiform; stigma minute. Follicles 2, 7.5-12.5 x 0.8cm, stalked, falcately curved, tapering at both ends, beaked, glabrous, striate; seeds 10-13mm long, flattened, linear-oblong, with a tuft of hairs at each end, the hairs shorter than the seed.

India (Kirtikar & Basu 1980).

To differentiate between the barks of A. constricta and A. scholaris – the former is very bitter, and inner bark turns almost blood-red with strong nitric acid, and brown in alcoholic iodine solution; the latter is less bitter, and inner bark turns red with strong sulphuric acid, yellowish-green with strong nitric acid, and almost black with alcohol-iodine solu-

tion (Lassak & McCarthy 1990).

ALTERNANTHERA

(Amaranthaceae)

Alternanthera lehmannii *Hieron.* **(A. fasciculata** *Suess.***; A. lanceolata** *(Benth.) Schinz***; A. mexicana** *Schltdl.***; A. microcephala** *(Moq.) Schinz***; A. panamensis** *(Standl.) Standl.***; A. stenophylla** *(Standl.) Standl.***; Achyranthes lehmannii** *(Hieron.) Standl.***; Ach. panamensis** *(Standl.) Standl.***; Ach. stenophylla** *Standl.***; Brandesia lanceolata** *Benth.***; B. mexicana** *Schltdl.***; Mogiphanes soratensis** *Rusby***; Telanthera lanceolata** *(Benth.) Moq.***; T. mexicana** *Moq.***; T. microcephala** *Moq.***)** – borrachera, chicha

This herb is used by the Kofan and Ingano of the Colombian Putumayo, and by the Siona of Ecuador, as an additive to their ayahuasca [see **Banisteriopsis**]; it is cultivated in home gardens in the Peruvian Amazon. It may also be added to the fermented drink 'chicha' [see *Methods of Ingestion*], after which it is named. Its addition is said to induce "a very strong intoxication which affects the voice" (Pinkley 1969; Schultes 1957, 1966, 1967a; Schultes & Hofmann 1980; Schultes & Raffauf 1990; Uscategui 1959). When smoked, the leaves were reported to produce a strange intoxication reminiscent of the tropane alkaloids. However, it was later revealed that this had been done shortly after the peak of a smoked **Salvia** divinorum experience (friendly pers. comm.). Later bioassays by numerous psychonauts have found no activity from smoking the plant, or from smoking concentrated extracts. It is thought that the true activity of this plant, if any, may lie in an ability to synergise with some other psychoactive substances (friendly pers. comm.; pers. comms.).

In Mocoa, the plant is decocted and taken as a purgative. The related A. sessilis ['racaba'] is cooked and eaten as food in Malaya, Indonesia and Congo (Usher 1974). In Queensland, Australia, A. nana and A. repens have been suspected of causing the death of sheep and pigs, respectively (Webb 1948).

The chemistry of A. lehmannii remains obscure, but the related A. repens has yielded triterpene saponins (Sanoko et al. 1999). A. sessilis tested positive for HCN in the seed and whole plant (Watt & Breyer-Brandwijk 1962). An unidentified Alternanthera sp. from Warwick, Queensland tested positive for alkaloids in the leaf, and more strongly in the root (Webb 1949).

Alternanthera lehmannii is a herbaceous plant, stem barely thickened at articulations, erect, branched, angled, upper parts mainly subvillous-pilose, lower parts glabrescent. Leaves petiolate, membranaceous, slender, lanceolate-oblong, up to 8.5 x 3.5cm, both ends attenuate, acuminate, mucronulate, margin entire or subundulate, long-ciliate, both sides sparsely pilose, upper side yellowish-green, under side pale, pinnatinerved, nerves slightly raised on both sides, lateral nerves c.10-11, curved, parallel; petiole 5-10mm long, moderately villous. Inflorescence terminal, solitary subglobose heads 4-5mm long, erect; peduncle to 6cm long, slender, villous; flowers shortly pedicellate; pedicels shortly villous, bracteate; bracts c.4, c.1mm long, glabrous, whitish, ovate, acuminate to elongate awns, awns 0.5-1mm long; perianth laciniate, trinerved, scarious, glabrous, oblong, acute, unequal, 2.5-3mm long, c.1mm wide, whitish-yellow; staminodes c.1.5mm long; filament long, apex deeply 4-dentate-laciniate, margin entire; anthers oblong, c.0.5mm long.

Growing near shady locations, 1700-1800m; Popayan [Colombia] (Heironymus 1895).

AMANITA

(Agaricaceae)

Amanita citrina *Schaeff. ex S.F. Gray* **(A. mappa** *(Batsch. ex Fr.) Quél.***)** – false death cap

Amanita cothurnata *Atkinson*

Amanita gemmata *(Fr.) Gillet* **(A. gemmata** *(Fr.) Bertil.***; A. junquillea** *Quél.***)** – jonquil Amanita, gemmed Amanita, crenulate Amanita

Amanita muscaria *(L. ex Fr.) Pers. ex Gray* – fly agaric, 'soma', toadstool, fairy mushroom, amanite tue-mouche ['fly-killer Amanita'], fliegenschwamm, fliegenpilz ['fly mushroom'], panx, tshashm baskon ['eye opener'], yuyo de rayo, yuy chauk ['herb of the thunderbolt'], kaqulja, kakulja, ruk'awach q'uatzu:y, itzel ocox, rocox aj tza ['devil's mushroom'], moscario, hongo mosquero, hongo matamoscas, benitengutake, miskwedo, mukhomor, flugsvamp, aka-haetori ['red fly catcher'], raven's bread

Amanita pantherina *(DC. ex Fr.) Secr.* – panther cap, the panther, panther agaric, pantera, pantherschwamm, krôtenschwamm, tignosa, pixaca, tengutake, hongo malo, hongo loco, false blusher

Amanita porphyria *(A. et S. ex Fr.) Secr.*

Amanita regalis *Fr.* **(A. muscaria var. regalis** *(Fr.) Maire***)**

Amanita rubescens *(Fr. ex Pers.) S.F. Gray* – blusher

Amanita strobiliformis *(Paul.) Quél.* – ibotengutake ['warted tengu-mushroom'], haetorimodashi ['fly killer']

Amanita tomentella *Kromb.*

A. muscaria is well known to many people, even if they do not know its identity. It is often seen as the prototypical mushroom, and has long adorned the artwork of children's story books. Its best known common name, 'fly agaric', stems from the use of the mushroom in stunning flies so that they may be easily dispatched. For this purpose, a cap was often placed in a shallow dish with some water and honey, and left on a window-sill to attract its victims. The fungus does not actually kill flies, despite much mythology to the contrary. Given the Scandinavian mythological association of flies with evil, this once-common use for A. muscaria might have existed in a context of magical protection against negative influences (Nichols 2001).

The shamanic use of A. muscaria is best known in Lapland and Siberia [by the Koryak, Khanty, Mansi, Forest Nenets, Selkup, Nganasan, Ket, Chukchi, Itelmen, Yukagir, Even, Eskimos and Russians living along the Kolyma River]. Many tribes allowed its use by anyone, but some reserved it for shamans – though shamans who could practice effectively without A. muscaria were considered 'stronger'. It is consumed as an oracle, to treat diseases, interpret dreams, communicate with spirits and other worlds, or to name a new-born – it is always 'told' in a loud voice the reason for its use. The mushroom is said to influence one via the A. muscaria 'manikins', little spirits who tell the consumer what they need to know, in the form of song, story, or taking one on journeys to other places and worlds. If the manikins do not appear, no revelations are received, or one is simply led to other realms but 'shown' nothing significant. The mushroom is also said to increase one's strength and endurance, and may be taken for performing arduous tasks. Potential users are first given a small amount, to test for violent tendencies – such people are not allowed to consume it. It is also never taken simultaneously with liquor, as this combination is believed to be very dangerous, even deadly. Others are left to do and behave as they wish while under the mushroom's influence (Heim 1963b; Saar 1991; Schultes & Hofmann 1980, 1992; Tyler 1966; Wasson 1968). Though once suppressed by Communism, shamanic use of this mushroom persisted more or less secretly in Siberia, and still exists there on a limited basis (Salzman et al. 1996).

Ancient Scandinavian use of A. muscaria has also been suggested, though such use is not known to exist there today, as it is widely [and falsely] believed to be a deadly mushroom (Nichols 2001). Use of this mushroom has been suggested to have contributed to the actions of the infamous Scandinavian 'berserkers'; in Norway, going berserk was outlawed in 1015AD [see also **Ledum**] (Fabing 1956; Tyler 1966). A. muscaria has also been used as a shamanic sacrament by native North Americans [Great Lakes region of Canada and the US], and was still used up until recently by some Ojibway shamans (Wasson 1979). The Quiche Maya regard A. muscaria as 'evil or diabolical', and Kekchi-speaking people of Guatemala call it the 'devil's mushroom'. These names may relate from poisonings after ingesting fresh specimens; it seems likely that its proper preparation and use was once better known to some of the Guatemalan Maya, as it is directly associated with Kakulja [god of thunder and lightning], one of the powerful Mayan deities mentioned in their holy book, the Popol Vuh (Lowy 1974, 1977).

A. muscaria has been proposed in a detailed set of arguments by R. Gordon Wasson to have been the original sacred 'soma' of the Hindus [see *Introduction*]. Many people accept this identification, though many also disagree, and several alternatives have been considered over the decades [see **Ephedra**, **Mandragora**, **Nelumbo**, **Psilocybe** and **Peganum**]. Some consider the effects of fly agaric intoxication to be not 'entheogenic' enough to have been soma, but differing chemical composition of material may be responsible for much of the discrepancies (Festi & Bianchi 1990; Flattery & Schwartz 1989; Heinrich 1992; McKenna 1991; Ott 1993, 1998b; Wasson 1968). Soma as a drug may have referred to a number of different psychoactive herbs [and/or combinations thereof] which induced the appropriate state, rather than being one mystery plant. In my subjective opinion, based solely on nature of effects, plant substances chemically analogous to *psilocin* or ayahuasca [see **Banisteriopsis**] would be most likely to have been the preferred sacraments of the ancient Vedists. However, I am certainly not a scholar in that field and my opinion should be taken with at least one grain of salt!

A. muscaria might also have been the mushroom involved in the Lesser Mysteries of Eleusis [see **Claviceps**, **Panaeolus**] (Samorini 2001; Webster et al. 2001). It has also been suggested that A. muscaria was used in the quest for enlightenment by early Buddhists; and that it may have been the cause of Buddha's enlightenment under the Bodhi tree. The latter may have been a birch [Betula spp.], the 'world tree' of many cultures, with which these fungi grow symbiotically (Hajicek-Dobberstein 1995).

Oddly enough, A. muscaria was even tested and proposed as a wine substitute in Italy, 1880, when a parasite threatened local vineyards. In rural Europe, the mushroom has a small reputed history of use as an inebriant (Samorini 1996a). In Catalonia [Catalunya], an autonomic territory in Spain, use of A. muscaria for psychotropic effects is known, and may

have been more prevalent in the past (Fericgla 1992). Use of A. muscaria has also been uncovered in the Shutul Valley of Afghanistan, which appears to be a remnant of older traditional use. The chief purpose for its use is as a stimulant, though it is also sometimes used for "treatment of psychotic conditions", or applied externally to frostbite. The mushrooms are gathered in late spring [often already dried from the sun], powdered, and boiled with Impatiens noli-tangere ssp. montana ['mountain snapweed'] and soured goat-cheese brine. Though its main use is reported to be as a stimulant, extracts of accounts from local informants described stronger inebriations. For example – "a feeling of weariness and a need for sleep overcomes me. I hear voices, although I am alone in my room"; "First, I am very sleepy, then I feel good. I forget sentences... Once I thought that I was a tree"; "I ran around in the woods and didn't know who or where I was." Further north in the valley, the extract is fortified with "calyx-tips of seed-bearing flowers" of **Hyoscyamus** niger, and applied externally by massage (Mochtar & Geerken 1979).

A. pantherina is also claimed to have been used as an inebriant in Japan. In 1927, Cape Province [S. Africa], there was a recorded incident of accidental ingestion by 7 people; 3 of them died, and this seemed to be due to muscarine poisoning [see below] (Watt & Breyer-Brandwijk 1932). The fungi were probably eaten fresh or in excess. A. gemmata has been reported as causing "intoxication" and "malaise" in a group of people who ingested it, presuming it to be edible (Heim 1963b); human intoxications from A. regalis have also been reported (Stijve 2000).

Today, A. muscaria and A. pantherina are sometimes used experimentally and sacramentally by western psychonauts, virtually wherever they grow. Their non-traditional use is particularly prevalent, though still infrequent, in the Pacific northwest US and adjacent Canada, southern Australia, and Europe (Weil 1977b; pers. obs.). In Germany, A. muscaria is available in pharmacies as a homoeopathic tincture [called 'Agaricus muscarius'; 100ml derived from c.35g fresh mushroom], used to treat depression, 'mental weakness', epilepsy, Parkinson's disease, menopausal flushes, tics, and paresis of the bladder, amongst other uses. The effect of the tincture may be increased by heating it twice for 3 minutes until boiling, in order to decarboxylate most of the *ibotenic acid* to *muscimol* [see below] (Waldschmidt 1992). Some people have taken to simply consuming a small piece of the mushroom everyday as a neurotropic (pers. comms.). With special preparation, it has even been eaten as food - in Mexico after peeling off the cuticle and throwing it away along with the water used to cook the mushroom, and in Italy boiled with the water then discarded and the mushroom pickled in brine (Michelot & Melendez-Howell 2003).

A. muscaria and A. pantherina have been prepared and consumed in a variety of ways, but to avoid toxic symptoms, they are usually thoroughly dried or toasted prior to consumption [to facilitate decarboxylation of *ibotenic acid* to *muscimol* – see below]. It is known that fresh specimens are much more toxic than dried, and that smaller amounts can be fatal [this is not a concern with sensible doses of properly dried mushrooms]. Often only the cap is used, though the whole mushroom may be taken – the inside skin of the cap seems to be richest in active compounds. Some Siberians believe the younger, partially open mushrooms are stronger in 'narcotic power', and are used to facilitate physical exertions, and mature mushrooms are used for visionary purposes – though this information seems to contradict itself. It is said that the cap "must not be bigger than the hollow of the hand with crooked fingers" [10-15cm across]. Dosages vary with individual tolerance and with batch potency – to test the water, beginners may start with one dried, moderate-sized mushroom [perhaps cap 10cm across fresh], or ¼-½ a cup of dried, finely chopped mushroom [which may be 2-4 specimens of mixed size – up to 21 or more have been used in Siberia, where odd-numbered doses are the rule]. It is said that "if you feel after eating two fungi that it is time to finish, you should still eat one more". They may simply be chewed and eaten, or chewed and the saliva swallowed, as is often the case in traditional practices. Alternately, they are extracted by water decoction or infusion, or macerated, and have been infused in fruit juice or with the juice of Epilobium angustifolium ['fire-weed', 'rose-bay willowherb' – see *Endnotes*] or of **Vaccinium** uliginosum, which is said to make the drink stronger (Emboden 1979a; Saar 1991; Stafford 1992; Wasson 1968; pers. exp.).

Some people prefer to smoke the dried skin of the cap (Rätsch 1990; pers. comms.), for a much weaker effect of shorter duration. However, the material does not burn well, and must be re-lit for each inhalation. Some people have noted no effects worth remarking on; often, large amounts must be smoked for a noticeable effect. In any case, it is actually the flesh just under the skin [cuticle] of the cap that is most potent, not the skin itself, which often causes some confusion (pers. comms.; pers. obs.).

The effect of A. muscaria is also claimed to be increased by drinking large quantities of cold water after ingestion. Drinking the urine of someone intoxicated by A. muscaria is also known to be effective, as is eating the flesh of a reindeer who had eaten it [only if killed when it is still inebriated]. This occurs because *muscimol* [see below] is passed through the body relatively unmetabolised.

Shortly after consumption, many feel the urge to lie down and rest or sleep [this is sometimes to minimise the transient nausea that may occur]. Physical effects are often felt before this, and manifest as nausea, trembling, sweating, and a mild sense of detachment – though in some batches, these adverse effects do not occur. Some of these side-effects might perhaps be due to small amounts of muscarine, a cholinergic toxin affecting muscarinic *acetylcholine* receptors [see *Neurochemistry*], or perhaps to vanadium or amavadin [a vanadium chelate] when present in large amounts. The sleep stage is light, and the subject may often still be partly aware of surrounding sounds, and in this phase the CNS effects of the mushrooms usually first become apparent, with strange lucid dreams occurring. After 1-2 hours, the subject arises and feels to have awoken to a different world – usually, things appear the same, yet undeniably different in an inexplicable way. A positive, even euphoric, playful mental state is experienced, yet physical co-ordination and basic motor skills may be greatly impaired, and twitching may occur. Pleasant auditory and visual effects may be experienced, as well as peculiar somatic hallucinations. Objects or the self sometimes appear either greatly magnified or shrunken. Sometimes, one's awareness of the outside world may be virtually non-existent for several hours. Adverse experiences are known, however – some have found themselves trapped in self-repeating time-loops, where they experienced the same short time-period over and over again until the effects wore off, and this usually produced a dysphoric reaction towards the episode. The main body of effects may last from 4-8 hours or so, with no notable after-effects (Festi & Bianchi 1990; Hatfield & Brady 1975; Ott 1993; Saar 1991; Stafford 1992; Weil & Rosen 1983; pers. exp.; pers. comms.).

The chemicals mainly responsible for the characteristic symptoms of A. muscaria and A. pantherina are the isoxazoles *ibotenic acid* and *muscimol*. *Muscimol* apparently does not occur in the fresh mushroom, but is formed during extraction or preparation, by simultaneous decarboxylation and dehydration of *ibotenic acid*. Pharmacologically, *muscimol* is 5-10 times as potent as *ibotenic acid*. Muscazone, which is closely related chemically to *ibotenic acid*, has not been adequately investigated pharmacologically. In animals it has shown 'sedative' activity similar to, but weaker, than that produced by *ibotenic acid* and *muscimol* under the same testing conditions (Bresinsky & Besl 1989; Waser 1967). The cholinergic toxin muscarine was once thought to be the psychoactive chemical present in A. muscaria, but it is now known to be present in quantities generally too small to be significant, and in any case, shows only weak oral activity (Eugster 1967; Waser 1967). The non-protein amino acids stizolobic acid and stizolobinic acid may also be contributors to the activity of species in which they are present. They are still little-studied, but have shown neuronal depolarising activity in rat spinal cord. Stizolobic acid, the most potent of the two, was more potent than *glutamic acid* in these tests. In rat cerebral cortex, stizolobic acid caused excitation in most neurons affected by *glutamic acid*, and potentiated other excitatory amino acids (Ishida & Shinozaki 1988). Amavadin is also found in some of these species [see below], and when present, is usually most concentrated in the stems (Koch et al. 1987). If amavadin is shown to have toxic effects, then there may be a chemical basis for some people's preference for the caps of psychoactive species [as some use only the caps and discard the stems] (theobromus pers. comm.).

Treatment for intoxication from A. muscaria and chemically similar relatives consists of inducing vomiting and taking activated charcoal (Michelot & Melendez-Howell 2003). However, this might only be useful if the ingestion was very recent - once the effects have taken hold it seems unlikely that much unabsorbed drug would remain in the stomach. Unless a very high and possibly dangerous dose has been consumed, the best course is probably to just deal with it in a safe place [not in hospital] until the effects inevitably wear off, as normal doses have no real risk except the possibility of inadvertent self-harm due to loss of motor coordination (pers. obs.). Cholinesterase inhibitors such as physostigmine, once considered an antidote to A. muscaria intoxication, are still suggested by some physicians (Michelot & Melendez-Howell 2003) yet in reality are useless in this context, deriving from the outdated belief that the mushroom is active due to its [low] muscarine content.

Some **Amanita** spp. contain highly toxic chemicals and are commonly responsible for deaths of careless mushroom hunters [usually seeking edible mushrooms, rather than the psychoactive species discussed here; for further discussion see the end of this entry]. Some **Amanita** spp. are also prized edible mushrooms, such as A. caesarea, A. rubescens [see below] and A. lanei [A. calyptroderma].

A. citrina has yielded 0.04-1.693% *bufotenine*, *bufotenine* N-oxide [Stijve (1979) reported that "all samples contained 300-600mg", though did not note whether this referred to individual specimens, and if so, their weights], 0-0.025% *tryptophan*, 0-0.593% *5-hydroxytryptophan*, traces of *serotonin* [Stijve reported "all samples contained 100-200mg"; see above], 0-0.039% N-methyl-*serotonin*, 0-0.06% *tryptamine* (Beutler & Der Marderosian 1981; Beutler & Vergeer 1980; Stijve 1979; Wurst et al. 1992), and traces of *DMT* and *5-methoxy-DMT*. Cultured mycelium of German A. citrina was shown to contain c.0.03% *bufotenine* and traces of other compounds (Tyler & Gröger 1964a). In European samples [pooled from Germany, Netherlands and Switzerland], *bufotenine* content was low [c.0.8%] in caps [reported as 'bulbs' – presumably immature specimens were analysed?], with higher yields obtained from stems [c.1.5%]. The 'bulbs' were richer in *5-hydroxytryptophan* content (Stijve 1979). An ex-

tract was shown to inhibit *glutamic acid* neurotransmission in rat hippocampus, due to activation of 5-HT receptors (Moldavan et al. 2002). A. citrina is easily confused with deadly species such as A. phalloides.

A. cothurnata from Virginia has yielded large amounts of *ibotenic acid* and *muscimol* (Chilton & Ott 1976).

A. gemmata has yielded *muscimol* (Beutler & Der Marderosian 1981) and *ibotenic acid* in small amounts, as well as traces of stizolobic acid and stizolobinic acid (Bresinsky & Besl 1989; Chilton & Ott 1976). Though others have found no isoxazoles in typical N. American samples, specimens that were intermediate with A. pantherina contained isoxazoles (Benedict et al. 1966).

A. muscaria fresh samples from Italy yielded 0.038% *muscimol* and 0.099% *ibotenic acid* from caps, and 0.008% *muscimol* and 0.023% *ibotenic acid* from stems (Gennaro et al. 1997). Japanese specimens [many lacking stems] were found to contain <0.001-0.28% *ibotenic acid* and 0.0046-0.1% *muscimol* in caps; neither were detected in stems of one sample. Cap cuticle contained <0.001-0.019% *ibotenic acid* and <0.0025-0.03% *muscimol*; cap flesh contained <0.001-0.14% *ibotenic acid* and 0.012-0.077% *muscimol* (Tsujikawa et al. 2006). Brazilian specimens yielded 0.08-0.13% *muscimol* (Stijve & de Meijer 1993). Samples from many locations have yielded large amounts of *ibotenic acid* and *muscimol* [up to 0.18% combined, though some yielded none], with traces of muscazone [Eugster et al. (1965) only found it in summer-fruiting Swiss specimens], 1-methyl-1,2,3,4-tetrahydro-β-carboline 3-carboxylic acid, R-4-OH-pyrrolidone, β-N-butyl-D-glucopyranoside, stizolobic acid, stizolobinic acid [A. muscaria var. formosa also yielded larger quantities of these latter two compounds] (Benedict et al. 1966; Chilton & Ott 1976; Eugster 1967; Eugster et al. 1965; Festi & Bianchi 1990; Hatfield & Brady 1975; Takemoto et al. 1964b), traces of muscarine [0.0002% or more, w/w] (Eugster 1967), muscaridine [0.00003%, as the chloroaurate; not stated whether w/w or d/w], *acetylcholine* (Kögl et al. 1960), *choline*, *atropine*, *hyoscine*, *hyoscyamine* and *bufotenine*. The presence of these last 4 alkaloids is now strongly doubted, and others have failed to detect them in this species. In any case, the quantities purported to have been found would be pharmacologically insignificant (Eugster 1967, 1968; Festi & Bianchi 1990; Stijve 1979; Tyler 1961; Waser 1967). Vanadium and amavadin [mostly in stems] have also been found (Gillard & Lancashire 1984; Koch et al. 1987). The pigmentation of the cap is due to muscaflavin, muscaurins I-VII, muscapurpurin (Hatfield & Brady 1975; Musso 1979), muscarubin and muscarufin. Dioleine 1,3 is thought to be the fly-attracting component. A glucan-derivative, AM-ASN, shows some antitumor activity. Worryingly, some researchers suspect this species of containing small amounts of amatoxins and/or phallotoxins, with one study apparently detecting traces of amatoxins, but this needs further study and confirmation. The haemolysin phallolysin, found in A. phalloides, has also been detected. The species may accumulate high levels of heavy metals from the environment, which is also a cause for concern (Michelot & Melendez-Howell 2003). An extract of A. muscaria was shown to excite glutamic-NMDA receptors and muscarinic *acetylcholine* receptors in rat hippocampus (Moldavan et al. 2002).

Extracts available in the Japanese drug underground, purporting to contain A. muscaria, contained only small amounts of *ibotenic acid* and/or *muscimol*, and also contained adulterants such as *caffeine*, *hyoscine*, *atropine*, *harmine*, *harmaline*, *5-MeO-DMT* and the synthetic 5-MeO-DIPT [5-methoxy-diisopropyltryptamine] (Tsujikawa et al. 2006).

A. pantherina from many locations yields large amounts of *ibotenic acid* and *muscimol* [up to c.0.46% combined, though some yielded none], with varying smaller amounts of stizolobic acid and stizolobinic acid (Benedict et al. 1966; Chilton & Ott 1976; Repke et al. 1978; Takemoto et al. 1964b); muscazone has also been found in some samples (Ott 1993), as well as (2R),(1R)- and (2R),(1S)-2-amino-3-(1,2-dicarboxyethylthio) propanoic acid [NMDA receptor antagonists] (Michelot & Melendez-Howell 2003). Small amounts of muscarine have been found, of which 53% was present as epi-muscarine (Stadelmann et al. 1976), which is apparently inactive (Bresinsky & Besl 1989). Japanese specimens were found to contain 0.019-0.027% *ibotenic acid* and 0.15-0.19% *muscimol* in caps, and <0.001% *ibotenic acid* and 0.064% *muscimol* in stems; cap cuticle contained 0.049-0.051% *ibotenic acid* and 0.093-0.13% *muscimol*, whereas cap flesh contained 0.038-0.098% *ibotenic acid* and 0.12-0.35% *muscimol* (Tsujikawa et al. 2006). It is said to have yielded *bufotenine*, but others have failed to replicate this (Stijve 1979; Tyler 1961). An extract was shown to excite glutamic-NMDA receptors and muscarinic *acetylcholine* receptors in rat hippocampus (Moldavan et al. 2002). A. pantherina may be easily confused with the similar A. spissa [A. excelsa], which is considered edible. They can mainly be differentiated by the fact that the 'bulb' of A. spissa runs gradually into the stipe, whereas that of A. pantherina is abruptly emarginate (Bresinsky & Besl 1989).

A. porphyria has yielded 0.01-0.617% *bufotenine*, 0-0.51% *5-hydroxytryptophan*, traces of *serotonin*, 0-0.072% N-methyl-*serotonin* (Beutler & Der Marderosian 1981; Wurst et al. 1992), *bufotenine* N-oxide and traces of *5-methoxy-DMT* (Tyler & Gröger 1964a). Another test found only 0.22-0.51% *5-hydroxytryptophan* and small amounts of *serotonin* (Beutler & Vergeer 1980).

A. regalis, considered by some to simply be a variant of A. muscaria [to which it is very similar], has yielded *ibotenic acid* and *muscimol* [0.1-0.62% combined in Swiss specimens] (Bresinsky & Besl 1989; Stijve 2000), as well as 0.0032-0.0192% vanadium (Meisch et al. 1979), and amavadin, the latter mostly in the stems (Koch et al. 1987).

A. rubescens collected in former Czechoslovakia was found by Wurst et al. (1992) to contain 0.018-0.02% *bufotenine*, although in the same research paper the authors also state that "A. rubescens contains no *bufotenine*" (Wurst et al. 1992). This species is considered edible only after cooking in water and discarding the water (Phillips 1981). It is rather similar in appearance to A. pantherina (pers. obs.).

A. solitaria has been found to contain 2 unidentified isoxazole-like compounds, solitaric acid and solitarine, which resembled *ibotenic acid* and *muscimol*, respectively, in chromatography and colour reactions (Benedict et al. 1966).

A. strobiliformis from Japan [but not those from North America or Europe] yielded *ibotenic acid*, as well as *aspartic acid*, *glutamic acid*, *glycine*, alanine, leucine, isoleucine, proline, threonine, serine, valine, *phenylalanine* and tyrosine (Chilton & Ott 1976; Takemoto et al. 1964a). It is now thought that the Japanese specimens may not have been A. strobiliformis, but possibly A. pantherina or another similar species (Benedict 1972; Benedict et al. 1966).

A. tomentella has also yielded *bufotenine* (Beutler & Der Marderosian 1981; Tyler 1961).

A. velatipes, considered a variety of A. pantherina, yielded 0.0397% vanadium from the cap (Meisch et al. 1979); amavadin was also found, mostly in the stems (Koch et al. 1987).

Amanita muscaria has a pileus 8-20cm across, globose or hemispherical at first then flattening, bright scarlet covered with distinctive white pyramidal warts which may be washed off by rain, leaving the cap almost smooth and the colour faded; stipe 80-180 x 10-20mm, white, often covered in shaggy volval remnants as is the bulbous base, the white membranous ring attached to the stem apex sometimes flushed yellow from the pigment washed off from the cap; flesh white, tinged red or yellow below the cap cuticle; taste pleasant to unpleasant, smell faint, becoming stronger on drying; gills free, white; spore print white; spores broadly ovate, nonamyloid, 9.5-10.5 x 7-8µ. Late summer to late autumn.

Grows in a mycorrhizal relationship with birch trees [Betula spp.] and other European trees [eg. oak (Quercus spp.) and pine (Pinus spp.)]; common (Phillips 1981); Europe, Great Britain, temperate Asia, N. America, Australia, New Zealand.

Care should be taken when collecting Amanita spp., as some species [A. bisporigera, A. dunensis, A. ochreata, A. phalloides ('destroying angel'), A. subalbiacea, A. tenuifolia, A. verna ('white death cap') and A. virosa ('destroying angel')] can be deadly. Violent gastric disturbance usually occurs 6-24hrs after ingestion, followed by an apparent remission of symptoms. Some 2-4 days later, effects related to serious liver and kidney damage emerge, and death may result. These species contain peptides that are toxic to the liver, such as the amatoxins, phallotoxins and virotoxins (Bresinsky & Besl 1989; Hatfield & Brady 1975; Low 1985); muscarine has also been found in A. phalloides, accompanied by epi-muscarine (Stadelmann et al. 1976). These fungi, however, bear little resemblance to A. muscaria, being mostly white. Still check a good guidebook, though…better safe than sorry [dead]! NEVER consume an unknown Amanita sp. or one that you feel at all uncertain about. The same can be said for all plants and fungi.

A simple field test has been devised to evaluate the presence of some amatoxins in fresh or dried mushrooms (Beutler & Vergeer 1980), which may be invaluable to the curious ethnomycologist [see *Producing Plant Drugs*].

AMARANTHUS

(Amaranthaceae)

Amaranthus spinosus *L.* **(A. caracasanus** *Kunth***)** – thorny amaranth, spiny pigweed, caruru de espinho, espina de la playa, quiltonil de burro, quiltonil de pajaro, achpar-ba, Janum leper-ara, auia kiaka, le xian cai

This weedy herb has interesting usage by the Lodha of west Bengal. The powdered dry roots are smoked to induce 'hallucinations', and it is said that eating the root paste can cause temporary insanity. In other areas, the leaves or root paste are applied externally to wounds and bubos (Pal & Jain 1989). The Cherokee use the leaf as an astringent, to relieve heavy menstruation (Hamel & Chiltoskey 1975); they also use the plant in 'ceremonial medicine' (Ott 1993). In Basutoland, the plant is used as an ash added to snuffing tobacco [see **Nicotiana**]; it is also used in snuffs in Transvaal, though the form of preparation was not mentioned. A. caudatus is also more commonly added to snuffs in south-eastern Africa (Watt & Breyer-Brandwijk 1962). In Mt Lamington, n. Papua New Guinea, the Orakaiva use an unidentified Amaranthus sp. ['tumeni'] with another unidentified cockscomb ['siroru'; Celosia sp.?], "to produce a ceremonial shaking fit" (Thomas 2001a).

In Australia, A. macrocarpus, A. paniculatus, A. spinosus and A. viridis have been suspected of causing poisoning in livestock (Webb 1948). In Brazil, A. spinosus is known to cause cattle intoxications, with symptoms including prostration, difficulty in walking, oedema in the neck, and dark, foetid diarrhoea (Pott & Alfonso 2000). Amaranthus spp. have been used as food in many countries, for the edible leaves and seed of many species (Genders 1988; Low 1991b).

A. blitum and A. graecizans, which are considered poisonous in Russia, contained 0.63-0.7% alkaloids in leaves, and 0.4-0.45% in stems (Abdulla-Zade & Agamirova 1965).

A. spinosus leaves and stems have yielded hentriacontane and α-spinasterol; roots have yielded α-spinasterol, α-spinasterol octacosanoate, oleanolic acid, D-glucose, D-glucuronic acid, and β-D-glucopyranosyl(1→4)-β-D-glucopyranosyl(1→4)-β-D-glucopyranosyl(1→3)-oleanolic acid; the plant has also yielded, from unspecified parts, quercetin, rutin, stigmasterol, campesterol, cholesterol, stearic acid, oleic acid and linoleic acid (Rastogi & Mehrotra ed. 1990-1993). Leaf, stem and root from Brisbane, Queensland [Australia], harvested in April, gave negative tests for alkaloids (Webb 1949). As well as A. angustifolia, it tested positive for HCN [whole plant] (Watt & Breyer-Brandwijk 1962).

Amaranthus spinosus is an erect, branched glabrous herb to 1m tall, varying in colour from green to red or purple, with 2-5 straight, divergent spines 5-10mm long at most axil nodes; stems terete. Leaves alternate, ovate-lanceolate or oblong, 3-10 x 1.9-5.1cm, narrowed to an obtuse mucronate apex, base broadly cuneate to petiole; petiole slender, equalling the blade or shorter. Flower spikes numerous, dense, 5-15cm long, 6-10mm thick, bisexual, flowers unisexual, c.1mm long, terminal parts mostly male, basal parts and axillary clusters mostly female; bracts setaceous, equalling or exceeding sepals; sepals of female flowers 5, oblong, obtuse, 1-1.5mm long, apiculate; sepals of male acuminate; stamens 5, free; anthers 2-celled; staminodes 0. Ovary compressed; style short or absent; stigmas 2, filiform or subulate; ovule 1, erect. Utricle rugose, nearly equalling sepals. Achene rugose, thin and loose, 1.5-2mm long, tip entire or 2-3-toothed, bursting irregularly, terminal portion spongy and rough; seed nearly circular, orbicular, compressed, 0.7-1mm wide, testa crustaceous, black, shining.

An abundant weed in warm zones of both hemispheres, in wasteland, crops and stock yards; of doubtful origin (Gleason 1952; Hooker 1954-1961). Found in Australia along the central and north coast of NSW, and the Queensland coast (Auld & Medd 1992).

AMSONIA

(Apocynaceae)

Amsonia tabernaemontana *Walter*

This North American herb has no ethnobotanical uses to my knowledge – however, it has yielded some interesting alkaloids.

As well as the green parts and roots yielding the β-carbolines *harmine* [0.0036% from whole plant, in one test], *harmalol* and *tetrahydroharman* (Lutomski & Nowicka 1969; Lutomski et al. 1968c), the leaves have yielded the indole alkaloids (-)-tetrahydroalstonine, (+)-*akuammidine*, (-)-dihydro-18,19-corynantheol, (+)-dihydro-19,20-condylocarpine, (+)-aspidospermidine, (+)-Δ1-aspidospermidine, (-)-N-formyl-aspidospermidine, (+)-1,2-dihydro-aspidospermidine, (-)-quebrachamine, and (+)-vincadifformine (Panas et al. 1972; Zsadon & Kaposi 1972), and roots have yielded the indole alkaloids (+)-Δ1-aspidospermidine, (-)-eburnamine, (+)-eburnamonine, (-)-nor-C-fluorocurarine, (-)-quebrachamine, and 2 unidentified alkaloids (Panas et al. 1973). Other indole alkaloids have been found in the plant – eburenine, (-)-tabersonine [hypotensive; see **Voacanga**], vincadine, 14,15-dehydrovincadine, epivincadine, dehydroepivincadine, 14,15-dehydroepivincadine, 16-α-carbomethoxy-quebrachamine, 16-β-carbomethoxy-(-)-quebrachamine, lochnericine, (-)-tetrahydropresecamine, tetrahydrosecamine, and decarbomethoxy-tetrahydrosecamine. Members of the genus have also reportedly yielded (+)-*yohimbine* and β-*yohimbine* (Buckingham et al. ed. 1994; Ganzinger & Hesse 1976).

The related A. elliptica [from Japan] has yielded 0.36% tabersonine hydrochloride, tabersonine N-oxide, 0.061% 3-oxo-tabersonine, 0.026% tetrahydroalstonine, 0.0008% Δ14-*vincamine*, 0.007% 16-epi-Δ14-*vincamine*, 0.051% 14,15-epoxy-3-oxo-vincadifformine, and 0.0028% 16-carbomethoxy-16-OH-14,15-epoxy-3-oxo-1,2-dehydro-aspidospermidine from the seeds (Aimi et al. 1978).

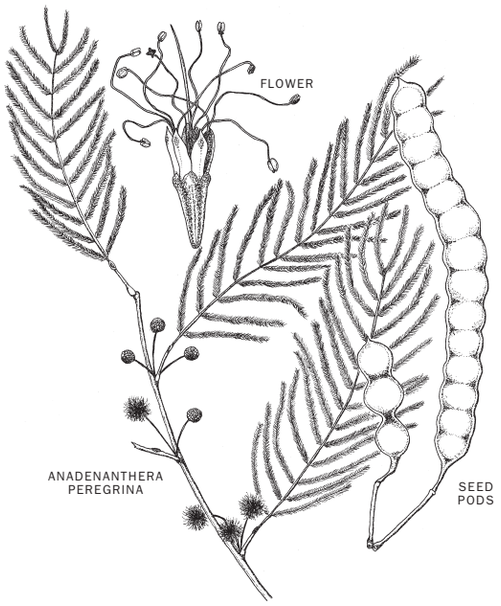
Amsonia tabernaemontana is an erect, perennial herb, with erect stems 40-100cm tall. Leaves alternate or irregularly scattered, thin,

opaquely green, narrowly lanceolate to ovate or broadly elliptic, 8-15cm long, acuminate, obtuse or acute at base, glabrous or finely pubescent beneath. Blue flowers in terminal cymes, cymes flat to pyramidal, many-flowered; calyx deeply 5-parted; corolla salverform, villous in the throat, its 5 lobes lanceolate, corolla tube 6-10mm long, corolla limb c.1cm wide; anthers separate. Ovaries 2, many-ovuled, without nectaries. Follicles cylindric, erect, 8-12cm long; seeds naked. Fl. May-Jun.

In moist or wet woods on the coastal plain, New Jersey to Vancouver, more widely distributed in the southern states west to Oklahoma and Texas, north in the interior to s. Indiana, c. Illinois, Montana and Kansas (Gleason 1952).

ANADENANTHERA [including PIPTADENIA]

(Leguminosae/Mimosaceae)



Anadenanthera colubrina var. colubrina *(Vellozo) Brenan* **(Acacia colubrina** *(Vell.) Mart.***; Mimosa colubrina** *Vell.***; Piptadenia colubrina** *(Vell. Conc.) Benth.***)**

Anadenanthera colubrina *(Vell.) Bren.* **var. cebil** *(Grisebach) Altschul* **(A. macrocarpa** *(Benth.) Brenan***; Piptadenia macrocarpa** *Benth.***; P. microphylla** *Benth.***)** – vilca, villca, huillca, wilka, cebil, hatáj, hatáj ilé, kurupa, curupáy-curú

Anadenanthera excelsa *Grisebach* **(Piptadenia excelsa** *(Gris.) Lillo***)**

Anadenanthera peregrina var. peregrina *(L.) Spegazzini* **(Acacia microphylla** *Willd.***; A. niopo** *(Humb., Bonpl., et Willd.) Humb.***; Piptadenia peregrina** *(L.) Benth.***)** – yopo, yupa, cohoba, niopo, ñopo, curupa, curupáy, hisiomi, huillca, mori, paricà, ai'ku:duwha, angico, acuja

Anadenanthera peregrina *(L.) Speg.* **var. falcata** *(Benth.) Alt.* **(A. falcata** *(Benth.) Speg.***; Piptadenia falcata** *Benth.***)**

Piptadenia communis *Benth.*

Piptadenia contorta *(DC.) Benth.* **(Acacia contorta** *DC.***; Newtonia contorta** *(DC.) Burkart***; Pseudopiptadenia contorta** *(DC.) G.P. Lewis et M.P. Lima***)** – angico, angico-branco, saia-de-comadre

Piptadenia gonoacantha *(Mart.) Macbr.* **(Acacia gonoacantha** *Mart.***; Pityrocarpa gonoacantha** *(Mart.) Brenan***)**

Piptadenia leptostachya *Benth.* **(Monoschisma leptostachyum** *(Benth.) Brenan***; Pseudopiptadenia leptostachya** *(Benth.) Rausch.***)**

Piptadenia moniliformis *Benth.* **(P. obliqua** *(Pers.) J.F. Macbr.***)** – jurema preta, angico de bezerro, estralador, feijaozinho braco, kip, quip

Piptadenia novoguineensis *Warb.* **(Prosopis insularum ssp. novoguineensis** *(Warb.) Bret.***; Schleinitzia novoguineensis** *(Warb.) Guinet***; S. novoguineensis** *(Warb.) Verdc.***)**

Piptadenia paniculata *Benth.* **(Pityrocarpa paniculata** *(Benth.) Brenan***)**

Piptadenia rigida *Benth.* **(Anadenanthera rigida** *(Benth.) Altschul***)** – curupáy rá, vilcarán

Piptadenia stipulacea *(Benth.) Ducke* **(P. communis var. stipulacea** *Benth.***; Pityrocarpa stipulacea** *(Benth.) Brenan***)** – jurema branca

The seeds, and occasionally the bark, of A. colubrina var. cebil and A. peregrina var. peregrina form the basis of an entheogenic snuff which was formerly consumed over a large portion of S. America. Based on archaeological findings, the seeds of A. colubrina var. cebil are known to have been snuffed in central Peru since at least c.1200BC, and in n. Chile since at least c.780AD. They have been smoked in pipes even earlier, in n.w. Argentina since c.2130BC. Smoking pipes have been uncovered in central Chile, dating to c.500AD, though so far there is no evidence to determine what was smoked in them. Ancient use has also been reported from Paraguay, the West Indies [A. peregrina var. peregrina], and the s. Brazilian highlands [probably A. colubrina var. cebil] (Falabella et al. 2001; Schultes 1967b; Torres 1993, 1995; Torres et al. 1991). 'Vilca' or 'villca', as this snuff has been known, seems to have a variety of meanings. In one Quechua myth, a slain warrior captain known as 'Villca Quire' transferred the quality of vilca to the fruits of the tree he was buried under. In the Aymara language, 'villca' was the old word for the sun, also referring to shrines dedicated to the sun or other deities, and to the purgative medicinal visionary herb which is now understood to be A. colubrina var. cebil (Torres 2001). The Taínos of the Greater Antilles were the first culture observed by foreign explorers to consume 'cohoba', a snuff now known to have been made from seeds of A. peregrina var. peregrina. The purpose of consuming this snuff was to come into contact with the 'zemís', spirits which took a variety of forms [eg. specific deities, 'nature spirits', and intermediaries between worlds] and were often represented in carved statuettes (Torres 1998).

Up to the 16th century, A. colubrina var. cebil seeds were used as a snuff by Inca shamans, who were also sometimes known to consume them as an enema, or in 'chicha' beer [see *Methods of Ingestion*]. The leaves might also have been used in the preparation of snuffs and enemas. A. colubrina var. cebil seed snuff is still prepared and used in parts of Argentina, Paraguay, Peru and Bolivia. Mataco shamans of n. Argentina sometimes also smoke a cigarette made from 8-10 crumbled seeds with tobacco [see **Nicotiana**] and sometimes other herbs ['aromo' leaves - **Amaranthus** spp., **Acacia** caven, A. farnesiana] for the same effect, though often the whole cigarette is not needed for one session. Sometimes they may snuff and smoke the seeds in the same session. A. peregrina var. peregrina is still used in the Orinoco Basin [including Colombia, Ecuador, Venezuela, Brazil and Peru], notably by the Yanomamo, who prefer it over **Virola** [which they also snuff] because of its greater strength. Some tribes have reportedly taken the seeds orally [besides the use in chicha mentioned above], eating them boiled and mixed with honey, or drinking them after boiling 2-3 seeds in water with Polypodium spp. root [see *Endnotes*]. In Paraguay, both A. colubrina var. cebil and A. peregrina var. peregrina, as well as Piptadenia rigida, are reportedly used as 'inebriants'. The Guahibo of the Orinoco have also been observed to snuff A. peregrina var. peregrina whilst chewing **Banisteriopsis** liana, which should noticeably intensify the effects. Some tribes seem to take the snuff as a daily stimulant, whilst others reserve its use for shamans only, or it is used communally for special circumstances. Some, such as the Yanomamo, use the snuff almost casually, at any time of day. Generally it may be used to invoke the 'hekula spirits', in order to divine the cause of illness or the success of an upcoming hunting expedition. Sometimes it is inhaled in order to engage a sorcerer in shamanic combat. Some use it to sharpen the senses and intuition before hunting, and some [such as the Catauxi] may even administer it to their dogs for such purposes. The usual snuffing dose may start at 1-2 tsp, and more is taken as needed to reach the desired state (Brewer-Carias & Steyermark 1976; Chagnon 1992; Chagnon et al. 1971; Cobo 1990; Davis 1996; Fish & Horning 1956; Lizot 1985; Ott 1993; Rätsch 1998; Schleiffer 1973; Schultes 1955a, 1967b; Schultes & Hofmann 1980; Torres 1993, 1995, 1996; Torres & Repke 1996; Torres et al. 1991; Uscategui 1959; Wassen 1967).

On a related note, a Piptadenia sp. known as 'angico' [a name applied to some other Leguminous plants, including **Anadenanthera** spp. (Trout ed. 1998)] is considered a protective tree by the 'jurema' drinking Kariri-Shoko of n.e. Brazil (Da Mota 1997). In Brazil, P. stipulacea is known as 'jurema branca', and P. moniliformis as 'jurema preta' (Queiroz 2000), though it is not known whether these trees are used as the names would suggest [see **Mimosa**, **Acacia**, **Pithecellobium**].

Methods for the preparation of these snuffs vary from group to group, but there are several basic variations. In the 19th century, the Matpure of the Orinoco were observed to break open and moisten the seed-pods, allowing them to ferment until they turned black. The softened seeds were then ground into a cake together with flour and lime from snail shells. Richard Spruce observed a Gauhibo man roast the seeds before grinding them into a powder. The snuff may or may not be mixed with an alkaline substance such as lime, and does not seem to consist of any additive plants, unlike snuffs made from **Virola** (Schultes & Hofmann 1980).

It was once thought that the addition of lime or other alkali was necessary to facilitate absorption of the alkaloids. It now appears that lime is unnecessary for activity of the snuff, and only serves to make the snuff more painful when administered. The whole seeds may simply be lightly roasted [in a frying pan over low heat, with frequent stirring] until a peanut butter-like smell emerges and the seeds become brittle [but before visible fumes emerge]. They can then be ground finely and snuffed from a tray or flat surface through a short tube, or blown into the nose through a long tube by another person. They may also be smoked for a similar ef-

fect. It is not necessary to consume the full amount in a short time, as one would attempt with *DMT* and *5-methoxy-DMT* [see below]. The effects creep up over several minutes to peak after about 5-10 minutes, lasting an hour or less overall. The effects are best appreciated in low or dim light levels, lying down or reclining. Effects are usually felt as heavy tranquillisation and relaxation of the body and mind, with alterations in somatic sensation and slowing and abstracting of thoughts, and with mild visual alterations, which are more intense behind closed eyes. Side effects, when present, may include headache, nausea and/or feelings of intense pressure; one person described feeling very unpleasantly like a 'plucked chicken' over his entire body after smoking 1 A. colubrina var. cebil seed (pers. comms.; pers. obs.). Anecdotal evidence suggests that undesirable side effects may be avoided by discarding the seed husks and instead smoking the roasted, ground inner seed; and by spacing inhalations a few minutes apart (friendly pers. comm.).

It seems that certainty of the source species not does guarantee that the seeds will produce desirable effects; with some seed batches, unpleasant side effects predominate, with minimal psychoactivity. It is unclear at this time which elements of seed chemistry are responsible for these toxic symptoms, though this could be deduced from a simple comparitive analysis of seed batches with known effects. In the past people had assumed such effects were due to *bufotenine*; however, seed batches verified to contain predominantly *bufotenine* have a good record of positive experiences resulting from their ingestion. Perhaps the difference could lie also in individual variations in human neurochemistry and metabolic function (pers. comms.; pers. obs.).

Jonathan Ott described "sinuous, multihued, arabesque patterns, first viewed behind closed eyes, then on a stuccoed wall in a darkened hallway, and at length even on surfaces" from an experiment using snuff prepared from A. colubrina var. cebil seeds (Ott 2001a).

In one experiment I smoked 5 A. colubrina var. cebil seeds, crumbled to powder with a small quantity of tobacco [see **Nicotiana**], through a water-pipe, whilst under the influence of LSD. This was done during the latter part of the LSD experience, when closed-eye visuals were barely apparent. The seeds have a strong, characteristic smell when smoked, somewhat comparable to an imagined mix between peanut butter and *DMT*. Effects as described above were felt whilst still smoking the mixture, and grew in strength after lying down in the dark. I had a headache previously, which was intensified by smoking the seeds, but wore off with the effects of the seeds. Visual effects were perceived clearly behind closed eyes for several minutes. I was shown a complex framed lattice-like pattern in shades of brown and sandy-yellow, which gave the impression of containing much information, and demanded closer inspection. The feeling was of being in a panoramic gallery which contained only the one work of art (pers. obs.).

The seed pods of A. colubrina var. cebil have also been found to be pleasantly psychoactive when smoked. One segment of a pod, crumbled or ground and smoked through a water pipe, may be sufficient to produce effects. These take several minutes to creep up, developing into a pleasant 'stoned' state with slight enhancement of perception. Many people who have experimented with this particular batch of seed pods feel that the major alkaloid present is probably *5-methoxy-DMT* (friendly pers. comm. 2002; pers. obs.). However, this alkaloid has not yet been reported from verifiable samples of this species [see below].

One friend experimented with A. colubrina seeds as the *tryptamine*-alkaloid component of an 'ayahuasca analogue' [see *Methods of Ingestion*]. A dose of 9 seeds proved to be active with MAOI, taking effect within 30 minutes of consumption. Visual effects included the perception of people's faces appearing as masks, and were generally characteristic of *bufotenine* psychoactivity, although no negative side-effects were reported (E pers. comm.).

In another interesting experiment, two psychonauts each consumed 4 toasted, ground A. colubrina seeds, mixed into a glass of fresh grapefruit juice [see **Citrus**], and drunk quickly [no MAOI was consumed]. Whilst one psychonaut was feeling the first effects within 15min., the other did not notice anything until 45min. later. To quote the first subject – "The feeling started with the familiar closed eye images [which he had experienced previously from smoking the seeds – Ed.], and soon escalated into a beautiful feeling of electricity throughout my mind and body. Open eye visuals, mental and physical effects were much fuller and more vivid [compared to the smoking experience – Ed.]. My depth perception was increased quite a bit, and 'tracers' seemed to be more detailed and 'worked in' to the visual patterns than with [**Psilocybe**] mushrooms or **Salvia** divinorum. The effects lasted several hours [...] I slept well that night with no physical effects the next morning" (Jake pers. comm.).

Anandenanthera seed snuffs contain psychedelic *tryptamine* alkaloids which are responsible for the effects. Those responsible were long presumed to be *DMT* and *5-methoxy-DMT* [*5-MeO-DMT*], as *bufotenine* [*5-OH-DMT*] was believed to be toxic with no redeeming qualities. However it is now apparent that these alkaloids are usually only present in trace amounts compared to the predominant *5-OH-DMT* component, and are not consumed in quantities that could be effective (Torres & Repke 1996; Torres pers. comm. 1999). It seems that *5-OH-DMT* is indeed psychoactive after all, and many of its adherents would class it as a psychedelic or entheogen (see also McLeod & Sitaram 1985; Ott 2001a; *Chemical Index*).

A sample of 'paricà' snuff [of unknown plant origin], as used by the Piaroa, was found to contain *DMT*, *5-OH-DMT*, *5-MeO-DMT* and *harmine* (Holmstedt & Lindgren 1967). Though the *5-OH-DMT* component suggests that the snuff was derived from an Anandenanthera sp., the presence of *harmine* is unusual, and may have arisen from an admixture of **Banisteriopsis**.

A. colubrina var. colubrina seeds have yielded 2.1% *5-OH-DMT* (Pachter et al. 1959) and *DMT*; two other unidentified peaks were observed by chromatography (Yamasato et al. 1972).

A. colubrina var. cebil seeds yielded 3.51-12.4% *5-OH-DMT* [some samples contain only *5-OH-DMT*; the high value here is an exception to the norm, which may usually hover around 3%], *5-OH-DMT* N-oxide, 0.57% N-methyl-*serotonin*, 0.06% *DMT*, *DMT* N-oxide (Fish & Horning 1956; Fish et al. 1955; Iacobucci & Rúveda 1964; Torres & Repke 1996), djenkolic acid, N-acetyldjenkolic acid, pipecolic acid [2-piperidinecarboxylic acid], 5-OH-pipecolic acid, and 4-OH-pipecolic acid [as P. macrocarpa], or 4-OH-pipecolic acid alone [as A. macrocarpa] (Krauss & Reinbothe 1973). Seed pods have yielded *5-OH-DMT* and *DMT* [some contained only *DMT*]; the bark has yielded 0.1% 5-MeO-*N-methyltryptamine* (Fish et al. 1955; Iacobucci & Rúveda 1964), and traces of *5-OH-DMT* and *DMT* (Torres & Repke 1996). Snuff samples recovered from archaeological sites at San Pedro de Atacama [n. Chile], believed to have originated from A. colubrina or A. colubrina var. cebil, were found to contain *DMT*, *5-MeO-DMT* and *5-OH-DMT* (Torres et al. 1991).

A. excelsa seeds have yielded *5-OH-DMT* and *5-OH-DMT* N-oxide; seed pods have yielded *DMT*. Bark contained no alkaloids, though earlier research found an uncharacterised quaternary alkaloid in bark of this species (Iacobucci & Rúveda 1964). As P. excelsa, seeds were screened for amino acids and shown to contain primarily albizziine, N-acetyldjenkolic acid, and 5-OH-pipecolic acid, with smaller amounts of djenkolic acid and S-(β-carboxyethyl)-cysteine (Krauss & Reinbothe 1973).

A. peregrina var. peregrina seeds have yielded 0.009-2% alkaloids [though up to 7.4% *5-OH-DMT* alone has been found] – mostly [6-100%] *5-OH-DMT*, *5-OH-DMT* N-oxide, *DMT* [0-75%], *DMT* N-oxide, *5-MeO-DMT* [0-19%], *N-methyltryptamine* [*NMT*] and traces of 2-methyl-THβC, 2-methyl-6-MeO-THβC [2-methyl-*pinoline*] and 1,2-dimethyl-6-MeO-THβC [1,2-dimethyl-*pinoline*] (Agurell et al. 1968a; Chagnon et al. 1971; De Smet & Rivier 1987; Fellows & Bell 1971; Fish et al. 1955; Holmstedt & Lindgren 1967; Schultes et al. 1977b; Stromberg 1954; Yamasato et al. 1972). Experiments on the changes in chemical composition through aging showed that freshly collected seed contained mostly *5-OH-DMT* and *DMT*, with smaller amounts of *5-MeO-DMT* and 2-methyl-THβC; when stored [20°C, in darkness] for longer than a year, only *5-OH-DMT* was detected (De Smet & Rivier 1987; Rivier 1980). Bark yielded *DMT*, 0.4% 5-MeO-*NMT*, 0.64% *5-MeO-DMT*, 0.4% *NMT* and traces of 2-methyl-THβC, 2-methyl-*pinoline* [0.001%], 1,2-dimethyl-*pinoline* [0.001%] and *pinoline* (Holmstedt & Lindgren 1967; Legler & Tschesche 1963; Shulgin & Shulgin 1997; Torres & Repke 1996). Another study of the bark found only 0.042% alkaloids, consisting of 59% *5-MeO-DMT*, 36% 5-MeO-*NMT*, 1% *DMT*, 2% 2-methyl-*pinoline* and 2% 1,2-dimethyl-*pinoline*; yet another found 0.041% alkaloids, which was 95% *5-MeO-DMT* and 5% *DMT*. Leaves yielded 0.013-0.107% alkaloids, of which 12-49% was *DMT*, 48-88% *5-MeO-DMT*, along with traces of *NMT* (Agurell et al. 1969a; Schultes et al. 1977b); twigs have yielded 0.038% alkaloids, made up of 94% *5-MeO-DMT*, 5% *DMT* and 1% *5-OH-DMT*. Seedlings yielded in one collection 0.001% alkaloids, entirely *DMT*, and in another collection, 0.025% alkaloids, of the same type and proportion as in the twigs; seedlings in other tests [during 1st week of germination] yielded *5-OH-DMT* from the first day, with *serotonin* [*5-HT*], N-methyl-*5-HT* and *tryptamine* appearing in that order over the next week. Roots yielded 0.699% alkaloids, which was 97% *5-MeO-DMT*, 2% *DMT* and 1% *5-OH-DMT* (Fellows & Bell 1971; Schultes et al. 1977b; Torres & Repke 1996).

A. peregrina var. falcata has been poorly analysed, but *5-OH-DMT* was initially found in the seed (Der Marderosian 1967); later analysis found 4.9% alkaloids in seeds [95% *5-MeO-DMT*, 3% *DMT*, 1% *5-OH-DMT*], 0.28% in fruit [70% *5-MeO-DMT*, 25% *DMT*, 2% *5-OH-DMT*] and 1.6% in bark [60% *5-OH-DMT*, the remainder not identified] (Nunes et al. 1982a).

P. communis seeds have been found to contain *5-OH-DMT* and related compounds which were not identified (Altschul 1964).

P. contorta seeds have tested positive for the presence of *DMT*, *5-OH-DMT*, and one other unidentified compound.

P. gonoacantha seeds have yielded 1.2% alkaloids [40% *DMT*, 10% *5-MeO-DMT*]; fruit yielded 0.7% [10% *DMT*]; and bark yielded 0.2% [35% *DMT*, 1% *5-OH-DMT*] (Nunes et al. 1982a).

P. leptostachya seeds yielded 0.03% *theobromine*, as well as *5-OH-DMT* (Altschul 1964; Yamasato et al. 1972).

P. moniliformis seeds tested positive for *5-OH-DMT* (Yamasato et al. 1972).

P. novoguineensis from Papua New Guinea yielded 0.05% of a base which was not identified. In animal assays, it appeared to be orally inactive below 2g/kg [in mice], causing weak CNS depression at this dose; in cats, 5-10mg/kg [i.v.] caused hypotension, and augmented the response to *epinephrine* (CSIRO 1990).

P. paniculata seeds tested positive for alkaloids (Fish et al. 1955).

P. paraguayensis was found to contain no alkaloids in seeds or seed pods, though traces of what appeared to be a non-indole alkaloid were detected in the bark.

P. rigida seeds were not found to contain any alkaloids.

P. viridiflora seeds and pods were not found to contain any alkaloids (Iacobucci & Rúveda 1964).

Anadenanthera peregrina var. peregrina is a small shrub to tall tree 3-27m tall, unarmed, or lower trunk with conical thorns or wedge-shaped projections, becoming tubercular-verrucose, slightly corky, rugose; trunk 20-40cm diam. at chest height, usually leaning, twisted, sometimes divided at base into several shafts, irregular branches spreading out above to form an umbrella-like crown; bark grey to nearly black, with many small lenticels; young twigs and foliage puberulent, occ. glaucescent; mature foliage glabrous, or nearly so. Leaves alternate, bipinnately compound, 12-30cm long incl. petioles, main rachis +- channeled ventrally; petioles somewhat darkened at base, 5-15mm above base bearing a flattish, oval or oblong gland 0.5-5mm long; 1-4 similar, smaller glands one between or just below each of the ultimate pinna pairs; pinna pairs 10-30 or more, each pinna 2-5cm or more long, opposite or subopposite; leaflets sessile, not always borne to very tip of pinna, usually imbricate, 25-80 pairs, 2-8 x 0.5-1.5mm, linear, oblong or lanceolate, mostly straight, base oblique or truncate, apex acute to acuminate-apiculate, membranaceous and dull, sometimes differing in colour and texture dorsiventrally, venation obscure but for single, nearly straight, slightly excentric midvein, margins usually ciliate or ciliolate; stipules small, bristly, fugacious, broad basal bracts enclosing new shoots often persistent. Inflorescence globose-capitate heads 10-18mm diam. (incl. stamens), greenish-white to creamy yellow, in fascicles of 1-5, puberulous to glabrous in bud, head axillary and subterminal, rarely in racemose patterns in branch apices; peduncles 1.75-4cm long, puberulous, filiform or thicker, c.¾ up bearing a puberulous, bidentate, campanulate involucre becoming detached and sliding down to loosely encircle peduncle base; flowers c.35-50 per head, small, sessile, each subtended by a linear-spathulate or deltoid bracteole ½ the length of mature corolla; calyx campanulate, 0.5-2.6mm long, 5-dentate; corolla tubular-campanulate, 2-3.5mm long, 5-parted; stamens 10, 5-8mm long, glabrous, exserted; anthers bilocular, elliptical and longitudinally dehiscent, eglandular in bud. Ovary sessile to subsessile, many-ovuled, glabrous, narrowing into elongate style which enlarges apically into tubular stigma. Legume 5-35cm long (incl. stipe but not peduncle), 1-3cm wide, usually straight, oblong-elongate, regularly, irregularly, vaguely, or not at all constricted between seeds, +- flattened, margins slightly thickened, base attenuate to obtuse, apex mucronate to acuminate to cuspidate (rounded if tip broken off), surface scurfy to verrucose, dull, dried specimens dark brown with rufous scales, dehiscing along one suture only; seeds 8-16, very thin, flat, orbicular to suborbicular, dark chestnut brown to black, shiny, 10-20mm diam., with a rim or sharp margin, attached to a non-persistent, filiform funicle.

Primarily in open plains areas, scrub or wastelands, savannahs along watercourses, woody hillsides, and on open ridges, preferring clay or sandstone soils; n. Brazil, British Guiana, Colombia, Venezuela, West Indies, ranging from 15°S to 20°N.

A. peregrina var. falcata differs by being shorter (to 8m tall), trunk and branches more corky; pinna pairs less numerous but more leaflets, which are also longer, more falcate, coriaceous and nitid; heads white to creamy yellow; legume more falcate. Ranges from 25°S to 15°S; s. Brazil, Paraguay.

A. colubrina var. cebil has leaflets which are dilated in the middle, with prominent secondary venation; anthers glandular in bud; legume smooth to reticulate, nitid, relatively short and wide, often irregularly contracted

A. colubrina var. colubrina is found in e. Brazil and Argentina, and A. colubrina var. cebil is found in Argentina, Bolivia, Peru, Paraguay and s.e. Brazil (Altschul 1964).

ANETHUM

(Umbelliferae/Apiaceae)

Anethum graveolens *L.* **(Peucedanum anethum** *Baill.***; P. graveolens** *(L.) C.B. Clarke***)** – dill, garden dill, dill weed, dilly, European dill, aneto, aneton, aneldo, hexenkraut

Anethum sowa *Roxb. ex. Flem.* – Indian dill, sowa-dill, variyali sowa

'Dill' is, of course, a common culinary herb; its name comes from the Norse 'dylla' [to soothe]. The ancient Greeks were said to place the leaves over the eyes to induce sleep. It may be hung over a door or carried in sachets for protection against malicious influences, according to magical lore. A bath of dill water is said to make the bather 'irresistible', and the plant is said to be aphrodisiac when eaten or smelled (Chevallier 1996; Cunningham 1994). Germanic peoples have known A. graveolens as a witches herb ['hexenkraut'] (De Vries 1991). In Mexico, the seeds are cooked in oil, and used as an analgesic hypnotic (Heffern 1974). Dill seeds, eaten or chewed, aid digestion, and an infusion may treat hiccups, insomnia, stomach pain and flatulence. In the kitchen, fresh, immature green seed heads have the best flavour; they are used in dill-pickles, vinegars, salads, sour cream, and meat and fish dishes. The seeds are mineral-rich, and are good for a salt-deficient diet. The distilled essential oil of the plant has been used to flavour drinks, food, and childrens medicines (Bremness 1994; Chevallier 1996).

Dill herbage mixed with monosodium glutamate [MSG] was called 'ZNA' by some in the late 60's US drug culture, claimed to be smoked for psychoactivity (Krikorian 1968). It has been suggested that the essential oil of dill may be ingested for psychotropic effects (Gottlieb 1992), and this should probably refer to A. sowa rather than A. graveolens. Of course, caution is advised with all internal use of essential oils. The technique of massage followed by exercise, as applied with 'nutmeg' essential oil [see **Myristica**], may be a preferable route of ingestion.

A. graveolens fruits have yielded 2.5-4% essential oil, containing d-carvone [40-60%], dihydrocarvone, α-*pinene*, dipentene, phellandrene and d-limonene (Karow 1969); also found in the fruits are *chlorogenic acid*, ferulic acid, caffeic acid, aesculetin, umbelliferone, umbelliprenin, *scopoletin*, bergapten, and other unidentified coumarins (Dranik & Prokopenko 1970). No *dillapiole* was detected (Bandopadhyay et al. 1972); *myristicin* has been reported from the seed oil but this may have been in confusion with A. sowa (Harborne et al. 1969). Leaf yields an essential oil rich in d-α-phellandrene, β-phellandrene, p-cymene, *myristicin*, and 3,6-dimethyl-2,3,3α,4,5,7α-hexahydrobenzofuran [this powerfully-aromatic compound is largely responsible for the smell of dill-herbage], with smaller amounts of *dillapiole*, iso-*myristicin*, limonene, terpinene, α-*pinene* and carvone (Huopalahti 1986; Karow 1969); aerial parts have also yielded *scopoletin* (Aplin & Page 1968). Roots have yielded 0.03-0.05% essential oil, containing mainly carvone, *apiole*, and *myristicin*, as well as *camphor*, and well over 100 other compounds (Goeckeritz et al. 1980).

A. sowa fruits yield an essential oil rich in *dillapiole* [12-50% of essential oil], carvone [21-35%], dihydrocarvone [0.1-43%], and limonene [up to 34.4%], with traces [3-4%] of other constituents. Fruits gave negative tests for coumarins and flavonoids (Bandopadhyay et al. 1972; Betts 1969; Chakravarty & Bhattacharya 1954; Shah et al. 1971). Others detected *myristicin* and *apiole* in the seeds (Harborne et al. 1969).

Anethum graveolens is a slender annual herb arising from a taproot, to 40-170cm tall; stems branching, glabrous and glaucous. Leaves oblong to obovate, 13-35 x 10-12cm, pinnately decompound, ultimate divisions filiform, 4-20mm long, less than 0.5mm wide; petioles 5-6cm long, narrowly sheathing. Flowers in lax, compound umbels; peduncles terminal and lateral, 7-16cm long; rays 10-45, spreading ascending, 3-10cm long, subequal to unequal; pedicels 6-10mm long, subequal; calyx teeth absent; petals yellow, suborbicular, with a narrower inflexed apex. Styles short, stylopodium conical; carpophore 2-parted. Fruit ovate, flattened dorsally, glabrous, 5-ribbed, dorsal ones filiform, lateral ones thin-winged; seed face plane or slightly concave, c.4 x 2mm.

Native to Eurasia (Wagner et al. 1990).

A. sowa is often considered synonymous with A. graveolens, but some choose to differentiate A. sowa based on the presence of *dillapiole* in the seed oil, as well as slight morphological differences in the fruits (Betts 1969).

ANTHEMIS and MATRICARIA

(Compositae/Asteraceae)

Anthemis nobilis *L.* **(Chamaemelum nobile** *(L.) All.***)** – English chamomile, Roman chamomile, perennial chamomile, camphor plant, babunike-phul, babunaj

Anthemis tinctoria *L.* **(Cota tinctoria** *(L.) J. Gay ex Guss.***)** – dyer's chamomile, yellow chamomile

Matricaria chamomilla *L.* **(M. courrantiana** *DC.***; M. recutita** *L.***; Chamomilla recutita** *(L.) Raschert***)** – German chamomile, Persian chamomile, annual chamomile, babunphul, babuna

Chamomile, in its many guises, has long been a popular herb for its scent and sedative properties. The ancient Egyptians held A. nobilis sacred to Ra, and they used its oil to anoint the body and to treat fever. The Arabs also valued it, and the Saxons revered it as one of their nine sacred herbs. It was much used in Mediaeval Europe to lend its pleasant scent to clothes and homes, and was soon being grown as a lawn, so that it would release its scent when walked on (Lawless 1994). A. tinctoria is used to make dyes, and has antispasmodic and menstrual-stimulating actions. In India, the root or flowers of M. chamomilla are used as a stimulant tonic, while the flowers are used as an aphrodisiac, analgesic, sedative, brain tonic, diaphoretic and carminative. They are sometimes used to treat conditions of hysteria, and are also antispasmodic. Flowers of A. nobilis share

similar usage (Bremness 1994; Chevallier 1996; Kirtikar & Basu 1980; Nadkarni 1976; Viola et al. 1995).

In Africa, M. nigellaefolia is said to be responsible for an intoxication known as 'bovine staggers' or 'brain staggers', thought to only affect bovines, and resulting in behavioural depression, instability and clumsiness, followed by twitching and salivation. In extreme cases, coma, convulsions, and death occur (Watt & Breyer-Brandwijk 1932).

Chamomile is usually prepared as an infusion, though it can be decocted. When made sufficiently strong, it acts as a sedative analgesic, with slight hypnotic and soporific qualities (pers. comms.; pers. obs.). Chamomiles are also disinfectant, antiinflammatory and digestive, and can be applied topically as a wash for tired eyes and skin inflammation. Also, A. nobilis flowers have shown antitumour activity (Bremness 1994; Lawless 1994).

A. nobilis has yielded 0.4-1.5% essential oil, containing monoterpenes [such as limonene, sabinene, *pinene*], butyric acid, isobutyric acid, isobutanol, 3-methylbutan-1-ol, 2-methylbutan-1-ol butyrates, azulenes and many other compounds. Also found are c.0.6% sesquiterpene lactones of the germacranolide group [see **Calea**], including eucannabinolide, nobilin, 3-epi-nobilin and other derivatives; flavonoids, including kaempferol [MAOI, potential neuroprotectant (Sloley et al. 2000)], and glucosides of *apigenin* (see below) and luteolin; phenolic acids; and coumarins, including *scopoletin* (Bruneton 1995; Rastogi & Mehrotra ed. 1990-1993).

M. chamomilla has yielded flavonoids including *apigenin* (Viola et al. 1995), *apigenin* 7-glucoside and 6"-acetyl-*apigenin* 7-glucoside in levels of up to 8% in the dried flower heads; on drying, these glycosides partially hydrolyse so that concentrations of *apigenin* increase. Also found are flavonols, including isorhamnetin [MAOI (Sloley et al. 2000)], patulitrin and glucosides of luteolin and quercetin; coumarins, including herniarin and umbelliferone; phenolic acids; sesquiterpenoid lactones; and 0.3-1.5% essential oil, containing 1-15% chamazulene, (-)-α-bisabolol, various oxidated derivatives of bisabolol, and other compounds. Both (-)-α-bisabolol and a plant extract have been shown to inhibit ulcer formation and increase rate of healing. Mucilage from flower ovaries yielded 45% glucuronic acid, 21% xylose, 15% galactose, 10% arabinose, 7% glucose and 2% rhamnose (Bruneton 1995; Rastogi & Mehrotra ed. 1990-1993).

Matricaria chamomilla is a glabrous much-branched aromatic herb to c.30cm tall, spreading, annual. Leaves alternate, 2-3-pinnatisect, segments almost filiform. Flower heads terminal, long-peduncled, solitary, 1.3-2cm diam.; ray flowers female, fertile or sterile, ligule elongate, white, rarely short; disc flowers hermaphrodite, fertile, tube terete or 20-edged, limb 4-5-fid; involucre hemispheric; bracts oblong, in few series, appressed, margin white, outer shorter; receptacle naked, conic, elongating during fruiting; ligules white, much longer than the bracts, deflexed after flowering or 0; anther bases obtuse, entire; style arms of hermaphrodite with truncate and penicillate tips. Achenes oblong, often incurved, faces glandular or rugulose, truncate, dorsally convex, with slender white ribs on the ventral face; pappus none.

Much cultivated; found in Europe, w. Asia to India and Japan (Kirtikar & Basu 1980).

ANTHOCERCIS

(Solanaceae)

Anthocercis angustifolia *F. Muell.*
Anthocercis anisantha *Endl.*
Anthocercis fasciculata *F. Muell.*
Anthocercis genistoides *Miers* **(A. spinescens** *F. Muell.***)**
Anthocercis gracilis *Benth.* – slender tailflower
Anthocercis ilicifolia *Hook.*
Anthocercis intricata *F. Muell.*
Anthocercis littorea *Labill.* – yellow tailflower
Anthocercis viscosa *R. Br.* – sticky tailflower
Anthocercis spp. – ray flower, tailflower

This Australian genus has no recorded traditional uses, though its members yield hallucinogenic tropane alkaloids. They are rather variable in constituency.

A. angustifolia aerial parts [harv. Sep.] yielded 0.11% alkaloids, consisting mostly of *hyoscyamine*, and lesser amounts of *hyoscine*, their apo-derivatives and tigloyl esters.

A. anisantha aerial parts [harv. Aug.-Sep.] yielded 0.02% alkaloids of similar constituency to A. angustifolia, also with nor-*hyoscyamine* and nor-*hyoscine*, and littorine in some samples (Evans & Ramsey 1983).

A. fasciculata aerial parts [harv. Oct.] yielded 0.05% alkaloids, which was almost entirely *hyoscyamine* (Cannon et al. 1969).

A. genistoides aerial parts [harv. Aug.] yielded 0.07% alkaloids, consisting mostly of meteloidine, as well as *hyoscyamine*, *hyoscine*, nor-*hyoscyamine*, 6-OH-*hyoscyamine* and tropine (El Imam & Evans 1984). In other samples [harv. Aug.-Sep.], aerial parts yielded 0.01-0.08% alkaloids, mostly *hyoscyamine* or *hyoscine*, as well as their nor-derivatives, tigloyl esters, tropine and possibly 6-OH-*hyoscyamine*; roots yielded 0.15% alkaloids.

A. gracilis aerial parts [harv. Oct.] yielded 0.03% alkaloids, mostly *hyoscine*, as well as *hyoscyamine* and their apo-derivatives (Evans & Ramsey 1983).

A. ilicifolia aerial parts [harv. Aug.] yielded 0.25% alkaloids, mostly *hyoscine*, as well as nor-*hyoscyamine*, apo-*hyoscine*, apo-*atropine*, 6-OH-*hyoscyamine*, littorine, meteloidine and tropine; roots yielded 0.23% alkaloids of similar constituency, with the omission of meteloidine, and addition of tigloidine and valeroidine (El Imam & Evans 1984).

A. intricata aerial parts [harv. Sep.] yielded 0.08% alkaloids, mostly *hyoscyamine*, as well as *hyoscine*, their nor-derivatives, tigloyl esters, littorine and 6-β-acetoxy-3-α-tigloyloxytropane (Evans & Ramsey 1983).

A. littorea aerial parts yielded 0.12-0.16% crude bases – apo-*atropine*, nor-*atropine*, *hyoscine*, nor-*hyoscine*, tropine, ψ-tropine, 6β-tigloyloxytropan-3α-ol, 3α-tigloyloxytropane, 0.02% meteloidine, 0.015% littorine, 0.001% *hyoscyamine*, and 0.006% of a mixture of littorine and *hyoscyamine*; roots yielded 0.1% alkaloids, consisting of the above compounds [without 6β-tigloyloxytropan-3α-ol], as well as tigloidine, cuscohygrine and 3α,6β-ditigloyloxytropan-7β-ol; flowers yielded 0.15% alkaloids, consisting of *hyoscyamine*/*atropine*, nor-*atropine*/nor-*hyoscyamine*, *hyoscine*, littorine and meteloidine (Cannon et al. 1969; Evans & Treagust 1973b).

A. viscosa ssp. viscosa aerial parts and roots [harv. Sep.] yielded 0.02% alkaloids, mostly *hyoscyamine*; aerial parts with lesser amounts of *hyoscine*, their apo-derivatives, tigloyl esters, and two unidentified bases; roots with apo-*hyoscyamine* and tigloyl esters (Evans & Ramsey 1983). Another sample [harv. Oct.] yielded 0.08% crude bases from aerial parts, consisting mostly of *hyoscyamine*, as well as 2% rutin and 0.5% ursolic acid (Cannon et al. 1969); yet another analysis, using samples of unstated harvest time, found 0.11% alkaloids in aerial parts, and 0.12% in roots (Evans & Treagust 1973b).

A. viscosa ssp. caudata aerial parts [harv. Oct.] yielded 0.04% alkaloids, mostly *hyoscyamine*, as well as *hyoscine*, their apo- and nor-derivatives, tigloyl esters and tropine; root bark yielded 0.02% alkaloids, with +- equal amounts of *hyoscyamine*, apo-*hyoscyamine* and tigloyl esters (Evans & Ramsey 1983).

Anthocercis ilicifolia is an erect shrub to 2.7m with 1-2 stems, often tinged with purple, branches and leaves glabrous, rarely with scattered glandular hairs; seedlings with prickles on stems. Leaves obovate to narrowly obovate-elliptic, occasionally spathulate or elliptic, sessile or almost so, 15-80 x 7-35mm, thick and fleshy, entire, or the juvenile leaves dentate. Inflorescence panicle-like, leafless except at base; pedicels 3-8mm long; flowers bisexual, slightly zygomorphic, subtended by a pair of opposite bracts; calyx 4-8mm long, campanulate to cupular, 5-lobed; corolla 12-27mm long, narrowly tubular with spreading 5-lobed limb, the lobes volutive in bud, bright yellow, the striations purple to maroon, tube often tinged with purple outside, lobes linear, 6-18 x 3-6mm; stamens 4, inserted at base of corolla-tube, 4-10mm long; staminode sometimes present; anthers bilocular, not cohering, dorsifixed, dehiscing by longitudinal slits. Ovary bilocular; stigma capitate, very shortly bilobed. Capsule narrowly ovoid-ellipsoid, acute to apiculate, 11-21mm long, opening from apex by 2 bifid valves, the lower part enclosed by persistent calyx, fruit often malformed due to galling; seeds 1.4-1.9mm long.

In calcareous sand; a colonising species after fire or disturbance. Endemic to s.w. coast of Western Australia from Kalbarri to Perth (Haegi et al. 1982).

ANTHOTROCHE

(Solanaceae)

Anthotroche myoporoides *C. Gardner* – wheelflower
Anthotroche pannosa *Endl.* **(A. blackii** *F. Muell.***; A. healiana** *F. Muell.***)** – wheelflower
Anthotroche walcottii *F. Muell.* – wheelflower

This Australian genus of three species has no traditional usage recorded, yet is known to be host to small quantities of hallucinogenic tropane alkaloids.

A. myoporoides aerial parts yielded 0.04% alkaloids, most of which was nor-*hyoscyamine*, as well as *hyoscyamine*, *hyoscine* and apo-nor-*atropine*; roots yielded 0.02% alkaloids, mostly tropine, as well as *hyoscyamine*, nor-*hyoscyamine* and 3-α-acetoxytropane.

A. pannosa aerial parts yielded 0.01% alkaloids, mostly *hyoscyamine* with lesser amounts of *hyoscine*, nor- and apo-derivatives of *hyoscine*, and tropine; roots yielded 0.02% alkaloids, mostly *hyoscyamine*, as well as nor-*hyoscyamine* and tropine.

A. walcottii aerial parts yielded 0.02% alkaloids, mostly *hyoscyamine*, as well as *hyoscine*, nor- and apo-derivatives of *hyoscine*, and apo-nor-*atropine*; roots yielded 0.04% alkaloids, mostly nor-*hyoscyamine* with lesser amounts of *hyoscyamine* (Evans & Ramsey 1983).

All plant parts tested were from mature specimens, harvested in September.

Anthotroche myoporoides is an erect, rounded, often intricately

branched shrub to 3m, closely and densely tomentose throughout with non-glandular, dendritic hairs and smaller glandular hairs, greyish, the new growth bronze-green. Leaves alternate, obovate to narrowly obovate-elliptic, mostly 20-35 x 5-15mm, juvenile leaves larger; petiole to 10mm long, sometimes very short. Flowers axillary or terminal, in loose 4-6-flowered clusters; pedicels absent or to 5mm long; calyx campanulate to cupular, 4.5-9mm long, 5-lobed, lobes 2-4mm long; corolla 5.5-8.5mm long, tube narrowly funnel-shaped or dilated, pale greenish with deep violet (rarely drab grey-green) striations; limb of (4-)5(-6) short broad lobes, volutive in bud, 2.5-4mm long, violet, rarely drab white, margins sometimes white; stamens 5, included; anthers unilocular, not cohering, dehiscing by a semicircular slit. Ovary bilocular; stigma capitate, very shortly bilobed. Fruit a smooth capsule, +- globose, 3-4mm diam., opening from apex by 4 valves, +- enclosed by calyx; seeds c.3mm long, subreniform.

In small populations on sand plains in shrubland or mallee; endemic in the n. Irwin district of s.w. Western Australia (Haegi et al. 1982).

ANTIRHEA

(Rubiaceae)

Antirhea lucida *(Sw.) Benth. et Hook.* **(Guettarda nitida** *Maza***; Laugeria lucida** *Sw.***; Malanea citrifolia** *A. Rich.***; M. lucida** *(Sw.) A. Rich.***; M. nitida** *Desr.***; Stenostomum lucidum** *(Sw.) Gaertn.***; Sturmia lucida** *(Sw.) Gaertn.***)**

The roots of this West Indian tree recently yielded 0.37% indole alkaloids – including 0.00125% *DMT*, 0.00112% 2-methyl-*pinoline*, 0.0035% N,N-methyl-3'-indolylmethyl-5-*MeO-tryptamine* [a new alkaloid], and 0.002% *gramine*. The test samples were about 3 years old, however [harv. Jun. 1992, Dominican Republic] (Weniger et al. 1995), and fresh material might perhaps yield greater quantities of *DMT*, due to its relative instability.

A. putaminosa from Rockhampton, Queensland [Australia], harvested in December, tested positive for alkaloids in the bark, leaf, mature fruits and [most strongly] root bark (Webb 1949). Bark has yielded 0.02% alkaloids; roots yielded 0.05%; leaves yielded antirhine as the major alkaloid, with unidentified trace constituents. Antirhine in mice had no observable effect at 100mg/kg [p.o.]; 300mg/kg "produced decreased motor activity, low posture, dyspnea, convulsions and death". The bark alkaloids, given p.o., caused "slight mydriasis, CNS depression and lacrimation" at 250mg/kg; given i.p., 20mg/kg "produced decreased activity, bradypnea and somnolence". Root alkaloids given p.o. caused miosis at 250mg/kg; "depression, ataxia, convulsions and hypothermia" at 500mg/kg; death resulted at 1g/kg (CSIRO 1990).

Other Antirhea spp. have yielded *yohimbine*- and corynantheine-type alkaloids (Weniger et al. 1995).

Antirhea lucida is a tree 6-13m tall; trunk to 45cm thick, with smooth bark; branchlets greyish or yellowish, slender, terete or subangulate, glabrous, usually densely leafy. Leaves opposite or whorled, oblong-ovate to elliptical, obtuse or acutish at apex, acute to rounded and short-decurrent at base, 6-12 x 3.5-6cm, glabrous, thin, firm-chartaceous, with very faint venation, costa subimpressed above, prominent beneath, lateral nerves inconspicuous, 7-13 on each side, irregularly spaced; stipules inter- or intra-petiolar, ovate-deltoid, acuminate, 5-8mm long, minutely sericeous outside, caducous; petioles stout, 3-8mm long, glabrous. Inflorescence axillary, once-forked, with numerous sessile or subsessile flowers along upper side of branches, inflorescence branches slender and 3-8cm long; peduncles slender, 2-3cm long; flowers mostly bisexual and actinomorphic, distant, alternate, sessile or subsessile, ebracteolate; perianth biseriate; calyx 2-3mm long, glabrous or minutely puberulent, limb persistent, 5-lobed, lobes semiorbicular, often unequal, ciliolate; corolla 5-7mm long, gamopetalous, white, campanulate, glabrous or minutely puberulous, tube 3.5-5mm long, lobes imbricate, half as long as tube, oval-oblong, obtuse; stamens inserted at or near corolla throat, epipetalous, as many as corolla-lobes and alternating with them; anthers included or partially exserted, mostly dorsifixed 2-locular, dehiscing lengthwise. Ovary inferior, crowned by disc, 2- or more locular, with as many ovules; ovules pendulous from top of loculi, solitary in each loculus; style usually slender, 2-lobed. Fruit a red or black drupe with hard endocarp, oval or oblong, 5-7(-10)mm long, 3-4.5mm thick; seeds 2, brown; endosperm absent or scanty. Fl. Jul.-Nov.

On limestone rocks in woodland, or in thickets, below c.2,450m; Jamaica [St. Thomas], Bahamas, British Honduras, Greater Antilles, St. Croix, St. Lucia, Trinidad, Virgin Islands (Adams 1972; Standley 1934), Dominican Republic (Weniger et al. 1995).

ARCHONTOPHOENIX

(Palmaceae/Arecaceae)

Archontophoenix sp. – king's date palm

The generic name of these large, attractive palms derives from the Greek 'archon', meaning king, or ruler, and 'phoenix', meaning palm or date palm. In New Britain, Papua New Guinea, the nuts of an Archontophoenix sp. are reported to be chewed as an inebriant with the leaves of **Pueraria** phaseoloides, seemingly in a manner analogous to the use of 'betel nut' [see **Areca**] (Paijmans ed. 1976). According to Dowe & Hodel (1994), this genus is endemic to Australia, with close relatives existing in the Pacific region. If this is the case, perhaps the species used in New Britain is introduced, or was confused with a closely related genus.

Archontophoenix spp. are moderately tall, solitary, erect, emergent, pleonanthic, monoecious palms; trunks slender, often with swollen base; leaf scars sometimes prominent. Leaves paripinnate, reduplicate, cleanly deciduous; sheaths tubular, forming an elongate crownshaft eventually splitting opposite the petiole, coloured green, brown, or purple; ligule absent; petiole absent to moderately long; rachis long; pinnae linear-acute, inserted in a single plane along rachis, subopposite, erect to semi-pendulous, rigid or lax, midrib prominent, secondary ribs frequently present abaxially, abaxial surface green or with silver-grey scales, sometimes very dense to give silvery-grey colour; ramenta lacking, or present on midrib abaxially, medi-fixed. Inflorescence intrafoliar at maturity, branched to 3-4 orders, erect to pendulous paniculate, branches divaricate, protandrous; bracts enclosing inflorescence 2, the prophyll attached at peduncle base fully enclosing peduncular bract; peduncular bract inserted slightly above attachment of prophyll, tubular, bracts deciduous immediately prior to floral anthesis, small to moderate rameal bracts often present; peduncle short, stout; rachis much longer than peduncle; rachillae erect or pendulous, elongate, zig-zagged throughout or only toward apex; flowers unisexual, sessile, lilac-purple or white-cream-light green, in well-spaced triads of a single pistillate flower subtended by a pair of staminate flowers one either side, borne spirally throughout rachillae, or only on proximal portion, and then with flowers distally, in pairs or solitary. Staminate flowers asymmetric in bud; sepals 3, imbricate; petals 3, valvate, much longer than sepals; stamens 9-35; anthers dorsifixed, near middle, basally bifid, apically pointed, latrorse; filaments curved or deflexed. Pistillate flowers smaller than staminate, symmetric; pistillode cylindric, about as long as stamens, tapered, apically lobed; sepals 3, imbricate; petals 3, imbricate, briefly valvate at apex; staminodes 3, tooth-like; gynoecium unilocular, uniovulate; style short; stigmas 3, recurved. Fruit conic-ovoid, ellipsoid, globose to subglobose, coral pink, red or dark brick-red at maturity; stigmatic remains apical or subapical; epicarp thin, smooth or lightly pebbled; mesocarp thin, crustaceous or brittle, non-operculate; seed 1, ovoid, globose to subglobose, hilum lateral, raphe fibres elongate, anastomosing, adherent to seed.

Six species endemic to eastern Australia, generally not further inland than Great Dividing Range; in coastal and near-coastal lowlands and ranges, to 1,200m altitude (Dowe & Hodel 1994). The genus includes such commonly cultivated palms as A. alexandrae and A. cunninghamiana.

ARCTOSTAPHYLOS

(Ericaceae)

Arctostaphylos alpina *(L.) Spreng.* **(Arbutus alpina** *L.***)** – alpine bearberry

Arctostaphylos patula *Greene* – manzanita, big dinas, dinas coh

Arctostaphylos pungens *Kunth* **(Daphnidostaphylis pungens** *(Kunth) Klotzsch***; Uva-ursi pungens** *(Kunth) Abrams***)** – manzanita, big dinas, dinas coh

Arctostaphylos uva-ursi *(L.) Sprenger* **(Arbutus uva-ursi** *L.***)** – uva ursa, uva ursi, kinnikinnick, sagackhomi, bear's grape, bearberry, mealberry, mountain box, mountain cranberry, sandberry

Arctostaphylos spp. [from the Greek, 'arcto' (bear) and 'staphylos' (grape-bunch); 'uva-ursi' also means 'bear-grape' in Latin] are widely used by native North Americans for both medicinal and ceremonial purposes. The Nitinaht called A. uva-ursi 'kinnikinnick' [roughly translated as 'that which is mixed', or 'he who mixes'], as it is one of the principal smoking mixtures amongst indigenous peoples of the northwest. Some would reportedly become so intoxicated by smoking bearberry leaves that they would fall into the fire and remain immobile! This use spread into Canada, and the plant became a major herb of exchange with other tribes, as well as with settlers, who mixed it with their tobacco [see **Nicotiana**] to make a mix called 'sagackhomi', also called 'larb' by some Western hunters. Peoples of the Pacific north-west sometimes smoked it with yew [see **Taxus**], and it was said to make a person dizzy; the Kwakiutl also smoked A. uva-ursi as a narcotic, and the Ojibway smoked leaves of both A. uva-ursi and A. alpina. The Navajo also smoke A. patula and A. pungens for rain prayers and good luck. The Menomini and Thompson smoke A. uva-ursi leaves, as well as making an astringent infusion from them to strengthen the bladder and kidneys. The Cherokee use it for dropsy and urinary diseases, as well as eating the berries as food. The Lower Chinook and Quinalt use the berries to allay appetite; the berries may make a bland sur-

vival food which is more edible after cooking. Dried berries may also be made into necklaces or rattles. Stems and berries have also been used to treat headache and scurvy. A. pungens has been used by the Tarahumara of Mexico, who made a wine from it (Bremness 1994; Emboden 1979a; Hamel & Chiltoskey 1975; Ott 1993; Siegel et al. 1977; Winter 1998). Today in herbal medicine, the leaves are used as an astringent, antiinflammatory and diuretic, and to expel stones (Chiej 1984).

A. alpina leaves have yielded 4.9% arbutin [see below] (Fromard 1985).

A. uva-ursi leaves have yielded 0.011% arbutin [diuretic, antitussive, urinary disinfectant, inhibits insulin degradation], 0.005% methylarbutin, 2-O-galloylarbutin, 4'-O-galloylarbutin, 6-O-galloylarbutin, monotropein [see **Monotropa**; content highest during exponential growth], hydroquinone [see **Vaccinium** for toxicity], [possibly] asperuloside, piceoside, ericoline, hyperin, uvaol, quercetin and myricetin derivatives, cyanidin, delphinidin, (+)-catechol, gallic acid [antibacterial, antiviral, antifungal, astringent, antiinflammatory, antitumour, antimutagenic, choleretic, bronchodilator, promotes smooth muscle contraction, inhibits insulin degradation], citric acid, ursolic acid, and quercetin [antiinflammatory, antibacterial, antiviral, inhibits smooth muscle contraction, inhibitor of many enzymes] (Buckingham et al. ed. 1994; Chiej 1984; Fromard 1985; Harborne & Baxter ed. 1993; Karikas et al. 1987; Kawaguti et al. 1939; Rastogi & Mehrotra ed. 1990-1993; Swiatek & Komorowski 1973; Waehner et al. 1975; Walewska 1966; Zechner 1931). One study reported obtaining arbutin yields of up to 18.6% (Fromard 1985), but I am uncertain whether this was a typographical error.

Arctostaphylos uva-ursi is a semi-trailing, mat-forming shrub with glabrous stems; throws out numerous rooting branches, usually 50-100cm long; branchlets glabrate or variously pubescent. Leaves alternate, persistent, coriaceous, oblong-obovate to spatulate or oblanceolate, 1-3cm long, obtuse or rounded at apex, tapered to base, entire, dark green and glossy on upper surface, paler beneath, leathery; petioles very short. Flowers pink, drooping, in groups of 3-10 in terminal racemate clusters in axils of fleshy, firm bracts; calyx saucer-shaped, deeply 5-lobed, sepals broadly ovate, c.1.5mm long, imbricate, distinct to base; corolla white to pinkish, globose, ovoid, bell-shaped, 4-6mm long, with 5 short lobes, spreading or recurved; stamens 10, filaments pubescent, much dilated in basal 1/3, much shorter than corolla; anthers subglobose, 2-awned, opening by pores. Ovary 5-celled, conic-ovoid, subtended by a 10-lobed disc; 1 ovule in each cell; style columnar, 5-lobed; stigma capitate. Fruit a smooth, dull red loculicidal drupe with a navel-like depression, sharply flavoured (or mealy and flavourless, depending on who you believe!), 6-10mm diam.; containing 5 bony nutlets, partly or wholly concrescent. Fl. late spring to early summer.

Native to n. US, Canada, and n. Eurasia, common in Scottish highlands, grows naturally through most of Europe in moist conditions among undergrowth or in grassy places where little light penetrates; sometimes on sandy or rocky soil in America, usually in moist to dry woods, and sandy roadsides (Bremness 1994; Chiej 1984; Emboden 1979a; Gleason 1952; Moss 1983).

ARECA

(Palmaceae/Arecaceae)

Areca caliso *Becc.*

Areca catechu *L.* **(A. catechu** *Willd.* **A. hortensis** *Lour.***)** – betel nut palm, areca palm, catechu palm, supari, piri, pinang, ping lang, bing lang, guvaka, guvka, popo

Areca macrocalyx *Zipp. ex Blume* – samaguk

'Betel nut', the fruit of [usually] A. catechu, is one of the world's most popular stimulants, being chewed by an estimated 10% of the world's population [largely in India and s.e. Asia, as well as in Australasian and Pacific countries]. A. macrocalyx is also chewed in Papua New Guinea, and A. caliso in the Philippines. Betel nut was mentioned in early Sanskrit texts [as 'guvka' or 'pinang'], and was also used by ancient Persians and Arabs. Moroccans burn the nuts on charcoal grills to ward off evil spirits, and wear them as amulets. Betel nuts are also chewed by the Swahili of Zanzibar and Tanzania, the Shambala of Kenya, the Ngazija of the Comoros, and Indians and s.e. Asians in South Africa. Betel is widely chewed by Mohammedans during Ramadan fasts. In India, betel use is a respected facet of society, due to the ritualised aspects of its preparation and use, encouraging social and spiritual exchange. In Ayurvedic medicine, betel nut is used as a digestive, anthelmintic, diuretic, astringent and cardiotonic. The nuts are used in TCM as an anthelmintic, and to treat dysentery and diarrhoea, slow heart rate, lower blood pressure and increase intestinal secretions. In Cambodia, the leaves are brewed and taken internally to treat bronchitis, and externally for lumbago. The root is used to treat liver disease, and the fruit is given with opium [see **Papaver**] to treat diarrhoea. Malay women sometimes use young shoots to procure abortion in early stages of pregnancy. The sweet inner shoots and young flower stems may be eaten raw, boiled or fermented as food. Unripe betel nuts are considered to be intoxicating, and cause dizziness (Bavappa et al. 1982; Chopra et al. 1965; De Smet 1998; Gowda 1951; Huang 1993; Kirtikar & Basu 1980; Marshall 1987; Nadkarni 1976; Ott 1995a; Paijmans ed. 1976; Rätsch 1992; Schmid 1991; Von Bibra 1855; Usher 1974); Nepalese shamans chew the fresh nuts with lime, salt and 'betel leaf' [see below] for shamanic travel (Müller-Ebeling et al. 2002). In parts of West Java, the roots are crushed and decocted with Imperata cylindrica roots and **Piper** nigrum seeds, and "drunk as an invigorating tonic to make men strong" (Wightmann et al. 1994).

Betel nuts may be prepared in several ways. The most popular preparation is that of whole, dried ripe nuts ['chali' or 'kottapak'], which are sundried for 35-40 days and then dehusked. When the nuts are cut in half and sundried for 10 days, before being dehusked and further dried, they are known as 'parcha'. Today, mechanical drying and dehusking methods are more common. Unripe nuts at 6-7 months of maturity may be made into 'kalipak' – the nuts are dehusked, cut into pieces, boiled in water [or a diluted extract of previous boilings], coated with 'kali' [a concentrate of previous water extracts] and dried, either in the sun or over a fire. 'Iylon' is made from unripe nuts which are simply sliced and dried; 'nayampak' is similar, but is made from nuts that are more immature. 'Scented suparis' are pre-made blends of betel nut pieces, spices and essential oils – recipes differ from region to region and from one manufacturer to the next (Bavappa et al. 1982).

Betel nut is often chewed [or rather, sucked in the corner of the mouth] as a quid ['paan' or 'sirih'] – a powdered, grated or crushed nut is mixed with a small pinch of burnt lime [to liberate the alkaloids as their bases; this also hydrolyses most of the *arecoline* to form arecaidine – see below], as well as a variety of spices and herbs [see *Methods of Ingestion*]. Tobacco [**Nicotiana**] is one of the most common additives today. These are wrapped in a [preferably] fresh 'betel leaf' [**Piper** betle – see **Piper 1**], and the morsel is ready for use. The copious red juice generated is either swallowed or spat out periodically. Initial use causes unpleasant symptoms such as nausea, dizziness, cold sweat, sore tongue, constricted throat and loose bowels. After regular use, these symptoms subside, except with large doses [up to 28g – normal dose of powder in Indian medicine is 0.6-2g]. The stimulatory effect is generally mild. Regular betel chewers have red to black stained teeth and gums, which they are usually quite proud of. This is largely due to catechin [see below], which turns bright red under strongly alkaline conditions. Although said to be good for the gums, regular and excessive use [it is usually chewed every day, and often after meals] is detrimental to oral health, irritating the gums and loosening the teeth. While it is excellent for reducing teeth caries and maintaining a healthy digestive tract in disease-ridden areas, the betel nut is now considered to be carcinogenic. This proposition has been questioned as relying on circumstantial evidence, and due to the ubiquitous use of tobacco additives (Bavappa et al. 1982; Gowda 1951; Kirtikar & Basu 1980; Lehane 1977; Marshall 1987; Nadkarni 1976; Ott 1993; Von Bibra 1855), though current research seems to support the notion, due to discovery of the formation of carcinocenic nitrosamines in the saliva, such as N-nitrosoguvacine, N-nitrosoguvacoline, MNPN [3-(methylnitrosamino)-propionitrile] and MNPA [3-(methylnitrosamino)propionaldehyde], when chewing betel nut with lime. Addition of tobacco brings formation of yet more nitrosamines (Prokopczyk et al. 1987; many more recent publications on this topic), and the addition of slaked lime has been shown to play a role in the oral carcinogenesis. Lime is known to cause a rapid turnover of cells, killing them, and increases the likelihood of cell mutation (Thomas & MacLennan 1992). It has been proposed that the co-use of betel leaf [see above] reduces formation of nitrosamines due to antioxidative activities deriving from the leaf (Jeng et al. 2002; theobromus pers. comm.). It is not known at this point whether oral usage of betel nut extracts without lime pose a similar health risk.

It has recently been shown that the non-alkaloidal dichloromethane fraction of the nut extract inhibits MAO-A in rat brain (Dar & Khatoon 2000). Betel nut has also shown adverse reactions when combined with certain pharmaceutical drugs, such as fluphenazine [resulting in tremors, stiffness and akithesia], flupenthixol and procyclidine [jaw tremors, rigidity, bradykinesia], prednisone and salbutamol [bronchoconstriction counteracts the positive effects of these drugs in treating respiratory disorders] (Fugh-Berman 2000). Although some asthmatics may have no problems, asthmatics in general should probably avoid betel nut, due to the bronchoconstriction that the nut, and the major alkaloidal constituent, *arecoline*, are known to cause (Kiyingi 1992; Taylor et al. 1992).

A. catechu nut has yielded 0.2-0.7% alkaloids, mainly *arecoline* [0.1-0.67%], as well as arecaidine [arecaine; *GABA*-uptake inhibitor], arecolidine, homoarecoline, guvacine [*GABA*-uptake inhibitor], guvacoline, isoguvacine, *coniine* and *choline*; as well as 15% condensed tannins [polyphenols, including leucocyanidin, catechin and epicatechin – catechin may inhibit MAO-B (Mazzio et al. 1998)], 15% lipids and 50-60% sugars. Green, unripe nuts yielded 0.1-0.15% alkaloids, of which 69.8% was *arecoline*, 24.4% ethyl-N-methyl-1,2,5,6-tetrahydropyridine-3-carboxylate, 1.8% methylnicotinate, 0.7% guvacoline, 0.49% ethylnicotinate, 0.21% ethyl-N-methylpiperidine-3-carboxylate, 0.2% methyl-N-methylpiperidine-3-carboxylate and 0.02% *nicotine*; as well as 17.2-43.85% polyphe-

nols, 8.1-12% fat, 8.2-9.8% fibre, 17.3-23% polysaccharides and 6.7-9.4% protein. Ripe nuts contain lower levels of polyphenols [11.1-17.8%] and protein [6.2-7.5%], and higher levels of extractable *arecoline* [0.12-0.24%], fat [9.5-15.1%], fibre [11.4-15.4%] and polysaccharides [17.8-25.7%]. Another study, probably using ripe nuts, found arecaidine to be the major alkaloid [1%], followed by *arecoline* [0.07%]. *Arecoline* is largely hydrolysed to form arecaidine when chewed with lime; like *arecoline*, arecaidine also has cholinergic and anthelmintic effects, though it is less toxic and has fewer parasympathomimetic side effects than *arecoline*. The body also produces nicotinic acid as a by-product of betel chewing (Bavappa et al. 1982; Bruneton 1995; Buckingham et al. ed. 1994; Holdsworth et al. 1998; Huang 1993; Johnston et al. 1975; Marion 1950; Marshall 1987; Nadkarni 1976; Rastogi & Mehrotra ed. 1990-1993; Schermerhorn et al. ed. 1957-1974).

Areca catechu has a solitary trunk, quite straight, 12-30m tall, usually c.50cm circumference, uniformly thick; stems erect, smooth, green in upper portion, annulate. Leaves pinnate, 1.2-1.8m, leaflets numerous, 30-60cm, upper confluent, glabrous, thin, with several midribs, attached to the rachis in a vertical line; base of petiole expanding into a smooth, green, amplexicaul sheath. Spathe double, compressed, glabrous; spadix much-branched, bearing male and female flowers in numerous close-set spikes; rachis stout, compressed; branches with filiform tips; male flowers minute, very numerous, sessile, bractless, occupying the upper portion of the spikes; calyx 1-leaved, small, 3-cornered, 3-parted; petals much longer than the small sepals, 3, oblong, rigid, striated; stamens 6, filaments short; anthers sagittate; female flowers much larger, few at base of spikes, sessile, bractless; sepals 3, orbicular, imbricate, cordate, rigid, fleshy, permanent; petals 3, orbicular, imbricate, with acute valvate tips; staminodes 6, connate; style scarcely any; stigmas 3, short, triangular. Fruit 3.8-5cm long, ovoid or oblong, supported by the persistent perianth, mesocarp fibrous; seed (nut) inside smooth, orange or scarlet, surface with attractive reticulate patterning, with a truncate base (Kirtikar & Basu 1980).

Tropics; India and s.e. Asia, to Pacific Islands.

Grow young plants in a mix of leaf-mold/loam or peat/loam; older plants prefer ½ sand and ½ loam. May require a greenhouse in colder climates. Water at least every 2 days. A tree may produce c.250 nuts a year. When the fruits are ripe, the nuts are removed from the mesocarp, washed free of pulp, and sun-dried. Sometimes the nuts are boiled before being sliced and sun-dried (Bremness 1994; Grubber 1973).

In the US, betel nut 5x extract powder is illegal (friendly pers. comm.); in England, betel nut is illegal to import, but the law there regarding this is not widely enforced (theobromus pers. comm.).

ARGEMONE

(Papaveraceae)

Argemone glauca *(Nutt. ex Prain.) Pope* – Hawaiian poppy, puakala

Argemone mexicana *L.* **(A. leiocarpa** *Greene***; A. mucronata** *Dum.-Cours. ex Steud.***; A. ochroleuca** *Sweet***; A. spinosa** *Moench***; A. versicolor** *Salisb.***; A. vulgaris** *Spach***; Echtrus mexicanus** *Nieuwl.***; E. trivialis** *Lour.***; Papaver spinosum** *Bauhin***)** – prickly poppy, Mexican poppy, chicalote, cardo santo, devil's fig, amapola del campo, pivla dhatura, satyanashi, kanre phul, palanti kanta, sungure kanda, thakal

Argemone munita *Durand et Hilg.* – flatbud prickly poppy, chicalote

Argemone polyanthemos *(Fedde) G.B. Ownbey* **(A. intermedia var. polyanthemos** *Fedde***)** – North American prickly poppy

Argemone spp. – prickly poppies

The Aztecs held A. mexicana to be sacred to Tlaloc, god of rain and thunder; they believed it to be eaten by all inhabitants of the underworld. Both Aztec and Mayan healers used it to treat headache, earache, asthma, flu, chest problems, constipation, fever, dizziness, halitosis and snakebite. The Mapuche also regard it as a sacred plant. Chinese immigrants in 19th century Mexico [Sonora, Sinaloa and Baja California] recognised its properties, and derived a type of opium [see **Papaver**] from it called 'chicalote tamales'. It was said to produce "blissful self-forgetfulness and complete absence of wants". An ointment of the latex is also said to be effective against sunburn, and an infusion of it treats nervousness and cramps. Seeds of the plant are also used in parts of Mexico for similar purposes, and the dried leaves are smoked for their 'aphrodisiac' properties. The roots of an Argemone sp. have been used by the Guarani of Paraguay, who brew them with 'yerba maté' [see **Ilex**] to make a medicinal stimulant. The North American A. polyanthemos is known as a strong irritant and narcotic, being feared as a poison. A. glauca from Hawaii is also said to be narcotic and psychotropic (Emboden 1979a; Heffern 1974; Pendell 1995; Rätsch 1992; Tyler 1966; Watt & Breyer-Brandwijk 1932). A. mexicana is used in Nepal to treat pain, itching and insomnia (Müller-Ebeling et al. 2002). In southern N. America, ash from the burnt leaves of A. intermedia is used by indigenous people for tattooing (Usher 1974). Other Argemone spp. share similar chemistry and pharmacology. Care should be taken with all species, as cases of poisoning have been recorded.

The seeds of Argemone spp. have been said to have '**Cannabis**-like' effects (Watt 1967), though they have apparently been eaten in cakes and other foodstuffs without consequence (Usher 1974). Such food use may have been in small amounts, or it may be that the heat and length of cooking destroys the alkaloids originally present. However, in India, A. mexicana seeds and their oil are sometimes encountered as an adulterant of Indian mustard seeds [see **Brassica**], and their consumption results in what has been called 'epidemic dropsy'. Symptoms include nausea, vomiting, diarrhoea, breathlessness, swelling of the limbs, and glaucoma; sometimes death results from cardiac arrest. The toxicity, attributed to the alkaloids sanguinarine and dihydrosanguinarine, primarily affects the liver, heart, kidneys and lungs, and results in extensive oxidative damage to cell membranes (Das & Khanna 1997; Thatte & Dahanukar 1999).

Usually the seeds, or the golden sap from the unripe seed capsules, are the portions ingested. The capsule can be pierced in the same way as with **Papaver** [though be careful of the prickles], and the sap similarly collected and dried, for use again in a similar fashion to true opium (Gottlieb 1992; pers. comms.). This may not be recommended with species rich in sanguinarine, due to the toxicity mentioned above. Recently, smokeable extracts of A. mexicana foliage have become popular on a small scale, and like many things, synergise well with **Cannabis**. However, the smoke is harsh and most likely not very healthy, even through a water-pipe, and it would seem best to vapourise the dried sap instead. Some people have reported dream-enhancement when smoking A. mexicana 5x extract before going to bed (pers. comms.; pers. obs.). Roughly 500mg [or ¼tsp] dried, powdered leaf of A. mexicana, A. glauca or A. munita ssp. rotunda [A. rotunda], taken orally with fruit juice, has been observed to provide pleasant mood-enhancement, with 2g more 'contemplative' in effect. A. grandiflora, A. polyanthemos and A. pleiacantha were found to be much weaker using the same methods. The same people noted that the leaf was preferable to the latex, as the latter "seems to be missing" something compared to the effects of the former (Lazar 2002).

These materials contain isoquinoline alkaloids related to those found in **Papaver**, some of which have anticholinergic and antihistamine properties (Capasso et al. 1997) as well as being narcotic sedatives (Preininger 1975). The alkaloids berberine and chelerythrine give the latex its yellow colour; on air contact, the latex turns orange, a colouration thought to be caused by sanguinarine [pseudochelerythrine] (Bandoni et al. 1975). Besides the toxicology of sanguinarine as mentioned above, this alkaloid has been shown to inhibit the activity of MAO (Lee et al. 2001) and *glutamic acid* decarboxylase enzymes (Netopilova et al. 1996), as well as having anticholinesterase, adrenolytic, sympatholytic, local anaesthetic, and bactericidal activities (Preininger 1975). See **Papaver** for further commentary on some of these alkaloids. Many of them [such as berberine, chelerythrine, coptisine and sanguinarine] inhibit AChE (Ulrichová et al. 1983).

A. alba [A. albiflora] has yielded allocryptopine, berberine, chelerythrine, coptisine, *protopine* and sanguinarine (Preininger 1986).

A. albiflora ssp. texana has yielded 0.02% alkaloids [33% sanguinarine, 28% allocryptopine, 23% *protopine*, 9% berberine, 6% coptisine] (Stermitz et al. 1973b).

A. aurantiaca aerial parts [still mostly in rosette stage, beginning to bud] from Texas yielded 0.1% alkaloids [60% *protopine*, 40% coptisine] (Stermitz et al. 1969).

A. brevicornuta has yielded 0.03% alkaloids [85% (-)-norargemonine, 15% berberine] (Stermitz et al. 1973b).

A. chisosensis flowering and fruiting aerial parts [harv. Texas] yielded 0.04% alkaloids [88% berberine, 11% allocryptopine, traces of *protopine*].

A. corymbosa ssp. arenicola flowering and fruiting aerial parts [harv. Arizona] yielded 0.09% alkaloids [92% berberine, 4% allocryptopine, 3% cryptopine, traces of sanguinarine] (Stermitz et al. 1969).

A. echinata has yielded 0.13% alkaloids [40% cryptopine, 30% berberine].

A. fruticosa has yielded 0.89% alkaloids [60% allocryptopine, 20% hunnemanine] (Stermitz et al. 1973a).

A. glauca var. glauca has yielded 0.47% alkaloids [40% *protopine*, 20% allocryptopine, 20% sanguinarine, 10% berberine, 10% chelerythrine] (Stermitz et al. 1971).

A. gracilenta aerial parts [harv. Jun., Arizona] have yielded 0.33% alkaloids [>90% argemonine, traces of argemonine N-oxide, argemonine methohydroxide, isonorargemonine, *protopine*, laudanine, muramine, munitagine, platycerine, reticuline] (Stermitz & McMurtrey 1969).

A. hispida aerial parts [harv. Jul., Wyoming] yielded 0.61% alkaloids [c.45% argemonine, 44% norargemonine, 5% bisnorargemonine, 6% reticuline] (Stermitz & Seiber 1966).

A. mexicana has yielded 5.5% alkaloidal residue, containing allocryptopine, berberine, (-)-cheilanthifoline, chelerythrine, norchlerythrine, coptisine, cryptopine, dihydrosanguinarine, norsanguinarine, sanguinarine, oxyhydrastinine, *protopine*, (-)-α-canadine methohydroxide, (-)-β-scoulerine methohydroxide, (-)-α- and (-)-β-stylopine methohydroxide, (-)-α-tetrahydropalmatine methohydroxide and 6-acetonyldihydrosanguinarine. Another investigation found 0.125% alkaloids,

1.75% resin and 1.1% tannins from roots and stems; alkaloids consisted of 0.084% *protopine* and 0.041% berberine. Vietnamese plants yielded 0.28% alkaloids from green aerial parts, and 0.425% from roots, consisting mostly of allocryptopine [37% of total alkaloids in green parts; 36% in roots] and *protopine* [21% in green parts, 16% in roots], as well as sanguinarine, heletrine, and 2 unidentified alkaloids. Seeds have yielded 22-36% of a toxic oil called 'argemone oil', consisting largely of sanguinarine and dihydrosanguinarine. The total alkaloids from this extraction antagonised *serotonin*, *acetylcholine* and *histamine* in animal experiments (Bose et al. 1963; Bui & Mura'eva 1973; Das & Khanna 1997; Onda & Takahashi 1988; Preininger 1986; Santos & Adkilen 1932). Its alkaloids have also been reported to reduce *morphine* withdrawal symptoms in animals (Capasso et al. 1997). Leaf and stem of Australian material growing in Rockhampton, Queensland [harv. Dec.] tested moderately strongly positive for alkaloids (Webb 1949).

A. munita ssp. argentea flowering and fruiting aerial parts [harv. Mar., California] yielded 0.28% alkaloids [c.60% allocryptopine, 20% isonorargemonine, 5% argemonine, 5% *protopine*, and 10% mixture of unidentified alkaloids]. The latex of this subspecies is nearly white (Stermitz et al. 1974).

A. munita ssp. rotundata aerial parts [harv. Jul., Utah] yielded 0.22% alkaloids [65% bisnorargemonine, 27% munitagine, 4% muramine, 2% cryptopine, 2% reticuline, 0.06% 2,9-dimethoxy-3-OH-pavinane] (Coomes et al. 1973; Stermitz & Seiber 1966).

A. pleiacantha subspecies were found to have variable alkaloid composition; all samples studied were harvested in June. A. pleiacantha ssp. pleiacantha from Ashfork, Arizona contained mostly bis-norargemonine [45% of total alkaloids], as well as *protopine* [15%], berberine [10%], munitagine [10%], and traces of norargemonine and cryptopine; plants from Sho Low, Arizona contained mostly berberine [50%] and *protopine* [35%], as well as allocryptopine [15%]; plants from Hurley, New Mexico contained mostly berberine [60%], as well as *protopine* [15%] and allocryptopine [10%]. A. pleiacantha ssp. ambigua from Peeples Valley, Arizona contained mostly berberine [30%], cryptopine [25%], bisnorargemonine [20%] and munitagine [10%]; plants from Prescott, Arizona contained mostly berberine [60%], as well as 10% each of *protopine*, cryptopine, and allocryptopine, and 3% each of munitagine and bisnorargemonine; plants from Seneca, Arizona contained mostly berberine [45%], allocryptopine [30%], and *protopine* [20%], as well as bisnorargemonine [3%] and munitagine [1%]; plants from Ashfork, Arizona contained mostly berberine [30%], *protopine* [25%], and cryptopine [25%], as well as traces of munitagine and bisnorargemonine; plants from Miami, Arizona contained mostly *protopine* [55%], as well as bisnorargemonine [20%], munitagine [10%], and traces of berberine. The less widespread A. pleiacantha ssp. pinnatisecta from High Rolls, New Mexico contained mostly munitagine [75%], as well as bisnorargemonine [15%] (Stermitz & Coomes 1969).

A. polyanthemos [harv. Argentina] aerial parts yielded 0.8% alkaloids [50% allocryptopine, <30% N-norchelerythrine, 15% chelerythrine, 12% berberine, and traces of *protopine* and sanguinarine]; roots also yielded 0.8% alkaloids, of similar composition. Aerial parts [flowering and fruiting] of plants from Wyoming and New Mexico yielded 0.07-0.12% alkaloids [82-86% berberine, 13-17% allocryptopine, traces of *protopine* and sanguinarine]; traces of chelerythrine and N-norchelerythrine have also been found in US specimens (Bandoni et al. 1975; Stermitz et al. 1969). Coptisine and (-)-scoulerine have also been found in the plant (Preininger 1986).

A. sanguinea flowering aerial parts [harv. Texas] yielded 0.05-0.07% alkaloids – alkaloids from the purple-flowered variety [which gave the slightly higher yield in this analysis] contained almost entirely berberine [94%], as well as muramine [6%]; alkaloids from the white-flowered variety contained 68% berberine, 22% allocryptopine, 6% argemonine, and 4% muramine (Stermitz et al. 1969).

A. squarrosa has yielded c.1% α-allocryptopine (Brochmann-Hanssen & Nielsen 1966).

A. subfusiformis ssp. subfusiformis [yellow-petal variety] aerial parts yielded 0.4% alkaloids [41% *protopine*, 28% allocryptopine, 9% berberine, 5% sanguinarine, 4% chelerythrine]; roots yielded 1.4% alkaloids [47% sanguinarine, 26% *protopine*, 18% allocryptopine, 7% berberine, 1% chelerythrine]. Aerial parts of the white-petalled variety yielded 0.8% alkaloids [55% *protopine*, 34% allocryptopine, 8% berberine, 3% sanguinarine]; roots yielded 0.4% alkaloids [28% *protopine*, 19% berberine, 17% allocryptopine, 3% sanguinarine, 3% chelerythrine]. The large quantities of sanguinarine in the roots are thought to form rapidly from dihydrosanguinarine, on exposure to air; previous studies suggest that only minor quantities of sanguinarine occur in this species. Incidentally, the petals of the white-petalled variety turn yellow a few days after picking, and at this stage were shown to contain berberine and sanguinarine; similarly aged petals of the yellow-petalled variety only contained berberine (Bandoni et al. 1975).

A. subfusiformis ssp. subinermis aerial parts yielded 0.6% alkaloids [46% *protopine*, 31% allocryptopine, 16% berberine, 4% sanguinarine]; roots yielded 0.9% alkaloids [42% sanguinarine, 20% *protopine*, 17% allocryptopine, 12% berberine, 2% chelerythrine] (Bandoni et al. 1975).

A. subintegrifolia flowering and early fruiting aerial parts [harv. Mar., s. of Mexicali, Baja California] yielded 0.14% alkaloids [c.70% allocryptopine, 20% *protopine*, 5% berberine, 5% mixture of unidentified alkaloids] (Stermitz et al. 1974).

A. turnerae has yielded 0.11% alkaloids [60% (-)-armepavine, 40% (-)-tetrahydropalmatine (see *Endnotes*)] (Stermitz et al. 1973b).

Argemone mexicana is a glaucous, erect, prickly annual herb, with bright yellow latex; stems mostly 1, often branched near base, bluish-green, pithy, smooth or slightly pubescent, 25-100cm tall, with scattered stiff yellow perpendicular or slightly reflexed prickles. Leaves glaucous, alternate, bluish-green, with conspicuous light blue markings over veins on upper side, smooth or with distant spines on main veins; basal leaves slightly stalked and crowded into a rosette, oblanceolate, lobes oblong, incised to ½ or more the distance to the midrib, sinuses comparitively narrow; upper leaves sessile and clasping the stem, 6-20 x 3-8cm, deeply divided into 7-11 irregular lobes (though more shallow than in lower leaves), broadly elliptical to ovate, margins wavy, with acute marginal teeth each tipped with a slender spine. Flowers creamy white to yellow, shortly stalked or sesssile at apex, 3-6(-7)cm across, closely subtended by 1-2 foliar bracts; buds subspherical or barely oblong, 9-13mm thick, 10-15mm long, smooth or sparingly prickly; sepals 3, hood-like, terete, smooth or sparsely prickled and with a large spine below apex, 5-10mm long incl. spine, sepals shedding as flower opens; petals 4-6, 2.5-3 x 1.4-4cm, the outer obovate, the inner obovate to obcuneate; stamens 30-50, filaments pale lemon-yellow; anthers yellow. Style to c.1(-3)mm long in fruit; stigma dark red to purple, c.1-2mm long, 1.5-4mm wide, 3-6 lobed, the lobes pressed against each other and appressed to the style at anthesis. Fruit a smooth or prickly capsule 2.5-5 x 2cm, oblong to broadly elliptic, 25-45mm long x 12-20mm wide, excl. spines if present, crowned with persistent style, spines to 6-10mm long; 4-6-carpellate; ripe fruits opening from apex down, dehiscing away from the style ribs attached to stigma, leaving a structure resembling the ribs of an umbrella; seeds dark brown to black, 1.6-2 x 1.5mm, oily and finely veined. Seed is dormant when shed, up until a few months later.

In subhumid semi-arid scrubland on a wide range of soils, on roadsides, rabbit warrens, cultivated fields, streambeds and waste places; Mexico, West Indies, Central America. A weed of crops in Argentina, Puerto Rico, Australia, Philippines, India, Pakistan, Madagascar, Mauritius, Morocco, Nicaragua, Tanzania, S. Africa, and parts of the US (Ownbey 1958; Parsons & Cuthbertson 1992).

ARGYREIA [including Merremia]

(Convolvulaceae)

Argyreia acuta *Lour.* **(A. festiva** *Wall.***; Lettsomia chalmersii** *Hance***; L. festiva** *(Wall.) Benth. et Hook. f.***)**
Argyreia barnesii *(Merr.) Ooststroom*
Argyreia capitata *(Vahl) Choisy* **(Convolvulus capitatus** *Vahl***)** – thao bac dau
Argyreia cuneata *(Wild) Ker-Gawl*
'Argyreia hainanensis' (Erycibe hainanensis *Merrill?***; Merremia hainanensis** *H.S. Kiu?***)**
Argyreia luzonensis *(Hall. fil.) Ooststroom*
Argyreia mollis *(Burm. f.) Choisy* **(A. championii** *Benth.***; A. obtecta** *(Choisy) C.B. Clarke***; Convolvulus mollis** *Burm. f.***; C. sericeus** *L.***; Lettsomia championii** *(Benth.) Benth. et Hook. f.***; Rivea obtecta** *(Wall.) Choisy***)**
Argyreia nervosa *(Burm. f.) Bojer* **(A. speciosa** *(L. f.) Sweet***; Convolvulus nervosus** *Burm. f.***; C. speciosus** *L. f.***; Lettsomia nervosa** *(Burm. f.) Roxb.***; Rivea nervosa** *(Burm. f.) Hallier f.***)** – Hawaiian baby woodrose, elephant creeper, wooly morning glory, bhuanath haku, samundra phul, samudrashokha, samudrapalaka, samandarkapat
Argyreia obtusifolia *Loureiro*
Argyreia osyrensis *(Roth) Choisy* **(Ipomoea osyrensis** *Roth***)**
Argyreia phillipinensis *(Merrill) Ooststroom*
Argyreia pseudorubicunda *Ooststr.*
Argyreia ridleyi *(Prain) Prain ex Ooststr.*
Argyreia rubicunda *(Wall) Choisy*
Argyreia splendens *(Hornem.) Sweet* **(Convolvulus splendens** *Hornem.***; Ipomoea splendens** *(Hornem.) Sims***; Lettsomia splendens** *Roxb.***)**
Argyreia wallichii *Choisy*
Argyreia spp. – woodroses

Merremia tuberosa *(L.) Rendle* **(Convolvulus gossypiifolius** *Humb.***; C. macrocarpus** *Sprengel***; C. tuberosus** *(L.) Spreng.***; Ipomoea glaziovii** *Dammer***; I. mendesii** *Welw.***; I. nuda** *Peter***; I. tuberosa** *L.***; Operculina tuberosa** *(L.) Meisner***)** – large baby woodrose, pilikai, xixicamatic, paktha' pok' laak, quiebra machete, bejuco de golondrina, foco de luz, quinamacal, rosa de barranco

The seeds of A. nervosa are said to have been a popular inebriating aphrodisiac with poor Hawaiians in earlier years (Rätsch 1990). In India, A. nervosa root is used as an aphrodisiac nerve tonic, and the leaves are applied topically as a stimulant and rubifacient (Kirtikar & Basu 1980). Soaked for 7 days in the juice of Asparagus racemosus and taken in a dose of 2.9-5.8g with ghee for 1 month, the root "improves intellect, strengthens body and prevents effects of age" (Nadkarni 1976). Recently it was found that Kirati shamans in Nepal use the seeds to 'fly' shamanically, with one fruit capsule containing sufficient seeds for a dose. The flowers are used as an offering to the 'nagas' [see **Naja and Ophiophagus**] (Müller-Ebeling et al. 2002). The Akha and Mien of n. Thailand use the whole plant of A. wallichii as a tonic and analgesic (Anderson 1993).

Merremia tuberosa has been proposed to have been the Aztec 'xixicamatic', a type of 'ololiuqui' [see **Turbina**]. While generally not thought to be psychoactive [see below], M. tuberosa acts as a purgative and antipyretic. Modern Mayans use it to treat headaches (Austin 1998).

In the latter part of the last century, the practice of using A. nervosa seeds as a psychotrope began amongst elements of the drug subculture, particularly as an ingredient in 'Utopian bliss balls' [see *Methods of Ingestion*]. For use, the seeds [removed from their pods] are scraped clean of their fuzzy outer coating and adhering fine whitish hairs. This can be tedious and fiddly, but failure to completely remove these portions reputedly results in a greater level of unpleasant side effects. The tiny hairs, in particular, may be irritating to sensitive membranes. The seeds are usually either chewed [preferably when fresh, or after soaking to soften the seeds], ground and eaten [as in 'Utopian bliss balls'], or extracted into water before ingestion. A water extraction of the same kind used with **Ipomoea** is sufficient. Recently, psychonauts have been experimenting with a lime juice [see **Citrus**] extraction method. This involves soaking the cleaned, ground seeds in 1-2 tablespoons of lime juice for roughly 30 min., with periodic agitation of the mixture. After this time, orange juice is added and the mixture drunk. Some people prefer to let this settle before drinking, to avoid consuming the seed solids. The lime juice soak has been claimed to eliminate nausea [perhaps by neutralising some nauseating component of the seeds]. Although this has not been the case for everyone who has tried this method, it may be that nausea is indeed reduced in intensity. In the case of A. nervosa, 4-8 seeds may constitute a dose, although their effectiveness declines with age (Ott 1993; Rätsch 1998; Stafford 1992; pers. comms.; pers. obs.). A similar number of the larger seeds of M. tuberosa has been claimed to be psychoactive (Gottlieb 1992), and though the species has generally been regarded as inactive, I have received recent confirmation that at least some samples of M. tuberosa seeds are indeed active, but weaker in potency, compared with A. nervosa (pers. comms.).

Effects of psychoactive Argyreia spp. seeds are generally similar to those of psychoactive **Ipomoea** and **Turbina** species, due to similar chemistry [ie. indole ergoline alkaloids] (Der Marderosian 1967). However, like these other plants, the exact nature of effects should be expected to vary from one batch of seed to another [also varying with freshness]. Nausea and mild stomach cramps may be experienced within the first hour or two after consuming the seeds [or an extract thereof], wearing off shortly after. This nausea can be minimised by keeping still; if for any reason movement is necessary, it is best to move slowly and gently (pers. obs.). These seeds should not be taken by pregnant women due to their content of uterotonic alkaloids.

A. acuta seeds were found to contain *ergine*, *ergonovine* and *chanoclavine*-I.

A. aggregata seeds were found to contain unidentified ergoline alkaloids.

A. barnesii seeds were found to contain isoergine, ergometrinine, lysergic acid α-OH-ethylamide, *agroclavine*, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine* and isolysergol.

A. capitata seeds were found to contain large amounts of ergolines including *ergine*, isoergine, *ergonovine* and *chanoclavine*, as well as an unidentified ergoline alkaloid (Chao & Der Marderosian 1973a). Roots and aerial parts yielded arcapitins A-C, dammarane-type triterpenes (Tofern et al. 1999b), but no ergolines (Tofern et al. 1999a).

A. cuneata seeds were found to contain isoergine, *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, *agroclavine*, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine*, *penniclavine*, lysergene, *lysergol* and isolysergol, as well as 7 unidentified ergolines.

A. hainanensis seeds were found to contain *ergine*, *ergonovine* and *chanoclavine*-I (Chao & Der Marderosian 1973a).

A. hookeri seeds were found to contain unidentified ergoline alkaloids; roots and aerial parts did not contain detectable ergolines (Tofern et al. 1999a).

A. luzonensis seeds were found to contain *ergine*, isoergine, *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, isolysergic acid α-OH-ethylamide, *agroclavine*, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine*, *penniclavine*, *lysergol*, isolysergol, ergosine and ergosinine, as well as 10 unidentified ergolines.

A. maingayi seeds were found to contain 5 unidentified ergoline alkaloids.

A. mollis seeds were found to contain *ergine*, isoergine, *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, *agroclavine*, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine*, *penniclavine*, isolysergol, ergosine and ergosinine, as well as 8 unidentified ergolines (Chao & Der Marderosian 1973a). The herbage was found to contain calystegines [see **Convolvulus**] (Schimming et al. 1998) as well as loline [see **Festuca**, **Lolium**], N-formylloline, N-methylloline, N-propionylnorloline [decorticasine], *nicotine*, pseudotropine, hygrine and cuscohygrine. Roots yielded loline, N-formylloline, N-methylloline, pseudotropine, hygrine, cuscohygrine, 2',4-N-methylpyrrolidinylhygrine and 2',3-N-methylpyrrolidinylhygrine. No ergolines were detected in aerial parts or roots (Tofern et al. 1999a).

A. nervosa seed has yielded 0.3-0.9% alkaloids. As % of dried seed, this may include 0.136% *ergine*, 0.188% isoergine, 0.049% *ergonovine*, 0.011% ergometrinine, 0.035% lysergic acid α-OH-ethylamide, 0.024% isolysergic acid α-OH-ethylamide, 0.006% *agroclavine*, 0.016% *chanoclavine*-I, 0.022% *elymoclavine*, and 0.113% other alkaloids, including *chanoclavine*-II, *festuclavine*, *penniclavine*, molliclavine, setoclavine, isosetoclavine, lysergene, *lysergol* and isolysergol, and up to 11 unidentified ergolines; pericarp yielded 0.0015% alkaloids (Chao & Der Marderosian 1973a, 1973b; Hylin & Watson 1965; McJunkins et al. 1969; Miller, M.D. 1970). No ergolines were detected in roots or aerial parts (Tofern et al. 1999a). As A. speciosa, leaves [from India] were found to be +- alkaloid-free, but yielded 1-triacontanol, epi-friedelinol, epi-friedelinol acetate and β-sitosterol (Sahu & Chakravarti 1971). However, identification is in question, as these researchers listed the plant as being synonymous with Stryptocardia tiliaefolia – which is presumably a spelling mistake, referring to **Stictocardia**.

A. obtusifolia seeds were found to contain *ergine*, isoergine, *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, *agroclavine*, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine*, *penniclavine*, ergosine, ergosinine and 5 unidentified ergolines.

A. osyrensis seeds were found to contain large amounts of ergoline alkaloids, including *ergine*, isoergine, *ergonovine* and *chanoclavine*, as well as unidentified ergolines.

A. phillipinensis seeds were found to contain *ergine*, isoergine, ergometrinine, lysergic acid α-OH-ethylamide, *chanoclavine*-I, *festuclavine*, *penniclavine*, *lysergol*, isolysergol and 2 unidentified ergolines.

A. pseudorubicunda seeds were found to contain large amounts of ergolines, including *ergine*, isoergine, *ergonovine* and *chanoclavine*, as well as unidentified ergoline alkaloids.

A. reticulata seeds were found to contain 2 unidentified ergoline alkaloids.

A. ridleyi seeds were found to contain ergosine, ergosinine and an unidentified ergoline alkaloid.

A. rubicunda seeds were found to contain *lysergol*.

A. splendens seeds were found to contain *ergine*, isoergine, *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, *chanoclavine*-I & -II, *elymoclavine*, *festuclavine*, *lysergol*, ergosine, ergosinine and an unidentified ergoline.

A. wallichii seeds were found to contain *ergine*, isoergine, *ergonovine*, *chanoclavine*-I, *festuclavine* and isolysergol (Chao & Der Marderosian 1973a).

Merremia tuberosa seed has not formally yielded alkaloids, though one sample of dried sepals did test positive for small quantities of alkaloids, which were not identified (Hylin & Watson 1965). Roots and seeds have yielded saponin-like resins, and coumarins [*scopoletin* and umbelliferone]; roots also contain tropinone, hygrine, cuscohygrine, other hygrine derivatives, and calystegines (Austin 1998); leaves yielded quercetin, gentisic acid, vanillic acid, syringic acid, napthoquinones, and traces of saponins (Nair et al. 1986).

Argyreia nervosa is a woody climber to 10m, containing white latex. Leaves petiolate, entire, ovate-orbicular, apex obtuse, acute or with a short cusp, base cordate, 18-27cm long, densely white, grey or yellowish-hairy beneath. Inflorescence 1-many-flowered, axillary, subcapitate, on a long, stout, white-tomentose peduncle; sepals 5, often dorsally pubescent, herbaceous to subcoriaceous, often persistent in fruit; corolla 6-6.5cm, tubular to funnel-shaped, lavender, base of tube darker, mid-petaline bands and tube densely wooly outside; stamens included or exserted; stigma 2-lobed. Fruit berry-like, indehiscent, fleshy, leathery or mealy; seeds 1-4, usually glabrous, brown, rounded on back, with 2 angled sides.

Native to India, Bangladesh, introduced to Hawaii, pantropically cultivated and naturalised (Burras ed. 1994), such as the naturalised population/s in Queensland [Australia] (Hnatiuk 1990).

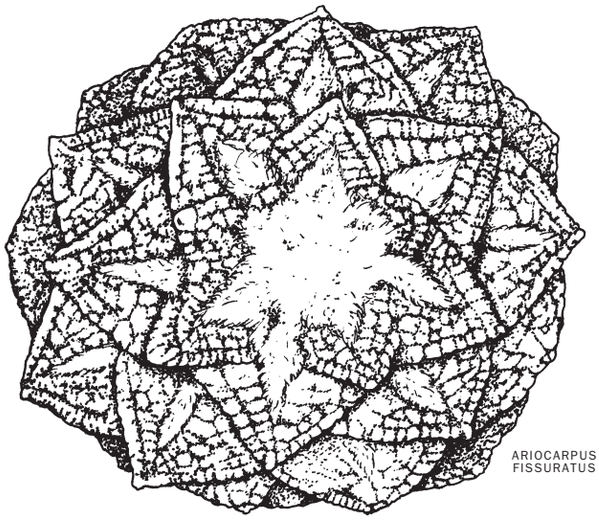
Propagate from scarified and soaked seed in spring, plant c.1-2cm deep; water sparingly after germination. Requires stout supports to climb, likes full sun and moderately fertile soil. Benefits from plenty of space for root development, from an early age. Will tolerate a winter low of 13°C; may require a greenhouse in colder climates (Burras ed. 1994; pers. comms.).

Some psychonauts have stated that A. nervosa exists in two virtually indistinguishable varieties – A. nervosa var. nervosa and A. nervosa var. speciosa. The former is most often sourced from Hawaii or n.e. Australia, the latter most often from India and Africa. A. nervosa var. speciosa seeds are reputedly lower in alkaloid content than the preferred A. nervosa var.

nervosa seeds, and are unfortunately much more prevalent in the commercial market (pers. comm.).

ARIOCARPUS

(Cactaceae)



ARIOCARPUS FISSURATUS

Ariocarpus agavoides *(Castañeda) Anderson* **(Neogomesia agavoides** *Cast.***)** – magueyitos ['little Agaves']

Ariocarpus fissuratus *(Engelmann) Schumann* **(A. lloydii** *Rose***; Anhalonium engelmannii** *Lemaire***; An. fissuratum** *Engelm.***; Mammillaria fissurata** *Engelm.***; Roseocactus fissuratus** *(Engelm.) Berg.***; R. intermedius** *Backeberg et Kilian***; R. lloydii** *(Rose) Berg.***)** – híkuli sunami, sunami, chaute, chautle, peyote cimarrón, peyote, dry whiskey, pezuña de venado

Ariocarpus kotschoubeyanus *(Lemaire) Schumann* **(A. sulcatus** *Schum.***; Anhalonium kotschoubeyanus** *Lem.***; An. sulcatum** *Salm-Dyck***; Roseocactus kotschoubeyanus** *(Lem.) Berger***)** – peyote, chaute, pata de venado ['deer's foot'], pezuña de venado ['cloved hoof of the deer']

Ariocarpus retusus *Scheidweiler* **(A. confusus** *Halda et Horacek***; A. elongatus** *(Salm-Dyck) M.H. Lee***; A. furfuraceus** *(Watson) H.C. Thompson***; A. retusus ssp. scapharostroides** *Halda et Horacek***; Anhalonium elongatum** *Salm-Dyck.***; An. furfuraceum** *Coult.***; An. prismaticum** *Lem.***; An. pulvilligerum** *Lem.***; Cactus prismaticus** *Kuntze***; Mammillaria furfuracea** *S. Wats.***; M. prismatica** *Hemsl.***)** – tsuwiri, peyote, chaute, chautle

Ariocarpus scaphirostris *Boedeker* **(A. scapharostrus** *Boedeker nom. illeg.***)**

Ariocarpus trigonus *(Web.) Schu.* **(A. retusus ssp. trigonus** *(Web.) Anderson et Fitz Maurice***; Anhalonium trigonum** *Weber***)** – chaute

Ariocarpus spp. – living rock, cactus edelweiss

These cacti are representatives of the group of 'false peyotes' known to some indigenous Mexican groups [see **Lophophora**], and their mucilage is sometimes used as a glue (Bravo 1937; Bruhn & Bruhn 1973; Schultes 1937a, 1937b). The Tarahumara consider A. fissuratus to be "even more powerful than wanamé" [**Lophophora** williamsii]. It is sometimes either eaten fresh or macerated in water and drunk, and is "strongly intoxicating". A "small, reddish cactus" referred to as 'peyote cimmarón', which may be an **Ariocarpus** sp., is said to be "considered ineffective by the Tarahumara, although one must not abuse it, or else one will die." A. retusus is regarded by the Huichol as a 'false peyote' that produces evil and undesirable effects. When on their annual peyote hunt, the Huichol believe that to any who had not properly purified themselves at the start of the pilgrimage by admitting all of their sexual encounters outside of marriage [see **Lophophora**], 'tsuwiri' [A. retusus] may appear to be a real peyote specimen. Eating it is reputed by the Huichol to send one into a deliriant-hallucinogenic state (Bye 1979b; Diaz 1979; Furst 1971; Schultes 1967a), which from the descriptions, seems similar to that experienced from anti-cholinergic tropane alkaloids in **Datura** and some other Solanaceous plants (pers. obs.). Amongst Huichol shamans who use A. retusus as an ally, 2 tubercles are eaten as one dose. The dried tubercle tips are reportedly smoked, presumably 'recreationally', by some Mexicans (Ben pers. comm. 2003; Sacred Succulents 2002). A. retusus is said to have been used medicinally, to treat malaria (Braga & McLaughlin 1969).

A. kotschoubeyanus is used as an external medicine for wounds, and its mucilage is used as a glue. A. agavoides is eaten in Tamaulipas as a food, for its sweet flesh; locals refer to the plants as 'magueyitos' (Smith 2000). When eaten in excessive amounts, it reputedly causes dizziness (Sacred Succulents 2002).

A. agavoides has yielded 0.001-0.01% alkaloids, over half of which was *hordenine*, with lesser amounts of N,N-dimethyl-3-MeO-*tyramine*, and traces of N-methyl-*DMPEA* and unidentified alkaloids (Bruhn & Bruhn 1973).

A. fissuratus has yielded *hordenine*, N-methyl-*tyramine* and 0.004% N-methyl-*DMPEA* (McLaughlin 1969; Norquist & McLaughlin 1970). Bioassays have confirmed the psychoactivity of this species, described only as "definitely psychoactive and possibly entheogenic" (Anon. 1998). Another experiment resulted in "non-hallucinogenic effects with strong narcotic pain killing qualities" (Smith 2000). One person, who referred to himself as a 'soft-head' [one who is easily affected by psychoactive drugs], experienced noticeable stimulation from a whole seedling [1g, including root], which was consumed after liquidising with vitamin C (theobromus pers. comm.).

A. kotschoubeyanus has yielded 0.089% *hordenine* and 0.019% N-methyl-*tyramine* (Neal et al. 1971). Bioassays have shown this species to be similarly psychoactive to A. fissuratus, though producing milder effects (Anon. 1998).

A. retusus has yielded 0.018% *hordenine*, 0.001% N-methyl-*tyramine* (Braga & McLaughlin 1969), 0.00045% N-methyl-4-MeO-*phenethylamine* and 0.00047% N-methyl-*DMPEA* (Neal & McLaughlin 1970), as well as the flavonoid retusin [0.041%] and 0.035% β-sitosterol (Dominguez et al. 1968).

A. scaphirostris [fresh] has yielded 0.012% alkaloids, consisting of *hordenine* [major alkaloid], N-methyl-*tyramine*, N-methyl-*DMPEA* and N,N-dimethyl-*DMPEA* (Bruhn 1975).

A. trigonus has yielded 0.013% *hordenine*, 0.0003% N-methyl-*tyramine* and 0.007% N-methyl-*DMPEA* (Speir et al. 1970).

These plants contain highest alkaloid levels when they are actively growing and healthy (Anderson 1960).

Ariocarpus fissuratus has a usually solitary stem, grey-green, inconspicuous, +- turnip shaped [including the root], only the flattened or slightly convex top protruding above ground; usually 4-5cm high, to 10cm diam.; tubercles flattened or somewhat angular on top, exposed portion deltoid, deeply fissured-tuberculate above, exposed portion usually 12-25mm long, 20-25mm across, densely wooly; spines none on mature plant. Flower on upper side of tubercle at end of groove, to 3.5(-4)cm diam. and long; sepaloids with magenta midribs and pale magenta to whitish margins, the larger oblanceolate, to 20-25mm long, 4.5(-6)mm wide, mucronulate, entire or slightly undulate; petals pale magenta, largest cuneate, to 30 x 15mm, apex rounded, margin entire or finely and irregularly toothed; filaments pale, c.6mm long; anthers yellow, 0.7mm long, plump; style pale, 15-19mm long, c.1mm greatest diam.; stigmas 5-10, mostly 3-4.5mm long, slender; ovary in anthesis 3-4.5mm long. Fruit white to greenish, at first fleshy but drying at maturity, becoming brown, +- smooth, globose to oblong, 6-15 x 3-6mm, remaining embedded in wool, finely disintegrating; seeds irregularly obovoid, 0.8 x 0.6 x 0.5mm.

Limestone soils often with rock fragments, in hills or ridges in desert at 500-1170m; s.w. Texas, Mexico [Chihuahua, Coahuila] (Benson 1982). Natural habitat has a pH of 7-8 (Anderson 1960). Prefers coarse, mineral-rich soil with a high proportion of gravel and rock. Slow-growing. Water sparingly. Enjoys partial sun, or full sun for part of the day (Trout & Friends 1999). Growth is greatly accelerated by grafting to a base stock of **Trichocereus** pachanoi or a similar fast-growing columnar cactus, though they can be difficult to graft successfully. One grower suggests only grafting "younger plants that are no more than 1½ to 2 inches in diameter." The root should also be left in the soil to regenerate (Anon. 1998).

ARMATOCEREUS

(Cactaceae)

Armatocereus laetus *(Kunth) Backeberg ex A.W. Hill* **(A. jungo** *Backeb.***; Cereus laetus** *(Kunth) DC.***; Lemaireocereus laetus** *(Kunth) Britton et Rose***)** – pishicol, pishicol blanco

In the valley of Huancabamba, high in the n. Peruvian Andes, this cactus is apparently considered to be equipotent with **Trichocereus** pachanoi, which it arguably resembles at a distance. It is said to be used in a similar manner by some of the locals who are aware of its powers (Davis 1983). A human bioassay of an unspecified quantity of A. arboreus resulted in no discernable activity (Stuart 2002).

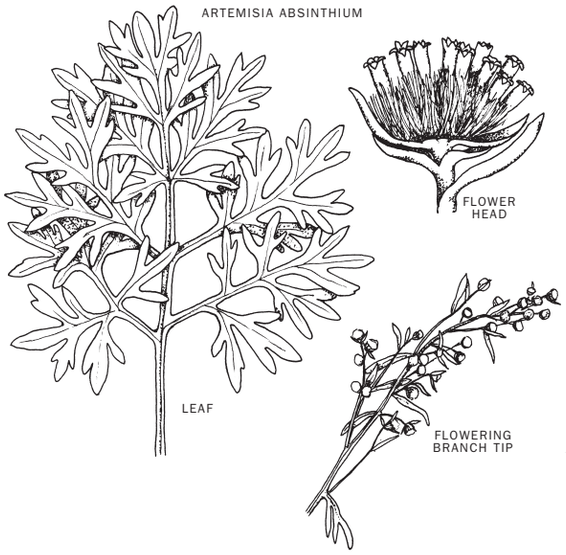
Chemistry of this obscure and rare cactus is unknown, but it would be expected to yield moderate quantities of *mescaline*, if the reports of Davis were accurate. One analysis of wild Peruvian material found a water content of 82.3%, but was unable to resolve any alkaloids or triterpenes; the method of analysis is questionable (Trout ed. 1999). Davis (1983) reported that results of an analysis for alkaloids would be published at a later date, but nothing has eventuated since the publication of his paper.

Armatocereus laetus is a large, tree-like cactus 4-6m high, much branched, columnar, bluish-grey to greyish-green, but not glaucous; 4-8 ribs, prominent; areoles 2-3cm apart; each bearing up to 12 spines, brown when young, becoming grey to nearly white with age, 1-3(-8)cm long, subulate. Flowers 6.5-8cm long, 5cm across, tubular-funnel shaped, nocturnal; perianth short, inner perianth segments white, 2cm long; pericarpel with small scales; receptacle tube short. Fruit green, with very spiny, wooly areoles; splitting down the side when ripe, white within; pulp edible. Seeds black, large, mostly flattened, ovoid or cap-shaped. Fl. summer.

N. Peru; Jaen, Sondorillo, Huancabamba and east of Abra Porculla. Also in s. Ecuador (Britton & Rose 1963; Davis 1983; Innes & Glass 1991). Requires good light; min. temp. 13ºC (Innes & Glass 1991). Should grow well with poor quality, well-drained soil, moderate sun and little water (Trout & Friends 1999).

ARTEMISIA

(Compositae/Asteraceae)



Artemisia abrotanum *L.* – southernwood, lad's love, hexenkraut
Artemisia absinthium *L.* – wormwood, absinthe, green ginger, wermuth, old woman, green muse, ajenjo, ajincuy, dhupma, shimali pati
Artemisia arborescens *L.* – shrub wormwood
Artemisia caerulescens *L.* **ssp. gallica** *(Willd.) Persoon*
Artemisia capillaris *Thunb.* – yin chen
Artemisia carruthii *A.W. Wood ex Carruth* **(A. vulgaris ssp. carruthii** *(Wood ex Carr.) F.C. Gates***)**
Artemisia cina *Bergius* – levant wormseed, hexenkraut
Artemisia copa *Phil.*
Artemisia dranunculus *L.* – tarragon, French tarragon, estragon, dragoncello
Artemisia frigida *Willd.* – chin-de-I-ze
Artemisia genipi *Weber* **(A. spicata** *Wulf. ex Jacq.***)** – black wormwood, genepi
Artemisia indica *Willd.*
Artemisia keiskeana *Miq.*
Artemisia ludoviciana *Nuttall* – sacred western mugwort, white mugwort, white sage, prairie sage, Mexican sagewort, xawiskarawirotapapanahi, lobed cudweed
Artemisia mexicana *Willd.* – itzauhyatl, estaphiate, ajenje
Artemisia nilagirica *(Clarke) Pamp.* – khel bijak, ote palandu
Artemisia scopulorum *A. Gray* – sage bush
Artemisia tilessii *Ledeb.*
Artemisia tridentata *Nutt.* – sagebrush, big sagebrush, sage among rocks, black coyote tobacco, rabbit candy, cetah c'ah, kah pilikhanik, mai lizin nat'oh
Artemisia vulgaris *L.* – mugwort, felon herb, sailor's tobacco, gypsy tobacco, English tobacco, old man, bollan bane ['white herb'], belfuss, armoise, cosi, moxa herb, muggar, muggons, ai-hao, hexenkraut, una, titepati, pati
Artemisia spp.

Artemisia is a large genus with many representatives bearing inebriating essential oils; they also find useage in medicine, often as tonics, anthelmintics and abortifacients. The genus is named after Artemis [identified with Diana], the 'mother of herbs', lady of the hunt and Greek goddess of wild places, wild beasts, the moon, and the sea. A. absinthium and A. vulgaris were sacred to her, and she was considered to be concentrated in those herbs, which were ingested during spring full-moon Artemis celebrations in the ancient Mediterranean, fertility rites which ended in group sexual bonding. In India, members of the genus are sacred to Shiva and Vishnu, and to Isis [the mother goddess] in Egypt (Albert-Puleo 1978; Jordan 1992; Pendell 1995; Rätsch 1992; theobromus pers. comm.).

The most famous of the Artemisia spp. is 'wormwood', A. absinthium. It has been believed to dispel evil spirits and cure poisoning, even though it is said to have grown along the route by which the serpent left the Garden of Eden. Burning it with sandalwood [see **Santalum**] is said to conjure spirits. It has been used to procure abortion, due to its uterine effects, and is known to repel insects and kill intestinal worms. A leaf infusion is tonic to the liver, blood, gall bladder and digestive system, reducing the toxicity of lead poisoning, as well as being antiinflammatory, antipyretic and antimalarial (Albert-Puleo 1978; Bremness 1994; Cunningham 1994; Simonetti 1990). In India, it is said to have "a remarkably tonic influence upon the brain, especially upon its higher faculties concerned with psychical function" (Nadkarni 1976).

Wormwood's real fame came with the invention in 1792 of 'absinthe', a potent alcoholic liqueur featuring A. absinthium as the principal herbal ingredient. The 'original' [a matter of debate] absinthe of Dr. Pierre Ordinaire ['La Fee Verte'] was 68% alcohol, and probably contained A. absinthium, aniseed [**Pimpinella**], sweet flag [**Acorus**], coriander [**Coriandrum**], chamomile [**Anthemis**, **Matricaria**], parsley [**Petroselinum**], hyssop, dittany, lemon balm [see *Endnotes*], veronica and spinach. It has been reported, though, that as early as 1559, independent London distilleries were making a crude absinthe by steeping dried leaves of A. absinthium in equal parts of malmsey wine and 'burning water thrice distilled'. Dioscorides mentioned that the inhabitants of Thrace and around the Sea of Marmara drank 'apsinthites oinon' ['wine with wormwood'] as a summer health tonic. Also, in Tudor-period England, an ale made with A. absinthium called 'purl', and a wine called 'purl royal', were being made and consumed, particularly as breakfast stimulants and appetite tonics (Conrad 1988; Gunther ed. 1934; Mabey 1997; Pendell 1995).

Since the wider introduction of true absinthe, its popularity and production spread, and many variations on the original recipes were marketed, but always with wormwood or its oil as the main additive. The best was generally considered to be 'Pernod Fils', which used wormwood, mugwort [A. vulgaris], hyssop, lemon balm, aniseed [see **Pimpinella**] and fennel seed [see **Foeniculum**]. In the 1840's, French soldiers in Algeria were issued absinthe as a fever-preventative. The drink was popular especially with artistic and creative personalities, having been consumed by such men as Vincent Van Gogh, Pablo Picasso, Oscar Wilde, Arthur Rimbaud, Charles Baudelaire and Ernest Hemingway. Pressure to ban absinthe soon came, largely after an alcoholic man claimed to have been under the influence of absinthe when he murdered his wife in 1905. Much of this pressure seemed to have originated from manufacturers of alcoholic beverages who were in competition with absinthe sales, and had heavy political influence. Claims of neurotoxicity were made [claims which extended to A. absinthium and *thujone*, one of its major constituents], which could in truth be related to the many counterfeit, poorly-manufactured absinthes on the market, many of which were not properly distilled and contained heavy metal additives to add the particular colour and turbidity that consumers would expect in their absinthe. The high alcohol content of these drinks would also account for more neurotoxicity than the herbal additives, wormwood being taken up as the culprit on dubious scientific grounds. Belgium banned it in 1905, and other countries soon followed suit. Bootleg absinthe is still made for local consumption in the Val-de-Travers region of Switzerland, and 'absenta', a Spanish version, was never outlawed. Otherwise, the closest drinks remaining are 'Pernod' [which contains no wormwood] and 'Vermouth' [which contains small amounts]. See *Methods of Ingestion* for more discussion (Albert-Puleo 1978; Conrad 1988; Mabey 1997; Ott 1993; Pendell 1995; Simonetti 1990; Usher 1974).

'Mugwort' [A. vulgaris] has long been used as a uterine stimulant, and is said to be an antidote to opium-poisoning [see **Papaver**]. It was once used in brewing beer, and is known in Germany as a witch's herb. It was the first of the 9 sacred herbs given to the world by Odin, and was known as 'una' by the Saxons in England. The Romans planted it alongside their roads, to be picked and placed in the sandals to relieve tired, aching feet. Placed under or in the pillow, it is said to produce wondrous dreams, an effect verified by some modern psychonauts. The Ainu use it to exorcise disease-causing spirits, by drinking an infusion of it before divination. In TCM, the herb is rolled into cones ['moxa'] to be placed on the body and burnt for heat-treatment ['moxibustion'], as well as being used to treat haemorrhage and diarrhoea. In India, it is used as an antispasmodic, larvicide, anthelmintic and stomachic. In parts of Asia, the leaves have also been smoked as an inebriant (Albert-Puleo 1978; Baill pers. comm.; Bremness 1994; Cunningham 1994; De Vries 1991; Mabey 1997; Mabey et al. ed. 1990; Misra & Singh 1986; Ott 1993; Simonetti 1990; Usher 1974). In Australia, some **Cannabis** smokers have used A. vulgaris foliage as an alternative when no **Cannabis** was available (pers. obs.). In

England, children would sometimes smoke mugwort in acorn-cup pipes, to become 'groggy', a state which they hid from their parents. On Tynwald Day [Jul. 5], the thousand year old parliament of the Isle of Man still meets outdoors at an ancient artificial mound at the centre of the island [Tynwald Hill]; nearly everyone present wears a sprig of mugwort ['bollan bane'] (Mabey 1997). The sprig is locally believed to guard against faeries (theobromus pers. comm.). It is said to be used as a 'sage' [see **Salvia**] in peyote ceremonies [see **Lophophora**] – it is rubbed over the body as a purifier, chewed before chewing peyote, or smouldered in the sweat-lodge (Schultes 1937a), though this might be a confusion with A. ludoviciana or another Artemisia sp. (pers. obs.). In Nepal, seeds and other aerial parts of A. vulgaris and other A. spp. are important shamanic herbs, required for all ceremonies [Chenopodium abrosioides is substituted if Artemisia can't be obtained - see *Endnotes*]; they are used for shamanic travel, ritual incense, as a protectant and medicine (Müller-Ebeling et al. 2002).

A. abrotanum is used in s. Europe to make a stimulating tonic drink; the herb is also put under the pillow to relieve insomnia. In Germany, it is considered a witch's herb ['hexenkraut']. In England, it was believed that a witch could not pass one of these plants without stopping to count every leaf. It has antiseptic, anthelmintic, and insect-repellant properties, as well as treating skin problems and acting as an emmenagogue. A. caerulescens ssp. gallica is used in Spain as an analgesic, antipyretic and antiinflammatory. A. arborescens has been used in European folk medicine as a contraceptive and abortifacient. A. cina is also a 'hexenkraut', effective against roundworm and threadworm, and said to be toxic in large amounts. A. afra is used as an ash with snuffing tobacco [see **Nicotiana**] in Basutoland, s.e. Africa. The Zuni of N. America inhale the smoke of A. carruthii as an analgesic. In Chile, an infusion of A. copa is consumed, said to be "probably hallucinogenic" (Bremness 1994; De Vries 1991; Ott 1993; Sacco et al. 1983; theobromus pers. comm.; Usher 1974; Watt & Breyer-Brandwijk 1962).

'Tarragon' [A. dranunculus] is a fiery herb with an unusual tang used as a cooking spice, and as a tonic, analgesic and appetite stimulant. The root acts as a soporific, and is used to treat toothache (Bremness 1994; Lawless 1995; Mabey et al. ed. 1990); the herb has also been used similarly to A. indica [see below]. The Apache inhale smoke from A. frigida to calm the nerves after a 'terrible fright'; the Potowatomi inhale its smoke as a stimulant. The Navajo drink a decoction of A. scopulorum to purify mind and soul. Crushed leaves of A. ludoviciana are snuffed by the Cheyenne to treat headaches, and the Winnebago use it as a smudge to 'revive consciousness'. To many Native American shamans, it is a very important and sacred herb, used to heal, purify, banish evil, and communicate with the Great Spirit. It is usually taken either by decoction, heated in a sweat-lodge, or smoked [as a smudge or incense]. A. mexicana was used by the Aztecs as an intoxicant – the inside of the stem was said to be used to lighten the mood, promote health and relieve cough, and flowers were used to treat 'lassitude'. The seeds of A. keiskeana are used in China to prepare 'elixirs of immortality'. In India, beds of A. indica are prepared for a person suffering from body pain; in Nepal, the leaves are heated and applied to treat dysentery (Heffern 1974; Kindscher 1992; Kindscher & Hurlburt 1998; Ott 1993; Rätsch 1992).

In Meghalaya, India, A. nilagirica leaf is used to treat 'brain diseases' and asthma, or decocted to apply to sores (Neogi et al. 1989). The Oraon of w. Bengal smoke A. nilagirica to produce 'hallucinations'; the burning herb also produces sedation and sleep, and the Santals of the same area use the leaf oil as a local anaesthetic. The plant has also been used as an asthma remedy (Pal & Jain 1989). A. capillaris is used in TCM for its dried young shoots, to treat jaundice; it has antipyretic, antibacterial, antiviral, antiasthmatic and hypotensive activities, though it can sometimes cause nausea, dizziness and distended abdomen (Huang 1993). The herb is pleasantly psychoactive when smoked, and is particularly effective smoked in combination with **Nymphaea** caerulea flowers (friendly pers. comm. 2002). A. genipi is used in Europe as a tonic, digestive expectorant, and in the manufacture of some liquors (Simonetti 1990). The Yupik of s.w. Alaska use A. tilesii to relieve joint pain and chest colds, and as a topical treatment for infections (Overfield et al. 1980).

A. tridentata, 'sagebrush', is used by Native Americans in 'smudging' [cleansing an area with smoke from a smouldering bundle of an aromatic herb] and sweat-lodges (Pendell 1995), for its purifying essence; it is also used as a digestive, anthelmintic, and disinfectant, as well as treating headache and colds (Winter 1998). It is said that apprentice shamans must learn to "tap the spirit of the sagebrush" in order to learn how to cure (Bremness 1994).

Many of these herbs contain *thujone*, which has narcotic and mildly 'psychedelic' effects; it may also be toxic in large amounts, and should be avoided by pregnant women. Many **Artemisia** spp. can be smoked to produce inebriation, which may differ qualitatively with different species bearing different chemical make-up, as *thujone* is not the only pharmacologically-active chemical in this genus, just the best-known. Richard Miller (1985) claimed that the sesquiterpene absinthin [which he called 'absinthine'], which is present in A. absinthium as the main bitter compound, "is listed as a narcotic analgesic in the same group as *codeine* and dextromethorphan hydrobromide". However, I have been unable to find any other sources which verify this seemingly unfounded statement.

A. absinthium essential oil is highest before blooming [0.2-1.7%], and may yield 2.76% α-*thujone*, 46-60% β-*thujone*, 2.7% sabinene, 3.2% trans-sabinol, 27.78% trans-sabinyl acetate, 1% myrcene, 1.4% geranyl-propionate, linalyl acetate, and thujols; the herb has also yielded absinthin, isoabsinthin, absintholide, anabsin, anabsinthin, artemisine, arabsin, arlatin, artabasin, artabsinolides A-C, artenolide, sesartemin, diasesartemin, episesartemin A, episyringaresinol, spinacetin, inuliobose, OH-pelenolide, ketopenelolides A & B, 7-ethyl-3,6-dihydro-1,4-dimethylazulene, 7-ethyl-5,6-dihydro-1,4-dimethylazulene, 5-(1-propenyl)-2-thiophenepropanoic acid (Bruneton 1995; Buckingham et al. ed. 1994; Lawless 1994; Ott 1993; Pendell 1995), and *choline*. An extract of the plant showed binding activity to nicotinic and muscarinic *acetylcholine* receptors in human brain, displacing *hyoscine* (MacKenzie 2000; Wakea et al. 2000).

A. annua aerial parts have yielded *scopoletin* and scopolin (Saitbaeva & Sidyakin 1971).

A. arborescens leaves and flowers from Italy yielded 1% essential oil, containing 45% β-*thujone*, 17.86% *camphor*, 11.32% chamazulene [antipyretic, antiinflammatory], traces of *methyleugenol*, α-*thujone*, humulene, *borneol*, and other compounds (Sacco et al. 1983).

A. caerulescens ssp. gallica contains *thujone* (Ott 1993).

A. capillaris shoots have yielded capillarin, capillene, capilline, capillone, scoparone, *chlorogenic acid*, caffeic acid, 4-OH-*acetophenone*, and an essential oil containing β-*pinene* (Huang 1993).

A. dranunculus might owe its hypnotic properties to its large content of *estragole* [68-80% of essential oil]; the oil also contains 6-12% cis- and trans-ocimene, 2-6% limonene, *thujone*, capilline, nerol, phellandrene, 9-OH-geraniol and cineol. The herb has also yielded methoxy-flavanones, naringenin [see **Citrus**], capillarin, capillone, scoparone, artemidiniol, artemidiol, 7-MeO-coumarin, 6,7-dimethoxycoumarin, inulobiose, L-pinitol, benzopyrans, 4-MeO-benzyl alcohol, 5-phenyl-1,3-pentadiyne, 4,6-heptadiyne-1,3-diol, iodine and vitamins A & C (Balza et al. 1985; Bremness 1994; Bruneton 1995; Buckingham et al. ed. 1994; Lawless 1995; Rastogi & Mehrotra ed. 1990-1993).

A. ludoviciana fresh flower heads yielded 0.01-0.1% anthemidin, a sesquiterpene lactone (Epstein & Jenkins 1979).

A. tilesii has yielded *thujone* and iso-*thujone* in a ratio of 4:1 [0.05% combined], with traces of *camphor*, cineole and artemisia ketone, as components of the essential oil (Overfield et al. 1980).

A. tridentata ssp. tridentata ['basin big sagebrush'] essential oil contains c.30% each of *thujone* and methacrolein [2-methyl-2-propenal], 11% 1,8-cineole and 3% *camphor*; ssp. vaseyana ['mountain big sagebrush'] essential oil contains no *thujone*, but is predominant in 1,8-cineole [57.8%], with smaller amounts of camphene [11.6%] and *camphor* [7.9%] (Weber et al. 1994). The herb has also yielded sesquiterpene lactones, including arbusculins A-C and desacetyl-matricarin (Shafizadeh et al. 1971); and artelin, artemisiole, artevasin, dehydroleucodin, dentatin A, dihydromagniolialide, 11-β-13-dihydro-santamarine, eupafolin, 1,2-epoxy-2,5-dimethyl-3-vinyl-4-hexene, 1-(3-OH-methyl-2,2-dimethylcyclopropyl)-2-methyl-1-propanone, p-mentan-9-ol, 2-methyl-2-propenal, 1-(3-OH-methyl-2,2-dimethylcyclopropyl)-2-methyl-2-propen-1-one, parishins B & C, santolinic acid, santolinolides A-C and tatridins A & B (Buckingham et al. ed. 1994).

A. vulgaris has yielded 0.1-0.2% essential oil, consisting of 0-82% α-*thujone*, 6-16% β-*thujone*, 3% *camphor*, 0.45-2.6% camphene, up to 15% camphone, 0.25-2% 1,8-cineole, 0.92% *eugenol*, the 3,5-dimethoxybenzene-isomer of *methyleugenol*, linalool, *pinene*, limonene, p-cymene, α-terpineol, geraniol, caryophyllene and cadinene; the plant has also yielded α-amyrin, ferneol, 12-tricosanol, vulgarin, vulgarole, epoxyartemisia-ketone, triyne-acids and 6-MeO-7,8-methylenedioxycoumarin (Bruneton 1995; Buckingham et al. ed. 1994; Lawless 1995; Misra & Singh 1986; Murray & Stefanovic 1986; Shulgin & Shulgin 1991).

Artemisia absinthium is a fragrant perennial herb c.40-100cm tall; stems finely sericeous or eventually glabrate. Leaves alternate, dissected, silvery-sericeous on both sides, or eventually subglabrate above, the lower long-petiolate and 2-3-pinnatifid, with mostly oblong-obtuse segments c.1.5-4mm wide, blade rounded-ovate outline, c.3-8cm long; upper leaves progressively less divided and shorter-petiolate, divisions often more acute. Inflorescence a panicle or raceme, leafy; heads discoid, flowers all fertile, the marginal pistillate; involucre c.2-3mm high, finely and densely sericeous; involucral bracts dry, imbricate; receptacle flat to convex or hemispherical, beset with numerous long white hairs between the flowers; anthers obtuse or subcordate at base; style-branches flattened, truncate, penicillate. Achenes nearly cylindric, narrowed to base and rounded at summit, glabrous. Fl. Jul.-Sep. (Gleason 1952).

Rocky hillsides and wasteland; native to Eurasia and n. Africa, established as a weed in Canada, US (Bremness 1994; Gleason 1952) and parts of Australia [Qld, WA]; cultivated as an ornamental and medicinal herb.

For absinthe manufacture, wormwood was planted in spring, and harvested the next year in July just before flowering. A plant may live for 6 years, with maximum leaf-production in the second year. The harvested leafy branches were stacked to dry for 1 month before being processed

(Conrad 1988) [see *Methods of Ingestion*].

ARUNDO

(Gramineae)

Arundo donax *L.* **(A. bifaria** *Retz.***; A. glauca** *Bubani***; A. latifolia** *Salisb.***; A. sativa** *Lam.***; Cynodon donax** *Raspail***; Donax arundinaceus** *P. Beauv.***; D. donax** *(L.) Asch. et Graebn.***; Scolochloa arundinacea** *(P. Beauv.) Mert. et Koch***; S. donax** *(L.) Gaudin***)** – giant reed, carrizo

A. donax has been asociated with Orpheus and the underworld; it is also considered sacred to Priapus and Silvanus, associated with sexuality and aphrodisia. Pan was said to have made the first 'pan-pipes' from the nymph Syrinx he was chasing, who had changed herself into a reed to avoid being raped. Since ancient times, A. donax has been used to make wind instruments such as 'shawms', which are often used in a magical context (Rätsch 1992; theobromus pers. comm.). It is still used today to make reeds for wind instruments, such as saxophones and clarinets. The Huichol of Mexico use its stems to make the arrows for their annual peyote pilgrimage [see **Lophophora**], as well as to make dance staffs to be held by the pilgrims (Ott 1993). Rhizomes of A. donax are decocted in Ayurvedic medicine as an emmolient, diuretic, anti-galactagogue and emmenagogue (Ghosal et al. 1969, 1971a).

There is vague anecdotal evidence that A. donax rhizome and **Peganum** harmala root are used together by some musical Sufi groups as a ritual entheogen; the practice is said to be very secretive (De Korne ed. 1996), if it exists at all. A. donax is reportedly used as an ayahuasca-additive in S. America (Rätsch 1998) [see **Banisteriopsis**], though supporting data is required. Due to their *tryptamine*-alkaloid content, A. donax rhizomes have been recently used experimentally in ayahuasca-analogues, though virtually no one has reported success. There is at least one seeming allergic reaction on record from ingestion of an A. donax rhizome extract with **Peganum** harmala seed extract. One person experienced blurred vision 1hr after ingestion, followed by the eyes becoming watery and swollen. Conjunctivitis and hives appeared the next day and persisted for 3 days (De Korne 1994; De Korne ed. 1996).

There is one report of psychoactivity from this plant, though the experience was qualitatively very different to *DMT*, and it is unclear how much of the effects were due simply to the strong dose of MAOI admixture [**Peganum** harmala]. Fresh rhizome [500g prior to washing, and removal of culm] was consumed with 15g **Peganum** harmala seed. The experience was described as 'rough' both mentally and physically, and 'projectile-vomiting' was experienced during the onset of effects. Early in the experience, there was contact with a strange-looking entity, who shared information with the psychonaut. Closed-eye imagery was described as "strikingly 3-dimensional and rotating like a carousel made entirely out of rising and falling waterfalls, and thin, almost fabric-like veils composed of pastel coloured lights". Open-eye imagery, in a slightly darkened room, was described by the psychonaut who was "in a place composed entirely of violet billowing fog with scattered glowing green dots (looking like a De La Warre 'electromagnetic node distribution' picture), where scattered curving 'cracks' in the clouds had bright orange light spilling out in radiating shafts, and drifting veils also composed of orange light". The psychonaut also found that he could observe anywhere in the world simply by thinking about the place or a person... "the entire world seemed quite transparent" (Trout pers. comm.).

A. donax whole plant [from India] has yielded 0.01% *DMT*, 0.064% *bufotenine*, 5-methoxy-*N*-*methyltryptamine*, 0.29% *gramine*, and *gramine*-N-oxide [c.14% of total alkaloids; actual yield not reported] (Dutta & Ghosal 1967). Rhizomes from Egypt have yielded 0.05% alkaloids [including *gramine*, *DMT*, *bufotenine* and 2 other alkaloids; in another test, *DMT*, *bufotenine*, dehydrobufotenine, bufotenidine (see below) and 5-MeO-*N*-*methyltryptamine* were found in rhizomes (no *gramine*), whilst aerial parts yielded *DMT*, *bufotenine*, 5-MeO-*N*-*methyltryptamine* and *gramine*], and in this case aerial parts yielded smaller quantities (Wassel 1982; Wassel & Ammar 1984). Rhizomes from India yielded 0.006% *DMT*, 0.002% 5-MeO-*N*-*methyltryptamine*, 0.026% *bufotenine*, 0.33% bufotenidine [neuromuscular blocker, anticholinergic, causes *histamine* release, uterine stimulant], 0.063% dehydrobufotenine [causes *histamine* release, has an anticholinergic effect on skeletal muscle, and is a uterine stimulant; see also **Bufo**], *tryptamine* and *gramine*-N-oxide. Flowers from India yielded 0.2% alkaloids, with 0.013% *DMT*, 5-MeO-*N*-*methyltryptamine*, 0.0016% *bufotenine*, 0.0009% *DMT* methohydroxide, *tryptamine*, 0.055% *gramine*, 0.096-0.104% *gramine* methohydroxide, 0.032% 3,3'-bisindolylmethyl dimethylammonium hydroxide, and 0.0005% *tetrahydroharman*. The *gramine* content remained constant for the first 2 weeks of flowering, then declined to almost nothing over the next week or so. Leaves and culms also contain alkaloids, as well as triterpenes and sterols. Leaf harvested in April from cultivated plants [Brisbane, Australia] tested strongly positive for alkaloids. A defatted ethanol extract of the rhizomes showed hypotensive and antispasmodic effects; total rhizome alkaloids have uterine-stimulant, anticholinergic and *histamine*-releasing effects (Bhattacharya & Sanyal 1972; Ghosal 1972; Ghosal et al. 1969, 1970b, 1971a, 1972b; Webb 1949). North American plants tested appear to be deficient in *DMT*, according to independent TLC analysis which found no *DMT*, except in new white roots <2mm diameter (Trout pers. comm.).

Arundo donax is a tall perennial reed, forming thickets, up to 7m tall, 2cm diam. at base, rising from a rough, knotty, branching rhizome. Leaves cauline, blades up to 100cm long, 5-7cm wide on main stem, blades numerous, broad, flat, glabrous, rounded and cordate at base; ligules short, membranous, with a minutely hairy margin. Inflorescence a dense, erect panicle, feathery, whitish to brown, up to 60cm long; spikelets several-flowered (2-7), 8-15mm long, laterally compressed, disarticulating above the glumes and between the florets; rachilla glabrous or shortly hairy; florets bisexual; glumes 2, unequal, membranaceous, 3-nerved, narrow, tapering into a slender joint, +- as long as spikelet; lemmas thin, 3-nerved, gradually narrowed at apex, with long silky hairs, the nerves ending in slender teeth, the middle one longer and ending in a straight awn.

Native to the 'Old World', frequently cultivated as an ornamental; common in gardens of the southern US, escaped along irrigation ditches from Texas to central California (Gleason 1952); escaped in Australia alongside roads and irrigation ditches along east coast, from Victoria to Queensland (Auld & Medd 1992).

ASARUM

(Aristolochiaceae)

Asarum arifolium *Michx.*
Asarum canadense *L.* – wild ginger, Indian ginger, Canada snakeroot, Vermont snakeroot, wamaxe
Asarum caudatum *Lindl.*
Asarum europaeum *L.* – hazelwort, asarabacca
Asarum forbesii *Maxim.* – batei-saishin
Asarum heterotropoides *F. Schmidt* **(Asiasarum heterotropoides** *(F. Schmidt) Maekawa***)** – oku-ezo-sai-shin, xi xin, saishin
Asarum sieboldii *Miq.* **(Asiasarum sieboldi** *F. Maekawa***)** – hsi-hsin, xi xin, saishin
Asarum sieboldii var. seoulensis *Nakai*

It is apt that the generic name of these herbs comes from the Greek 'asaron', meaning 'nausea'. They generally act as emetics, and are toxic to the kidneys and uterus in large amounts, but in smaller quantities they have medicinal applications, and have been used as snuffs to promote sneezing. A. europaeum is used as an immune stimulant and antiasthmatic; it has also been given as a snuff to cause sneezing. The herb is emetic, expectorant and diaphoretic. It has been used in alcoholic spirits, and was once used for dyeing wool due to the apple-green pigment that can be obtained from the plant (Bremness 1994; Chiej 1984).

A. canadense is used in N. America as a nerve tonic, stimulant, uterotonic, diaphoretic, carminative and diuretic (Hutchens 1973, 1992; Kindscher & Hurlburt 1998). A bioassay of A. canadense fresh roots [amount unspecified], which tasted similar to **Acorus** calamus rhizomes, revealed a sedative-hypnotic activity (pers. comm.).

The whole plant, or only the rhizome of A. heterotropoides and A. sieboldii, is used in TCM [0.9-3g] to treat colds, headache, toothache, vomiting, and inflammation of the mouth. The herbs also act as an analgesic, local anaesthetic, sedative, expectorant, emetic, purgative, diuretic, diaphoretic, respiratory stimulant, antispasmodic and antirheumatic. They can cause headache, sweating, irritation, dyspnoea, and even coma, although they are said to "be used to wake a person from unconsciousness" (Huang 1993; Huang et al. 1999). The essential oil caused, in animals, irritability, followed by paralysis and death (Perry & Metzger 1980); the doses used were probably very high.

A. arifolium rhizome essential oil contains mostly *safrole*, as well as *asarone*, *eugenol*, *methyleugenol*, *methylisoeugenol*, l-*pinene* (Miller 1902) and *eugenol* methyl ether (Power & Lees 1902).

A. canadense rhizome essential oil contains *eugenol*, *methyleugenol*, *borneol*, geraniol, *pinene*, linalool and terpineol (Lawless 1995; Power & Lees 1902); fresh leaves have yielded chalcone glycosides [0.006% chalcononaringenin 2',4'-di-O-glucoside and 0.012% chalcononaringenin 2'-O-glucoside-4'-O-gentiobioside] and flavonol glycosides [quercetin- and kaempferol-derivatives] (Iwashina & Kitajima 2000). A. canadense var. reflexum has yielded small quantities of aristolochic acid, which has anti-tumour properties (Doskotch & Vanevenhoven 1967).

A. caudatum rhizomes yielded 2-4% essential oil, consisting of 60-75% *methyleugenol*, 10% *asarone*, 10% azulene, and traces of *pinene* (Burlage & Lynn 1927).

A. europaeum rhizome essential oil has yielded 30-35% *asarone*, 15-20% *methyleugenol*, 2-3% asarylaldehyde, 12-15% bornyl acetate, 10-12% of a sesquiterpene, 1-2% of a terpene and 10-12% resins (Bruckner & Széki 1932); others also reportedly found sinapic acid [a phenylpropanoid], *methylisoeugenol* (Harborne & Baxter ed. 1993), trans-iso-*asarone* [bronchospasmolytic, secretolytic] (Farnsworth & Cordell 1976), *camphor* (Chiej 1984), *chlorogenic acid*, iso-*chlorogenic acid*, amino acids and sugars

in the rhizomes (Rastogi & Mehrotra ed. 1990-1993).

A. forbesii has yielded *elemicin*, trans-*asarone*, asarumins A-D and linoleic acid (Bian et al. 1990).

A. heterotropoides rhizome essential oil has been shown to contain 21-39% *methyleugenol* and 17-33% *safrole* (Wang et al. 1997), as well as *asaricin* (Harborne & Baxter ed. 1993); highest *methyleugenol* levels were found during sprouting, and after fruiting, while *safrole* was most abundant at these same times, as well as during flowering. The essential oil of aerial parts was shown to contain 1.4-9.6% *methyleugenol* and 0.36-2.1% *safrole*; both were most abundant during flowering, later decreasing in concentration (Wang et al. 1997). The plant has also yielded β-*pinene*, cineole, eucarvone, asarylketone, asarinin and dl-demethylcoclaurine (Huang et al. 1999). A. heterotropoides var. mandshuricum rhizomes have yielded pellitorine [(2E,4E)-N-isobutyl-2,4-decadienamide], (2E,4E,8Z,10E)-N-isobutyl-2,4,8,10-dodecatetranamide, and (2E,4E,8Z,10Z)-N-isobutyl-2,4,8,10-dodecatetraenamide (Yasuda et al. 1981).

A. sieboldii rhizome has yielded 3% essential oil, containing *methyleugenol*, *safrole*, *elemicin*, *pinene*, phenol, *asaricin*, eucarvone and palmitic acid (Chou & Chu 1936; Perry & Metzger 1980).

A. sieboldii var. seoulensis rhizomes yielded 2.21% essential oil, containing *safrole*, *methyleugenol*, l-*pinene* and palmitic acid (Kaku & Kondo 1931); glycosides are also found in the rhizomes (Hashimoto et al. 1992).

Some Asarum spp. are also reported to contain *1-allyl-2,3,4,5-tetramethoxybenzene* (Buckingham et al. ed. 1994).

Asarum heterotropoides is a perennial herb; rhizomes creeping, with short internodes. Leaves annual, membranous, thin, usually paired, long-petioled, cordate or reniform-cordate, entire, yellowish-green, usually obtuse, 4-6cm wide, scattered short-pilose on both sides, especially when young. Flowers radical, terminal, solitary, short-pedicelled, bisexual, glabrous, actinomorphic or scarcely zygomorphic; perianth-tube depressed-globose, 3(-4)-lobed, lobes fleshy, flat, obtuse, recurved above after anthesis, adnate at base to ovary then free above or gamosepalous; stamens 12 in 2 series; filaments longer than anthers. Ovary semi-inferior or superior, (3-)6-locular; ovules many, 2-seriate in each locule; styles 6, free or connate at base, very short. Fruit berry-like, the seeds exposed by the decaying lower portion, ellipsoidal, rounded on back, involute on margin, flat and with fleshy appendage on ventral face. Fl. May.-Jun.

Hohkaido [Japan]; Sakhalin, south Kuriles. Very similar to A. sieboldii (Ohwi 1965); A. heterotropoides var. mandshuricum is considered by some to be synonymous with A. sieboldii.

The plant is collected in its native range from May to June (Perry & Metzger 1980).

ASPERGILLUS

(Hyphomycetaceae/Aspergillaceae/Eurotiaceae)

Aspergillus flavus *Link.* – Aspergillus ear, kernel rot
Aspergillus fumigatus *Fres.*
Aspergillus niger *Van Tiegh.* – ear rot
Aspergillus spp.

It has been proposed that the mould A. fumigatus, rather than 'ergot' [see **Claviceps**] or mercury compounds, was the bread contaminant responsible for the case of mass poisoning in Pont-Saint-Esprit, France, in 1951. Those affected suffered from "bouts of violent hysteria" and were "overwhelmed by visual hallucinations and other sensorial illusions, as well as convulsions and cramps". Seven people died over the next four days, and psychic effects amongst those affected took up to two months to subside completely (Samorini 1997b).

Cattle feeding on hay infected with Aspergillus spp. have been known to experience irritability, 'anomalous behaviour', diarrhoea, and sometimes death (Samorini 1997b). Complex toxic syndromes resulting from consumption of Aspergillus-contaminated plant matter have been observed in a wide array of wild and domesticated animals (Pammel 1911). Worth mentioning is a case involving a large flock of Canada geese which became intoxicated from feeding on wet barley; they were described as "obviously stoned out of their tiny minds, judging by their erratic flight behaviour" (Smullen 1989). Although fermentation of the plant matter, producing alcohol, should be an obvious initial consideration, the possibility of infection by a psychotropic Aspergillus sp. or similar fungus should not be overlooked.

Another species, A. oryzae, known as 'koji', is used in the manufacture of many Japanese foods, such as 'shoyu' [soy sauce], 'tamari', 'miso', 'amazake' [a sweet fermented rice or millet porridge] and 'sake', presumably for its ability to produce maltose and diastase. A. oryzae is processed into a product known also as koji by innoculating steamed rice, which has been spread out to cool, with spores of the fungus. This is then placed in a cellar and stirred every 12 hours as the mould develops – four days later it is ready, and it is usually dried for storage. This koji is then used in the manufacture of sake and other products. A crude sake [c.14% alcohol] can be made in only 10-14 days, with just rice, koji, and yeast. A similar rice wine from Java ['raggi'] is also made using a mould fungus, but it is not known what species is used. Rabbits inoculated with the fungus showed convulsive symptoms (Bock & Voogelbreinder in press; Nadkarni 1976; Pammel 1911; theobromus pers. comm.). It is worth noting that the above-mentioned sake has some interesting history. In Japan, the beverage is associated with the god Susanoomikata, who is said to have created it to stupefy a serpent-monster so that it could be safely killed. The beverage has been used as an offering to tengu spirits and the gods in general, as well as being consumed in Shinto shamanic rites. In Korea, related rice wines of similar manufacture are still used as sacred inebriants by indigenous shamans (Rätsch 1999b). For related uses of Aspergillus spp. in the production of fermented beverages, see **Delosperma**.

For at least several decades, **Cannabis** smokers have on occasion buried their moist herb [packed in a tin or jar] to age underground for up to several weeks; another similar method adds a pinch of sugar to the small amount of water used to moisten the herb, but simply calls for storing the container in a 'cool, dark, damp place'. The aim is to increase the potency of the **Cannabis** by infecting it with a mould fungus, which often appears to be an Aspergillus sp. [probably A. flavus, A. fumigatus or A. niger]. The resulting foul mass must be dried to be used [usually smoked]. In the U.S., it has been known as 'black merta' or 'Harold's disease'. In Australia, it is sometimes called 'buddha', though sometimes this term is freely applied to any aged, compressed or imported Asian **Cannabis**. Although it would seem on occasion that such fungal infections can indeed synergise with smoked **Cannabis**, some users occasionally reporting minor psychedelic effects, the practice is anything but healthy. It is also quite risky as the user can have little control over which species and strains of mould will colonise the **Cannabis**. Many moulds will also decrease the potency of **Cannabis** if allowed to colonise, by degrading the herb and its active constituents (Bock & Voogelbreinder in press; Dennis & Barry 1978; Margolis & Clorfene 1978; pers. comms.).

The above common Aspergillus spp. have been shown to infect **Cannabis** [and **Nicotiana**] even when in storage. Sweat-curing increases the likelihood of infection. Spores and pathogens may be transferred to the user through smoke inhalation from infected herb, giving rise to a number of serious complications. Transmission is only partially blocked with the use of a water pipe, which should itself be cleaned regularly to prevent internal mould growth (Doctor 1993; Kagen et al. 1983; Llamas et al. 1978; Llewellyn & O'Rear 1977; Lucas 1965; Moody et al. 1982; Ungerleider et al. 1982).

One individual who had been attempting to grow psilocybian mushrooms [see **Psilocybe**] unintentionally inhaled spores from a green mould contaminating the culture [possibly A. fumigatus?]. Half an hour later, the person felt a chill run through the body, followed by other effects lasting c.48 hours and peaking at 12 hours. "At first it was like *psilocybin*, but it turned into high anxiety with the fear that something terrible was about to happen. Waves of relative relaxation alternated with high anxiety and ran from the base of my spine up into my thought processes" (C 1996a). Since that exposure, the same person had similar reactions whenever smelling clean mycelial cultures or aquariums containing living fruiting bodies of **Psilocybe**. "Seven to fifteen minutes after inhalation I get a speedy head buzz with tinnitus. My hands and feet become cold and clammy, my heart rate increases from 70 beats a minute to 100. There is usually some anxiety because I don't understand what the mechanism of this reaction is" (C 1996b).

Inhalation of Aspergillus is usually productive of Allergic Bronchopulmonary Aspergillosis [ABPA], which is characterised by symptoms of asthma, due to pulmonary inflammation causing saccular enlargement and plugging of the bronchial tracts. Infected subjects also become more sensitive to viral and bacterial infection, and the fungus may even grow inside internal cavities (Bennett & Klich 1992; Kozakiewicz 1984; Llamas et al. 1978; Rippon 1988).

A. alliaceus has yielded benzodiazepines called asperlicins; asperlicin is used to treat CNS and GI disorders (Rahbaek et al. 1999).

A. candidus cultivated on rice produced aflatoxins [see below] (Samajpati 1979).

A. flavipes has yielded spiroquinazoline and ascyl aszonalenin [substance-P inhibitors], benzodiazepinedione, N-benzoyl-L-phenylalaninol, and 7 diketopiperazines (Barrow & Sun 1994).

A. flavus has yielded 0.019% alkaloids from lab-grown cultures, containing the clavine alkaloids *agroclavine* and *elymoclavine*, as well as ergokryptine [see **Claviceps**] (El-Refai et al. 1970; Sallam et al. 1969) and coumarins called aflatoxins [extremely toxic and carcinogenic, affecting RNA & DNA synthesis], aspertoxin, flavotoxin, aspergillic acid, kojic acid, β-nitropropionic acid, thiamin and vitamin C (Harborne & Baxter ed. 1993; Kozakiewicz 1984; Llewellyn & O'Rear 1977; Samajpati 1979).

A. fumigatus has yielded moderate quantities of *agroclavine*, *elymoclavine*, *chanoclavine*, *festuclavine* and fumigaclavines A, B (Spilsbury & Wilkinson 1961; Yamano et al. 1962) and C [tremorgenic]; as well as a wide range of toxins, such as verruculogen, TR-2 [both tremorgens], fumitremorgins [6-MeO-indoles; tremorgens], tryptoquivalines [indole substances], gliotoxin [immunomodulating, antiviral, highly toxic], aflatoxins, the sesquiterpene fumagillin, fumigatin, sphingofungins, monotrypa-

cidin, helvolic acid and 1-trans-2,3-epoxysuccinic acid (Bennett & Klich 1992; Harborne & Baxter ed. 1993; Powell ed. 1994; Samorini 1997b). In cultures, the yield of clavine alkaloids was highest after 60 days (Spilsbury & Wilkinson 1961).

A. glaucus cultivated on rice produced aflatoxins (Samajpati 1979).

A. niger has yielded toxins such as genistein [MAOI (Hatano et al. 1991)], malformin and 3-(2-OH-ethyl)indole (Buckingham et al. ed. 1994); it tested weakly positive for alkaloids (Spilsbury & Wilkinson 1961).

A. ochraceus has yielded benzodiazepines called circumdatins, as well as mellein, viomellein, 4-OH-mellein, penicillic acid, vioxanthin and xanthomengin (Rahbaek & Breinholt 1999; Rahbaek et al. 1999); it tested positive for alkaloids (Spilsbury & Wilkinson 1961).

A. oryzae and A. restrictus cultivated on rice produced aflatoxins (Samajpati 1979); A. oryzae may also produce the toxin sporogen-AO1 (Demyttenaere et al. 2002).

A. terreus has been found to produce (+)-aristolochene and (-)-γ-cadinene in mycelial culture (Demyttenaere et al. 2002).

A. ustus strain TC 1118 yielded new isoquinoline alkaloids, TMC-120A, B and C (Kohno et al. 1999); an unspecified strain tested positive for alkaloids (Spilsbury & Wilkinson 1961).

A. zonatus has yielded the benzodiazepines aszonalenin and LL-S490β (Kimura et al. 1982).

An unidentified Aspergillus sp. yielded a new benzodiazepine, LL-S490β (Ellestad et al. 1973). A. fischeri, A. ruber, A. sulphureus and A. versicolor tested positive for alkaloids, A. ruber only weakly so (Spilsbury & Wilkinson 1961).

Aspergillus fumigatus is a mould with a texture ranging from velvety to deeply felted, white at first, becoming green with the development of columnar, conidial heads (shade of green varying considerably), becoming dark green to almost black in age. Conidial heads compact, densely crowded, up to 400 x 50µ, usually shorter; conidiophores short, smooth, up to 300(-500) x 5-8µ, +- green, esp. in upper part, arising directly from submerged hyphae or as very short branches from aerial hyphae, gradually enlarging upward, passing almost imperceptively into the apical vesicle; vesicles flask-shaped, up to 20-30µ diam., often same colour as conidiophores, usually fertile on upper half only; sterigmata similarly coloured, usually c.6-8 x 2-3µ, crowded, with axes roughly parallel to axis of conidiophores; conidia green in mass, echinulate, globose to subglobose, (2-)2.5-3(-3.5)µ diam.

There is apparently much variation in strains, and many different strains may be found in the one patch of growth. Chemical variation is also expected to exist across different strains (Thom & Raper 1945).

Common in soils at all altitudes, growing from 10-65°C and favouring moist conditions. Found on **Cannabis** and **Nicotiana**, in stored products that have heated and spoiled [such as hay, dried beans, grains], on wheat and barley just prior to and during harvest, in grain silos and active compost heaps [wear a face mask when turning your compost!]; has also been found on or in plastic, cotton, synthetic rubber, hydraulic oil, aircraft fuel, fuel filters and microscope lenses (Bennett & Klich 1992; Kagen et al. 1983; Kozakiewicz 1984; Llamas et al. 1978; Llewellyn & O'Rear 1977; Powell ed. 1994; Ungerleider et al. 1982). It is claimed that ultraviolet light will cause aflatoxin-producing A. flavus on **Cannabis** to fluoresce green (Doctor 1993).

ASPIDOSPERMA

(Apocynaceae)

Aspidosperma excelsum *Benth.* **(Macaglia excelsa** *(Benth.) Kuntze***)** – remocaspi

Aspidosperma quebracho-blanco *Schltdl.* **(A. chakensis** *Speg.***; A. crotalorum** *Speg.***; A. quebrachoideum** *Rojas Acosta***; Macaglia quebracho-blanco** *(Schltdl.) Kuntze***)** – quebracho ['axe-breaker'], white quebracho, ualek-eiaj

Aspidosperma spp.

A. quebracho-blanco was once used by natives of Paraguay in the preparation of a magical drink, which was based on a fermented product from the seeds of Schinus molle and a paste of corn [Zea mays]. After fermentation, several pieces of quebracho bark were added. The tree was also considered to have magical properties, by female shamans amongst the Mocoretas of Alto Parana. These shamans divined by chanting and dancing around a fire at the base of a quebracho tree, and interpreting the way in which the moonlight interacts with the tree's branches and foliage. Some native groups drink a bark decoction to treat coughs, colds, malaria and liver pain, and it was often decocted with 'maté' leaves [see **Ilex**], which would at least make for an effective asthma remedy. It is also esteemed by many indigenous peoples as an aphrodisiac – partly due to its rock-hard wood (Rätsch 1992), lending easily to metaphor, and partly due to chemical content. In Peru, A. excelsum is consumed under a strict diet to gain 'esoteric' knowledge. Death is said to result if the proper diet is not kept. It is also used in a dangerous initiation rite, involving the fermentation of a tobacco decoction in the sealed hollow of this tree [see **Nicotiana**]. These uses may, however, be a confusion with **Pithecellobium** laetum (Bear & Vasquez 2000; Luna & Amaringo 1991). The barks from Aspidosperma spp. have also been used in tanning leather (Usher 1974).

Plants of this genus have yielded a great variety of indole alkaloids [see also **Corynanthe**].

A. auriculatum bark yielded 0.03% dihydrocorynantheol, and traces of reserpinine [possibly *rescinnamine*?] (Gilbert et al. 1965).

A. exalatum bark has yielded *harman* 3-carboxylic acid (Shulgin & Shulgin 1997), as well as 21-oxoaspidoalbine and (+)-21-oxo-O-methylaspidoalbine (Ganzinger & Hesse 1976); seed has yielded mostly O-demethylpalosine, as well as aspidospermine, demethoxyaspidospermine, demethoxypalosine, limaspermine, cimicine, and 21-oxo-O-methylaspidoalbine (Medina & Hurtado 1977).

A. excelsum has yielded *yohimbine*, O-acetyl-*yohimbine* and excelsinine [10-MeO-corynantheine] (Burnell & Sen 1970).

A. polyneuron has yielded *harman* 3-carboxylic acid (Shulgin & Shulgin 1997).

A. pruinosum bark has yielded 0.076% *yohimbine*, 0.023% β-*yohimbine*, 0.0066% 10-MeO-*yohimbine*, 0.014% 10-MeO-dihydrocorynantheol, 0.003% compactinervine, 0.0022% normacusine B, 0.016% 10-MeO-geissoschizol, 0.008% 10-MeO-4-methylgeissoschizol and 0.028% 3,4,5,6-tetradehydrositsirikine (Nunes et al. 1992).

A. quebracho-blanco bark has yielded up to 1.5% *yohimbine*-type alkaloids (Rätsch 1992), including aspidochibine, aspidospermatidine, aspidospermatine, (+)-aspidospermidine, (-)-aspidospermine, dihydroaspidospermatine, N-methylaspidospermatidine, (-)-quebrachamine, quebrachidine, vincarine, rhazidigenine, rhazidigenine N-oxide, (R)-rhazinilam, (-)-pyrifolidine and 3-oxo-14,15-dehydrorhazinilam (Buckingham et al. ed. 1994; Ganzinger & Hesse 1976). As A. quebracho-blanco var. pendulae, the bark has yielded 4.098% alkaloids, consisting of *yohimbine*, aspidosamine, aspidospermine and aspidospermicine; as well as saponins, resins, fats and sugars (Floriani 1938).

A. ramiflorum bark has yielded indole alkaloids – 0.038% ramiflorine A, 0.046% ramiflorine B and 0.09% 10-MeO-geissoschizol. Seeds have yielded 0.3% β-*yohimbine* and 0.024% 10-MeO-geissoschizol (Marques et al. 1996).

A. rhombiosignatum has yielded 1-methyl-3-carboxyethyl-β-carboline (Shulgin & Shulgin 1997).

Aspidosperma quebracho-blanco is a tree 5-20m tall, trunk to 1m thick; bark corky, heavy, rugose, greyish-yellow; roots long, horizontal. Leaves simple, persistent, rigid, coriaceous, whorled in threes, rarely opposite, glabrous, elliptic-lanceolate, margins smooth, c.2-5cm x 5-15mm, acuminate with a spine in apex 1-4mm long, base decurrent, pinnately nerved, with c.10-20 secondary nerves on each side; petiole 1-3mm long. Inflorescences axillary and terminal; flowers hermaphroditic, actinomorphic, white-yellowish, very perfumed, 5-13mm; calyx of 5 triangular-ovate sepals, caducous, 1-1.5mm long, 0.8-1.5mm wide; corolla subhippocrateriform, slightly fleshy, with latex, tube 3-6mm long, glabrous externally, pubescent internally, with a ring of silky hairs, retrorse between filaments; lobules (4-)5, sublinear, involute, equal in length to tube; stamens 5, included, adhering until the upper 1/3 of the corolla tube, free portion of filaments very short; anthers ovate-lanceolate, dorsifixed, introrse; pollen grains elliptic, 4-colpate. Ovary superior, bilocular, glabrous, ovoid, bipartite; carpels 2; style cylindric, short; stigma slightly thickened, with a ring of hairs. Capsule lenose, dehiscent, clear greyish-green, verruculose, bivalvate, asymmetric, ovate, elliptic to orbicular, compressed laterally, 7-13cm long x 4-8cm wide x 1-2.5cm thick; seeds numerous, subcircular, white-yellowish, funicule large, erect, surrounded by a very thin, wide membranous wing, circular-oblong, 5-6cm x 4.5cm.

In xerophyll forest; Bolivia, Paraguay, Uruguay, Argentina [w. Gran Chaco, to San Juan, San Luis, south of Cordoba and Entre Rios] (Burkart 1979).

ATHEROSPERMA and DORYPHORA

(Monimiaceae)

Atherosperma moschatum *Labill.* – southern sassafras, black sassafras

Doryphora aromatica *(Bailey) L.S. Smith* – grey sassafras, northern grey sassafras, net sassafras, cheedingan

Doryphora sassafras *Endlicher* – yellow sassafras, New South Wales sassafras, canary sassafras, golden deal, boobin, caalang, tdjeundegong

Both of these similar Australian genera are unrelated to the true **Sassafras** of N. America, but share some similar chemical properties. A. moschatum bark was once sold in England as 'Victorian sassafras'. It was used as a tonic and laxative tea by early settlers and indigenous people in eastern Australia; the bark has also reportedly been used to treat venereal diseases. A tincture of the bark has been used to treat asthma, bronchitis, and as a cardiac sedative, diaphoretic and diuretic. Similar tonic teas

have been made from the barks of D. aromatica and D. sassafras (Cribb & Cribb 1981; Lassak & McCarthy 1990; Webb 1948). A. moschatum has reportedly been used in beer brewing, and in Tasmania it is made by some people into a psychoactive beer (Rätsch 1998).

The person who first made me aware of these plants reported that he often chews the leaves and stems of A. moschatum while bushwalking, and spits them out when he starts to feel an effect. He reported experiencing mild euphoria and colour-enhancement, lasting several hours. He also claimed that the root is more potent, and may be used as an aphrodisiac (Hastings pers. comm. 1996). After learning of this, I experimented with leaves and stems of D. sassafras collected from a botanical garden. I found that a good method was to fill one cheek with a sizeable wad of healthy leafy matter, preferably more tender leaves [as much as will comfortably fit] and to chew on the cud for about 1hr, stopping occasionally to suck and let the juices circulate in the mouth. Excess saliva is swallowed when the mouth becomes too full. The vegetable matter is expelled when one wishes to stop chewing, and the quid does taste quite nasty after a while. The effects seemed to creep up after an hour or more, and consisted of, at first, a brief, pleasant euphoria followed by a period of pleasant mental stimulation and mild physical tranquillity. Friends and associates who attempted to chew the leaves did not report any effects. I suspect they did not chew enough material, and did not persist for long enough, due to the taste!

A. moschatum bark contains aporphine alkaloids – berbamine [spasmolytic, vasodilator, antibiotic, tumour-inhibitor], isotetrandrine, isocorydine, moschatoline, atheroline, atherospermidine, atherosperminine [CNS stimulant, *dopamine*-receptor agonist], spermatheridine and MeO-atherosperminine. Leaves, bark and root yield an essential oil [1.7-2.65% from leaves] which may contain 50-60% *eugenol* methyl ether, 5-10% *safrole*, 15-20% *pinene*, and 15-20% *camphor* (Bhattacharya et al. 1978; CSIRO 1990; Harborne & Baxter ed. 1993; Lassak & McCarthy 1990; Scott 1912).

D. aromatica bark contains similar alkaloids – isocorydine, aromoline, homoaromoline, daphnoline, daphnandrine, isotetrandrine and 1,2-dehydroapetaline; the essential oil is rich in *safrole* (Lassak & McCarthy 1990).

D. sassafras bark has yielded 0.3% alkaloids, 11 different ones in total – the benzylisoquinoline reticuline, the isoquinolines corypalline, doryphorine and doryanine, the aporphines liriodenine, isocorydine [antiadrenergic, sedative, cataleptic at high doses] and anonaine, *choline*, alkaloids A & B and aristolactam alkaloids, as well as doryflavine (Chen et al. 1974). An older study found 0.63% alkaloids [as doryphorine] in the bark, 0.3% in the leaves, and 0.1% in the fruit (Webb 1948). Leaves have yielded 0.0019% liriodenine, 0.0023% doryafranine, 0.0005% doryanine, 0.0047% *choline*, and small amounts of alkaloids A, B, C & D (Gharbo et al. 1965). The leaves also yield an essential oil containing 30-65% *safrole*, 1-3.5% *eugenol*, 10-30% *camphor*, 10% *pinene*, 10% sesquiterpenes, and *eugenol* methyl ether (CSIRO 1990; Harborne & Baxter ed. 1993; Hurst 1942; Penfold 1922). In frogs, the alkaloid 'doryphorine' [may have been a complex of alkaloids] was shown to "produce loss of power of movement and of response to touch, then paralysis and death" (Webb 1948), presumably administered by injection.

Doryphora sassafras is a tree 10-42m tall, up to 1.2m diam.; bark grey or brownish-grey, finely scaly. Leaves opposite; in seedling, short petioles 2-4mm, broad-lanceolate with serrate margins, 10-14-toothed, 5-8 x 2-3cm, dark glossy green above, paler beneath, stems lightly quadrangular, venation reticulate with secondary venation; intermediate – leaves broadly lanceolate, up to 10 x 5cm, toothed; in adult – opposite, short petioles c.1cm long, simple, elliptical or oblong-lanceolate, acuminate, narrowed at base, 7-10 x 1.5-5cm, coarsely toothed, glossy green above, dull green beneath, glabrous, strongly fragrant of sassafras oil when crushed [see **Sassafras**], midrib distinct, lateral and net veins faintly visible on upper surface, raised and distinct on underside. Inflorescence axillary, usually 1-2 per leaf axil, usually 3-flowered, on short peduncle 0.2-1cm long; flowers white, silky-downy, 2-3cm across; perianth lobes 6, tapering to fine point; stamens 6, with anthers towards base of stamens and with long bristle-like points, with 6 alternating shorter staminodes; carpels several, free, superior; styles plumose. In fruit, lower perianth is enlarged, becoming narrowly egg-shaped, 0.6-2cm long with long neck, splitting down one side when ripe to expose several dark brown, hairy carpels. Fl. May-Jul.

Cool to warm temperate rainforest in a variety of sites, from near sea level to 1000m; from near the Victoria/NSW border, north along coastal areas [w. inland in NSW to localities near Oberon, Mt Wilson, Barrington Tops and Mt Coricudgy, near Mudgee] to Queensland, mostly in MacPherson Ranges and Kilarney and Tambourine districts (Boland et al. 1992).

ATROPA

(Solanaceae)

Atropa acuminata *Royle ex Lindl.* **(A. belladonna** *C.B. Clarke, non L.***)** – Indian Atropa, Indian belladonna, luckmuna, suchi, sage-angur

Atropa baetica *Willk.*

Atropa belladonna *L.* – belladonna ['beautiful lady'], banewort, deadly nightshade, death's herb, devil's cherries, sorcerer's berry, walkerbeere ['berry of the Valkyries'], dwayberry, dwale ['stupor'], naughty man's cherries, moonpods [referring to the fruits]

Atropos was one of the three Fates of Greek myth, who holds the power to cut the thread of life. The Italian name 'belladonna' refers to the use of A. belladonna extract to dilate the pupils of the eye, making a woman appear 'more beautiful and seductive'. This same property is now exploited for eye-examination. A. belladonna was reputedly a key ingredient in many witch's potions and flying ointments (Bremness 1994; Schultes & Hofmann 1980, 1992). Ancient Sumerians used it to treat problems associated with demons. According to tradition, priests worshipping Bellona, Roman war goddess, drank a potion of A. belladonna before calling on her. Early Germanic peoples knew the plant as 'berry of the Valkyries', hinting at a knowledge of its ability to produce 'violent' intoxication, and it has been added to wines and beers to strengthen their effects [see *Methods of Ingestion*] (Cunningham 1994; Rätsch 1990, 1992). Apparently, Duncan I of Scotland had MacBeth's soldiers drug a Danish army with belladonna-laced alcohol, so they could be easily killed in their comatose state (Polunin & Robbins 1992).

Today, A. belladonna is used in Morocco as an aphrodisiac and memory stimulant – this is odd due to the cognitive deficits that can be caused by the anticholinergic alkaloids present. In Nepal, it is used as a sedative (Ott 1993; Sitaram et al. 1978). In India, A. acuminata is used for similar medicinal purposes, and is sometimes adulterated or confused with Phytolacca acinosa [see *Endnotes*] (Chopra et al. 1965; Morton 1977). Also, bees feeding on the nectar of A. belladonna are known to produce intoxicating honey that has hallucinogenic effects in humans who consume it (Ott 1993, 1998a).

In medicine, A. belladonna is useful in relieving intestinal cramps by relaxing digestive tract muscles. The ability of *atropine* to reduce mucus led to its use in nasal sprays and decongestants, and its bronchodilating properties are useful for asthma. The plant has been used to control bedwetting, epileptic seizure, symptoms of Parkinson's disease, whooping-cough spasms, and to stimulate the heart after a heart-attack. It is also often administered to counter the effects of muscarinic mushroom poisoning [see **Amanita**, **Inocybe**], and for opiate overdose (Blackwell 1990). Effects of A. belladonna [30-200mg dried leaves or 30-120mg root] include trembling and excitement, sedation, delirium, hallucinations, pupil dilation, rapid heartbeat, weak pulse and dry mouth; overdose may result in coma and death by respiratory paralysis (Gottlieb 1992; Rätsch 1992; Tamplon 1977). In mice subjected to stress, low doses of A. belladonna had a neurotropic effect, and protected against stress-induced gastric alterations (Boustaa et al. 2001).

A. acuminata leaves have yielded 0.13-0.78% alkaloids, mostly *hyoscyamine*; roots yielded 0.29-0.8% alkaloids, mostly *hyoscyamine* – volatile bases are also present. Alkaloid content of aerial parts is highest when in flower [Jul.-Sep.], and in this period are best collected early August (Chopra et al. 1965).

A. baetica leaves have yielded 0.82-1.06% alkaloids, roots 0.94% and fruit 1.09% – these consisted of *hyoscyamine* and *atropine*.

A. belladonna contains mostly *hyoscyamine* [0.72-2.2% in leaves], as well as *hyoscine* [0.19% in leaves], *atropine*, and traces of *nicotine*, cuscohygrine [in roots only], hygrine, atropamine, belladonnine, and tropine, as well as flavonoid glycosides. Leaves have yielded 0.09-1.23% alkaloids [highest levels in young top leaves, lowest in bottom leaves], roots 0.1-0.7%, and seeds 0.83%. Young plants are high in *hyoscine* – alkaloid content increases with age, with *hyoscine* decreasing and *hyoscyamine* becoming dominant; *atropine* is found at its highest level when the fruits are ripening. Root alkaloid content is highest just before flowering; it may also be higher in younger roots, which are very small [up to 0.72% in 1yr-old roots]. Prolonged drying of the leaves decreases alkaloid content due to enzyme activity (Chopra et al. 1965; Evans 1979; Harborne & Baxter ed. 1993; Henry 1939; James 1953; Morton 1977; Rastogi & Mehrotra ed. 1990-1993; Rimpler 1965; Saber et al. 1962a; Schultes & Hofmann 1980; Wilms et al. 1977). Leaves have also yielded 0.014% of the coumarins *scopoletin* and aesculetin (Kala 1958), and aerial parts were shown to contain 5 calystegines [see **Convolvulus**] (Bekkouche et al. 2001). *Phenethylamine* has also been found in the plant (Hartmann et al. 1972).

Atropa belladonna is an erect perennial herb, green, glabrous to glandular-pubescent; stems 50-150(-200)cm long, much-branched. Leaves alternate or opposite, simple, entire, not crowded, up to 20cm, ovate, acuminate, cuneate at base; petiole short. Flowers solitary, axillary; pedicels nodding; calyx campanulate, with 5 acuminate lobes, somewhat accrescent, becoming stellate; corolla 2.5-3cm, tubular-campanulate, not more than 2.5 times as long as calyx, brownish-violet or greenish, limb short, 5-lobed, lobes up to ½ as long as tube; stamens 5(-8), included or slightly exserted, subequal, inserted at base of corolla, adnate to corolla tube and alternating with the lobes; filaments tomentose at base; anthers ellipsoid, whitish, usually dehiscing longitudinally. Ovary superior, with usually 2 loculi, with annular receptacular disc at base; style sim-

ple, included or slightly exserted; stigma peltate, entire to 2-lobed. Fruit a berry 15-20mm diam., globose, shiny, black, rarely yellowish-green, flesh usually reddish-purple, poisonous.

In damp or shady places, mainly in mountains, also woods and thickets on calcareous soils, in graveyards, and around old buildings and in hedges, rather rare; south, west and central Europe, east to w. Ukraine, and west to England and Wales, from Westmorland southwards; also cultivated and naturalised in some places (Clapham et al. 1987; Mabey 1997; Tutin et al. ed. 1964-1980).

Propagate from cuttings of new growth, or by rootstock division in spring; seed cultivation is more common. Requires rich, moist, well drained, limey, fertile soil. Weed regularly and protect from snails and slugs. Unfortunately, higher alkaloid content is achieved by growing in open, freshly cleared land, or burned forest, though the plants prefer shady spots (Morton 1977; pers. comm.). Gather leaves in late spring, flowers in early autumn (Chiej 1984).

There is also a yellow-flowered variety, A. belladonna var. lutea (theobromus pers. comm.).

AZTEKIUM

(Cactaceae)

Aztekium ritteri *(Böed.) Böed.* **(Echinocactus ritteri** *Böed.***)** – peyotl, peyote chino

This small and rare cactus, the only member of its genus, is known as a 'peyotl' by the Tarahumara of Mexico, though it is not actually known to be so used [see **Lophophora**] (Schultes 1937b, 1969c).

When fresh samples were analysed relatively recently, *mescaline* was found, although in small amounts [0.0009%], as well as 0.0036% N,N-dimethyl-*DMPEA*, 0.0031% N-methyl-*tyramine*, less than 0.0001% each of 3-MeO-*tyramine* and *hordenine*, 0.0008% anhalidine and 0.0026% *pellotine* (Štarha 1994); also detected were glucaric acid and quinic acid. A report of *caffeine* in this species needs verification (Trout ed. 1999).

Aztekium ritteri is a flattened, wrinkled, globular cactus, solitary to clustered, c.5cm wide, with 9-11 distinct lateral ribs, c.1cm high, 8mm wide, olive-green; areoles minute, closely spaced, forming continuous rows on ribs; spines none, except for 1-4 at tip, flattened, twisting, papery, white, 3-4mm long, soon falling. Flowers close to the crown from new areoles, scaleless, c.1cm long, 8mm wide, white or pink, petals and stamens few; seed with a membranous attachment point (strophiole).

On steep slate slopes; Nuevo León, Mexico.

May be difficult to grow successfully in very cold climates; grows very slowly. Needs porous, mineral-rich soil and full sun (Cullmann et al. 1986; Innes & Glass 1991). Does not need much water when young, but will take more when established. Can survive frosts if kept dry (Trout & Friends 1999).

BACOPA

(Scrophulariaceae)

Bacopa monnieri *(L.) Wettst.* **(B. monnieri** *(L.) Pennell***; Bramia indica** *Lam.***; Br. monniera** *(L.) Drake***; Br. monnieri** *(L.) Pennell***; Calytriplex obovata** *Ruiz et Pav.***; Gratiola monnieria** *L.***; Habershamia cuneifolia** *(Michx.) Raf.***; Herpestis cuneifolia** *Michx.***; He. monnieri** *(L.) Kunth***; He. procumbens** *Spreng.***; Limosella calycina** *Forssk.***; Lysimachia monnieri** *L.***; Monnieria africana** *Pers.***; M. brownei** *Pers.***; M. pedunculosa** *Pers.***; Septas reptans** *Lour.***)** – brahmi, jala-brahmi, neer-brahmi, safedkammi, sambranichettu, water hyssop, thyme-leaved gratiola

This herb is thought by some to represent the 'brahmi' tonic of the ancient Hindus, yet today, brahmi is commonly though to be represented by **Centella** asiatica. The Hindus do, however, infuse the plant as a brain tonic, and treatment for insanity and epilepsy; it also acts as a nerve and heart tonic, diuretic and laxative. The herb is the main constituent in an Ayurvedic compound medicine, 'brahmi rasayan', made up of 10 parts B. monniera leaf, 2 parts clove flowers [see **Syzygium**], 1 part **Piper** longum stalks [see **Piper 1**] and 1 part Elettaria cardamomum ['cardamom'] seed [see below]. The herb is used in China to warm the kidneys and stimulate yang energy. It treats impotence, premature ejaculation, irregular menstruation, rheumatism, and kidney-related back-ache. The succulent herbage may also be eaten as a salad herb which has a slight bite (Bremness 1994; Chopra et al. 1965; Lassak & McCarthy 1990; Malhotra & Das 1959; Nadkarni 1976; Shukia et al. 1987).

Given in doses of 2-6g a day, it acts as a sedative brain tonic [improving memory, concentration, and learning], mild anticonvulsant and anti-inflammatory, and protects against nervous deficit due to injury, stroke, nervous exhaustion, or chemical impairment [such as induced by phenytoin] (Bone 1996; Vohora et al. 2000). The herb increases oxidative free-radical scavenging activity (Bhattacharya et al. 2000; Tripathi et al. 1996). It is an ingredient [with **Cyperus** rotundus, and Saussurea lappa ('costus')] in the Ayurvedic preparation 'brahmighritham', which is used to control epilepsy (Shanmugasundaram et al. 1991). As a brain tonic, the herb synergises well with an equal amount of **Convolvulus** pluricaulis (friendly pers. comm.).

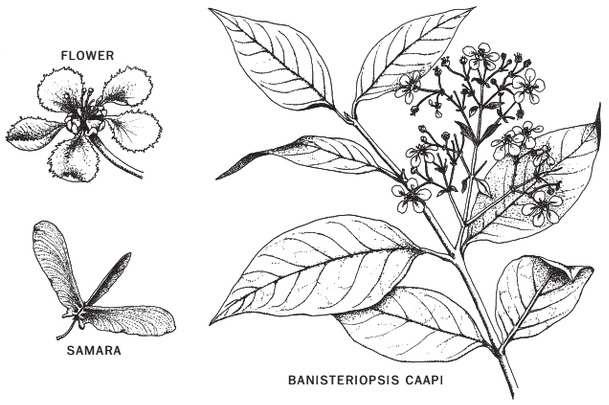
B. monnieri aerial parts have yielded saponins which are thought to be the main active constituents. These include bacosides A & B [which on acid hydrolysis yield bacogenins A1, A2 & A3, ebelin lactone, arabinose and glucose], bacopasaponins A-F and pseudojujubogenin. Octacosane, 3-formyl-OH-α-pyrone and d-mannitol have also been found. *Nicotine* was found, as one component of three from 0.05% total alkaloids. Extracts of the saponin and alkaloid fractions showed CNS-depressant, hypnotic, analgesic, vasoconstrictive and cardiotonic effects; the alkaloid fraction also showed neuromuscular-blocking effects. LD50 of the crude total extract was 33.1mg/100g [i.p.] in albino rats (Buckingham et al. ed. 1994; Chatterji et al. 1965; Chopra et al. 1965; Das et al. 1962; Garai et al. 1996; Kawai et al. 1974; Malhotra & Dass 1959). 'Brahmi rasayan' has been shown to posess CNS-depressant and anticonvulsant activity in rats and mice (Shukia et al. 1987). B. monnieri should probably not be combined with Viagra™, as bacoside A causes nitric oxide release and may result in dangerous interactions (theobromus pers. comm.).

Bacopa monnieri is a small herb of shallow water; stems creeping and forming mats, glabrous. Leaves sessile, opposite, entire, oblanceolate with a few obscure lateral veins diverging from the midvein, succulent. Flowers single from some of the nodes, on pedicels 1-2.5cm long; bracts linear, 2-3mm long; sepals 5, ovate-lanceolate to lanceolate, c.6mm long, the upper 2.5mm, the lateral 1.5mm wide; corolla white or nearly so, campanulate, nearly regular, 8-10mm long; lobes 5, obovate, rounded, or emarginate, slightly spreading, a little longer than tube; stamens (2-)4, didynamous, inserted below middle of corolla tube; anther sacs parallel; stigmas 2, distinct. Capsule ovoid, acute, 5-7mm long, septicidal. Fl. summer (Gleason 1952).

Marshes, pond edges, wet sandy shores, coastal areas in warm temperate areas and tropics; Australia [coastal areas of Qld and NSW to south of Sydney], US [s.e. Virginia to Florida and Texas], Asia.

BANISTERIOPSIS

(Malpighiaceae)



Banisteriopsis caapi *(Spruce ex Grisebach) Mort.* **(B. inebrians** *Mort.***; B. quitensis** *(Niedenzu) Mort.***; Banisteria caapi** *Spr. ex Gris.***)** – yajé, yagé, yagé delmonte, yagé sembrado, ayahuasca ['spirit vine'], caapi, nepe, name, natém, natema, bejuco, bejuco de oro ['vine of gold'], bejuco de boa, jagube, shuri, shuri-fisopa, rambi, rami appane, rami wetseni, rami, reé-ma, undi, tsipu, kamarampi, ammarón huasca, ambiwáska, sacawáska, biaj, bichemia, biáxa, batahua, batsikawa, hapataino', iñotaino', oo'-na'-oo, he-kahi-ma, kahi-ukó, kumuabasere-kahi-ma, suari-tukuro-kahi-ma, oo-fá, cauupuri mariri, tiwaco miriri, mão de onça

Banisteriopsis longialata *(Ndz.) Gates* **(B. rusbyana** *(Ndz.) Mort.***)** – ayahuasca, chagro-panga, oco-yajé, yagé

Banisteriopsis lutea *(Gris.) Cuatrecasas* **(B. nitrosiodora** *(Gris.) O'Donell et Lourteig***)** – huillca bejuco, cipó de São de Jõao

Banisteriopsis martiniana *(Jussieu) Cuatr.* **var. subenervia** *Cuatr.* **(B. martiniana var. laevis** *Cuatr.***)** – yagé, e-pe-pee-yoo-wee, ñuc-ña-wasca

Banisteriopsis muricata *(Cavanilles) Cuatr.* **(B. argentea** *(Humb., Bonp. et Kunth.) Rob.***; B. metallicolor** *(Juss.) O'Donell et Lourteig***)** – mii, ayahuasca, sacha ayahuasca ['wild ayahuasca'], ayahuasca de los brujos, ayahuasca rosada, sacha ayahuasca, ala de pompopo, bejuco de casa, bejuco hoja de planta, carapë nihi, pastora, sarcelo, sombra de tora

'Yajé' is one of many names given to represent both a species of Amazonian vine, and the visionary drink prepared from it. The species most commonly used is B. caapi, which is slowly becoming threatened due to both overharvesting and careless harvesting [ie. where the bottom parts of the climbing plant are cut out with a machete, leaving hundreds of kilos of the now rootless liana to rot in the canopy above]. B. muricata is much more commonly found, but is much less potent, and only rarely used. Also sometimes used as additives or foundations for the potion are B. longialata, B. lutea and B. martiniana var. subenervia [see below]. Yajé, more commonly referred to in the west as 'ayahuasca' [another indigenous (Quechua) name representing both the vine and the drink made from it], has been a vital healing agent amongst shamans in the jungles of the Amazon for centuries. It is still used widely in Ecuador, Bolivia, Peru, Colombia, Venezuela and Brazil. Its use has even spread to areas of Panama. The brew is prepared primarily from a Banisteriopsis sp., with other plants used as additives to modify or increase the effects [especially tobacco – see **Nicotiana**], or, in the case of *DMT*-rich plants such as 'chacruna' [**Psychotria** viridis] or 'oco-yajé' [**Diplopterys** cabrerana], largely create them (Bristol 1966; Ott 1994; McKenna 1991; McKenna et al. 1984a; Pinkley 1969; Prance 1970; Rivier & Lindgren 1972; Rätsch 1992; Schultes 1950, 1957, 1972; Schultes & Raffauf 1990; Uscategui 1959)! Some reported uses - and the common names - attributed to B. longialata might instead refer to D. cabrerana, arising from confusion between the two species related to the name 'B. rusbyana' [see **Diplopterys**]; Gates (1982) does not give any of these common names for B. longialata but does for D. cabrerana. For more discussion on ayahuasca admixture plants, consult *Methods of Ingestion* and *Endnotes*.

Sometimes, B. caapi is used alone as a beverage. It has also occasionally been observed to be snuffed or given as an enema (Ott 1994). Both B. lutea and B. leiocarpa are known as 'huillca bejuco', a name suggesting they may have been used as sources for a snuff [see **Anadenanthera**] (Trout ed. 1998). The legendary ethnobotanist Richard Evans Schultes [r.i.p.] witnessed leaves and young bark being smoked as cigarettes made from a leaf wrapping of a Heliconia sp. (Schultes 1985), and also witnessed the vine being chewed, while the user also snuffed 'yopo' [see **Anadenanthera**] (Davis 1996), a practice that would be expected to greatly increase the effects of the yopo snuff. Recently, this practice was observed amongst the Pume of Venezuela, who also chew the root (Gragson 1997). Incidentally, many 'Indians' recognise different varieties of yajé with different effects, which all seem to derive from the same species – these are different strains of the plants that presumably have slightly differing chemical makeup. A few examples are 'cají-vaíbucura-rijoma' [causes visions of howler monkeys], 'cielo-huasca' [used "for seeing heaven and the great protector spirits"], 'hapataino' [transforms one into a boa], and 'kadanytaino' [transforms one into a hawk] (Bristol 1966; Schultes 1972, 1986; Trout ed. 1998).

Other species, such as B. lutea, B. martiniana var. subenervia and B. muricata may sometimes be used in place of B. caapi as the base plant in the brew (Schultes 1950; Ott 1994). B. muricata is observed by the Witoto to be weaker than B. caapi. Shamans of the Waorani use B.muricata in secret to supposedly call upon evil spirits to wreak havoc on others [see **Dictyonema**]. When still young, Waorani boys sometimes have a tiny wad of it blown into their lungs through a bird windpipe by their uncle or grandfather, in order that they may grow up to be great hunters with powerful lungs (Davis & Yost 1983). The related B. lucida is used in fishing magic in Venezuela (Trout ed. 1998).

Shamans who use ayahuasca regularly and ritualistically adhere to a strict diet, usually of plantains and certain fish, and they abstain from sexual contact, for lengthy periods of time (Bear 1997; Bear & Vasquez 2000; Luna 1984). Before consuming ayahuasca, the participants are not to eat or drink anything except water for 6 hours or more (Flores & Lewis 1978); sometimes a ritual emetic is consumed the morning before the ceremony (Bear & Vasquez 2000; Schultes & Raffauf 1990).

Methods of preparing the brew differ in their approach – some simply crush the vine segments in a mortar and knead the material in cold water, straining and drinking after a period of steeping – this would not be a very efficient method of extraction. Others, such as in the Purús region, take stems totalling c.900 x 1-4cm, which after being sliced and crushed, are piled into a large pot in layers alternating with the admixture/s [in this case **Psychotria** sp.] and boiled with 10 litres of water for 1 hour before being cooled, strained and drunk. It was not stated how many people this should serve. Others may boil it down for hours, add more water and continue boiling for a total of up to 15 hours, which would probably result in a fair amount of degradation of the active chemicals, as well as a more thorough extraction (Bristol 1966; McKenna et al. 1984a; Ott 1994; Rivier & Lindgren 1972; Uscategui 1959). Sometimes, only the bark scrapings are used (Schultes 1957), and these would possibly contain the bulk of the stem alkaloids. The Machiguenga prepare a 10-dose brew by boiling a 5m length of vine, and 170 **Psychotria** leaves, for 2 hours (Russo undated). Western psychonauts have found 30g or more of dried liana [or even up to 500g w/w] to be effective as an MAOI. The leaves may be even more potent, and less damaging to harvest (Trout ed. 1998; pers. comms.). There is not really a 'typical' dose for ayahuasca in terms of volume, due to variations in concentration and potency, though in the Amazon doses have been reported to range from 55-200ml (McKenna et al. 1984a). For more discussion on ayahuasca preparation, see *Methods of Ingestion*. Once prepared, the brew will only retain its potency without refrigeration for a few days.

It is not exclusively used by shamans – often, most members of a community will consume it together, and it is usually prepared by the person who harvested the material. It is consumed usually in groups [though with some, such as the Shuar, it is consumed only by the shaman and the patient, or by the shaman alone] at night around a fire, or in darkness. Two reasons have been suggested to explain the adherence to night-time ceremonies – that the beverage induces sensitivity to light which can irritate the eyes; and that sorcerers work their malicious magic at this time, and is thus the best time to counteract such spirit attacks. The participants treat the beverage with reverence, and will often pray to the spirits for good visions before drinking their share. Vomiting usually occurs about half-an-hour later at most, and this is often considered a necessary and purifying aspect of the experience. The effects generally begin manifesting strongly at around this point, also, and singing and drumming commences. The melodies channelled through the shaman, known as 'icaros', are an integral part of the traditional ayahuasca experience. Indeed, for shamans, a primary purpose of dieting with ayahuasca is to learn the icaros of individual plants or other spirits. With these icaros [and sometimes the 'mariris', the words which go with an icaro] the shaman can call upon the desired spirit for its powers, whether they be for healing, for harm, or for divination. These songs are taught by the plants themselves, and serve other specific purposes within the session, including directing the visions of all participants. More experienced 'ayahuasqueros' [ayahuasca shamans] keep an eye on the other participants to make sure they do not have a bad experience – in this event they may cradle the person's head and blow tobacco smoke over it, or they may hand the person an aromatic plant such as the basil **Ocimum** micranthum, to produce a state of calm, as well as singing calming icaros. Tobacco [see **Nicotiana**] is often smoked throughout the ceremony, serving to protect against evil spirits (Bear & Vasquez 2000; Bennett 1992; Bristol 1966; Luna 1984; Prance 1970; Rivier & Lindgren 1972; Uscategui 1959).

The effects of Banisteriopsis alone are quite removed from those of the drink prepared from Banisteriopsis with what some would call [strictly speaking, falsely] its 'classic' partner, **Psychotria** viridis. Alone, the vine is a hypnotic sedative with relatively little vision-inducing capacity other than dancing colours behind closed eyes, and slight perceptual shifts. It is also a strong emetic and produces trembling, sweating and nausea. Greater doses increase the physical side-effects without greatly enhancing the mental experience. Addition of a *DMT*-containing admixture plant in the appropriate amount adds more of a mental stimulation to the experience, with extremely vivid and bizarre visual and psychological effects commencing after ½-1 hour and continuing for up to c.4 hours. This is made possible by the MAOI- and serotonergic-effects of the harmala alkaloids found in B. caapi [see *Methods of Ingestion*].

Today, ayahuasca is widely used throughout much of the Amazon, and even in urban areas. Many fraudulent self-proclaimed ayahuasqeros have sprung up, selling poorly prepared brews of dubious constituency, largely to cater to tourists, who have begun to flock to the Amazon. In many cases the 'ayahuasca tourism' that has been occurring is having a decidedly negative impact on the local traditional inhabitants, who are rapidly losing knowledge of their culture through Western contact [although, admittedly it may be helping some of them survive due to the small income derived from conducting ayahuasca sessions for such people]. There are at least two major recognised churches based on the use of ayahuasca [as B. caapi + **Psychotria**] as the sacrament in Brazil, the UDV [Uniao do Vegetal] and Santo Daime, who are not harassed anymore by government officials after the members were found to be well-adjusted, intelligent and non-violent people with a spiritual focus, rather than the rabid drug users previously depicted in anti-ayahuasca propaganda (Callaway et al. 1999; Grunwell 1998; McKenna 1991; Grob et al. 1996; Saunders et al. 2000; Shulgin & Shulgin 1997).

Tests in human volunteers from the UDV revealed peak plasma concentrations of alkaloids after ingesting ayahuasca [dose of 2ml/kg body weight; beverage contained 1.7mg/ml *harmine*, 0.2mg/ml *harmaline*, 1.07mg/ml *leptaflorine* and 0.24mg/ml *DMT*] – 36.4-222.3ng/ml *harmine*, <1-9.4ng/ml *harmaline*, 49.2-134.5ng/ml *leptaflorine* and 11.5-25.5ng/ml *DMT* (Callaway et al. 1996). Broader samples of prepared ayahuasca have yielded 5.85-8.19% alkaloids, consisting of 53-67% *harmine*, 18-30% *leptaflorine*, 5-6% *harmaline*, 6-11% *DMT* and traces of *harmol* (McKenna et al. 1984a). An earlier study obtained much lower yields from beverage samples [0.005-0.064% alkaloids], consisting of 22-62% *harmine*, 0-4% *harmaline*, 6-40% *leptaflorine*, 0-41% *DMT* and 0-20% of an unidentified alkaloid ['232'], probably a β-carboline (Rivier & Lindgren 1972). Prolonged heating of ayahuasca brews may result in the breakdown of some of the *harmaline* present, possibly forming extra *harmine* and/or *leptaflorine* as byproducts. In acidic conditions, *harmaline* may oxidise to *harmine*; under alkaline conditions it can be converted to *leptaflorine* (Ott 1994).

B. caapi stems have yielded 0.05-1.36[-1.6 crude]% alkaloids; the seeds contain similar amounts; roots yielded 0.61-1.95%; and leaves 0.25-1.9%. Of the stem alkaloids, *harmine* is the main constituent [36-96%], followed by d-*leptaflorine* [1-47%] and *harmaline* [1-44%]; also found in trace amounts are *harmol* [up to 2.6% of total alkaloids] (Der Marderosian et al. 1968; Hochstein & Paradies 1957; McKenna et al. 1984a; Ott 1994; Rivier & Lindgren 1972; Schultes et al. 1969), shihunine and dihydroshihunine (Kawanishi et al. 1982), and from leaves 0.0005% 1-OH-3,4-dihydronorharmine [keto-tetrahydronorharmine], 0.0005% *harmine* N-oxide, 0.005% harmalinic acid, 0.0002% harmic acid methyl ester, 0.007% harmic amide and 0.0001% 1-acetylnorharmine [arenarine C] (Hashimoto & Kawanishi 1975, 1976; Shulgin & Shulgin 1997). Unusually, 0.88% *caffeine* was reported from the plant (O'Connell 1969). This was most likely due to a confusion of plant material before the analysis, as O'Connell had been supplied with both B. caapi and **Paullinia** yoco [a *caffeine* containing species] by R.E. Schultes; these plants are both lianas (Rivier & Lindgren 1972). Different cultivars of this species have been analysed, but there seems to be no positive correlation between cultivar types and chemical content, though there is widespread variation in such chemical makeup across different collections (McKenna et al. 1984a).

A sample of 'epéna' snuff [of uncertain plant origin], as used by the Surára of n.w. Brazil, was found to contain c.1.3% *harmine* [0.38% purified] and 0.2% *leptaflorine* [0.08% purified] (Bernauer 1964). Similarly, a Tucano 'paricà' snuff [again of unknown plant origin] was found to contain only *harmine*, *harmaline*, and *leptaflorine* (Holmstedt & Lindgren 1967). These snuffs were probably manufactured from B. caapi, or a related species with similar chemistry. See also **Anadenanthera** and **Virola**.

Some specimens of B. lutea have been shown to yield *harmine* (Der Marderosian 1967), yet others have been almost free of alkaloids (Ott 1994).

B. muricata grown in India contained 0.02% alkaloids in its leaves, yielding in total 0.006% *harmine*, 0.005% *leptaflorine*, 0.004% 5-MeO-*tetrahydroharman*, 0.02% N-methyl-*tetrahydroharman*, 0.001% *harmaline*, 0.003% *DMT* and 0.001% *DMT* N-oxide, as well as smaller traces of *choline*, betaine and two unidentified indole-3-alkylamines (Ghosal 1972; Ghosal et al. 1971c; Ghosal & Mazumder 1971).

Banisteriopsis caapi is a liana; young branches sparsely appressed-sericeous to glabrate; old branches glabrous, terete, bark becoming fissured into shallow corky splits in age, sometimes with conspicuously lobed wood; stipules triangular, glabrous or appressed-sericeous, 0.5-1mm long. Leaves (4.8-)8.2-15.9(-20.5) x (2.5-)3.5-7.7(-11.5)cm, smaller in inflorescence, often coriaceous when mature, sparsely appressed-sericeous or glabrate, eglandular or with a pair of cupulate glands near apex, broadly ovate to ovate, base obtuse to truncate, apex short- to long-acuminate, margin flat to slightly revolute, bearing abaxially 2-5 pairs of sessile glands near or at margin, and another pair near midrib at base, glabrate adaxially, very sparsely appressed-sericeous to glabrate abaxially, hairs T-shaped; primary veins prominulous adaxially, reticulation sometimes impressed, primary and secondary nerves prominent abaxially; petiole 9-25mm long. Inflorescence of 4-flowered umbels in axillary cymes, subtended by very reduced leaves or inflorescence leaves deciduous before anthesis, sparsely tomentose to velutinous; bracts and bracteoles 1-1.8mm long, triangular to elliptic, appressed-pubescent abaxially, glabrous adaxially, caducous before or during flowering [rarely immediately after]; pedicels sessile, 7-11 x 0.4-0.6mm [0.3-0.5mm diam. without hairs], appressed-sericeous or tomentose-sericeous; sepals 5, elliptic, apex obtuse, 2-3.5mm long, 1.5-2mm wide, sericeous abaxially, minutely tomentose adaxially, all eglandular or the 4 lateral sepals biglandular; petals 5, pale pink, turning yellow in age, fimbriate, 4 lateral petals reflexed between sepals, claw 1-1.5mm long, 0.2-0.4mm diam., limb 5-8.5mm long, 4-6mm wide, broadly obovate, basal fimbriae tipped with glands; stamens with filaments 2-4mm long, basally connate, the posterior 3 flexuous and inflexed between posterior styles, locules sparsely pilose to glabrate, those of the 3 anterior stamens 0.7-1.2mm long, those of other 7 stamens 0.3-0.9mm long, connectives of 5 posterior stamens not glandular, those of 5 anterior stamens glandular, those opposite antero-lateral sepals enlarged and overtopping the locules by 0.5-1mm. Ovary 1-1.2mm tall, white-sericeous; anterior style straight, 2.8-3.2mm long, 0.2mm diam., posterior styles diverging and lyrate at base, 3-4mm long, 0.15mm diam.; stigmas capitate. Fruit a samara with carpophore up to 4mm long, 0.4mm wide, wing 18-42mm long, 8-22mm wide, appressed-pubescent becoming glabrate, wings of posterior samaras somewhat rotated to lie nearly parallel to wings of anterior samara, abaxial margin with tooth at base, appressed-pubescent to glabrate; nut 5-11mm tall, 3-5mm long, locule hairy throughout within. Fl. Dec.-Aug., fr. Mar.-Aug.

Amazonian Brazil, Bolivia, Ecuador, Peru, Colombia; found both wild and cultivated, origin uncertain (Gates 1982).

Can be cultivated from stem cuttings; leaf propagation might also be possible [see **Psychotria**, **Tabernanthe**]. Enjoys a mix of full sun and shade, with adequate watering. Water less frequently in winter. Responds well to high humidity. Best temperature range said to be 7-32°C; will tolerate lower temperatures if established, but is frost-sensitive. In areas with cold winters, plant survival may be ensured by trimming back heavily at the start of winter, and bringing indoors. Plants that have dropped all leaves due to transport-shock have been successfully nurtured back to health by keeping the plant in shade and spraying every few days with seaweed-emulsion. Otherwise, said to be very hardy once established (pers. comms.).

BEILSCHMIEDIA

(Lauraceae)

Beilschmiedia miersii *(Gay) Kosterm. nov. comb.* **(Bellota miersii** *Gay***;**
Peumus boldo *Mol.* (incorrect)**)** – bellota, belloto, belloto del norte
Beilschmiedia spp.

The Chilean B. miersii is of interest because of the presence of uncommon phenylpropenes in its essential oil [see below]. Beilschmiedia spp. are also known for their content of aporphine alkaloids. Several members of the genus have ethnobotanical uses. In Guinea, B. mannii ['spicy cedar'] bark and leaves are decocted to relieve headache; its seeds are commonly roasted and ground as food. In the Congo, B. gaboonensis bark is used as a topical analgesic (Burkill 1985-1997). B. giorgii ['djombi'] of the Congo is used to make body perfume. B. tawa [Nesodaphne tawa] of New Zealand has edible fruits which are eaten by Maoris. Many species are also used for their wood, which is useful in construction (Usher 1974).

B. elliptica from Australia has yielded large amounts of the aporphine alkaloids isoboldine [see Peumus boldo in *Endnotes*] and laurelliptine from its bark (Johns et al. 1969). Boldine itself is reputedly psychoactive [see Peumus boldus in *Endnotes*]. Plants from Toonumbar [NSW] yielded 2.17% alkaloids from bark, consisting mostly of laurelliptine. In mice, the alkaloid mixture [given orally] produced "ledge unsteadiness, slight ataxia, and slightly decreased activity" at 250mg/kg; 500-1,000mg/kg resulted in death (CSIRO 1990).

B. miersii has been found to contain contain *asaricin* and *carpacin* in its essential oil, as well as azaleatin (Buckingham et al. ed. 1994).

B. podagrica [from Omaura, Papua New Guinea] bark has yielded 1.15% alkaloids, consisting of laurelliptine, and what was probably isoboldine; leaf yielded up to 2.5% alkaloids, containing glaucine, (+)-2,11-dihydroxy-1,10-dimethoxyaporphine, (+)-2-OH-1,9,10-trimethoxyaporphine, (+)-2-OH-1,9,10-trimethoxynoraporphine and isocorydine (Johns et al. 1969). The leaf and bark alkaloids had similar effects in animals. Orally in mice, leaf alkaloids "produced intention tremors, seizures, dyspnea, gasping, asphyxial convulsions and death" at 1g/kg. Given i.p., 200mg/kg "resulted in slight stimulation in one animal, slight depression in another" (CSIRO 1990).

The genus Beilschmiedia has also yielded the aporphines N-methyllindcarpine, predicentrine, norpredicentrine and thaliporphine [O-methylisoboldine; thalicmidine] (Guinaudeau et al. 1975).

Beilschmiedia miersii is a tree to 25m tall; branchlets stout, subangular, compressed, dense rusty-tomentellous; branches cylindrical, dark brown, smooth, glabrous. Leaves subopposite, coriaceous, ovate to broadly ovate, rarely ovate-elliptical, 4-12 x 2-7cm, base obtuse or subcordate, rarely acutish, apex obtuse or slightly emarginate, rarely acutish, margin slightly recurved; young leaves sparsely appressed-pilose, adult ones glabrous, conspicuously, prominently and rather laxly reticulate on both sides, top surface green and shiny, midrib and primary nerves (10-12 pairs) prominent on both sides, straight, underside dull, pale or pruinose; petioles rather thick, densely rusty-tomentellous, slightly caniculate, 5-12mm long. Inflorescence axillary panicles, near apex of branchlets, densely rusty-tomentellous, many-flowered, broadly pyramidal, 2-10cm long; peduncles thick, compressed, 1-4cm long; bracts and bracteoles deciduous; pedicels rather slender, tomentellous, 1-3mm long; flowers greenish-yellow, broadly obconical, densely rusty-tomentellous, 3-4mm long, 2.5-3mm diam. at apex, tube 1mm long, pilose inside; tepals erect-patent, fleshy, acutish, 1.5mm long, outer ones narrowly ovate, inner ones ovate-orbicular, pilose inside; stamens included, as long as tepals, outer 6 with ovate, obtuse, glabrous anthers, filaments conspicuous, 0.5mm long, pilose, partly adnate to tepals, inner stamens with narrowly ovate, glabrous, truncate anthers; basal glands rather large, globose, sessile, touching each other; staminodes narrowly ovate, acute, pilose, 0.5mm long, cell-rudiments hardly conspicuous within. Ovary glabrous, ellipsoid, 1mm long, merging into a slightly shorter, cylindric-conical style with obtuse, sub-capitellate, papillose, rather small stigma. Immature fruit with persistent tepals, mature fruit ellipsoid, smooth, to 40mm long, 30mm diam., top obtuse, base sometimes with short, broad, obconical neck; pericarp 0.75mm thick, woody, brittle; testa membranaceous, dark, shining, adnate to pericarp.

Chile (Kostermans 1938).

BOLETUS, HEIMIELLA and RUSSULA

(Boletaceae)

Boletus flammeus *Heim* – nonda ulné kobi
Boletus kumaeus *Heim* – nonda ngamp-kindjkants, ngamp-kindjkants
Boletus manicus *Heim* – nonda gegwants ngimbigl, nondo galwans, gagwants ['penis']
Boletus nigerrimus *Heim* – nonda tua-rua, tuadwa, twaadwa
Boletus nigro-violaceus *Heim* – kermaipip, kermaiph, kermaikip
Boletus reayi *Heim* – nondo ngam-ngam, ngam-ngam
Boletus sp. – guukhraan, waakhriin
Heimiella anguiformis *Heim* – nonda mbolbe, nondo bolbe, mbolbe
Heimiella sp. – notiin

(Russulaceae)

Russula agglutinata *Heim* – nonda mosh, nonda mos
Russula kirinea *Heim* – nonda kirin, kirin
Russula maenadum *Heim* – nonda mosh, nonda mos
Russula nondorbingi *Singer* – nondo bingi, nonda bingi
Russula pseudomaenadum *Heim* – nonda wam
Russula sp. – wuutwuukiin

These fungi are part of a complex array of mushrooms used in parts of Papua New Guinea. Those named specifically have been implicated in the 'mushroom madness' epidemics that have been observed in the Western Highlands amongst the Minj [including the Kuma] of the Wahgi Valley. They are eaten apparently all year as food, only having psychoactive effects during the late dry season. Not everyone partaking experiences effects, and susceptibility to the mushrooms is said to be hereditary, but only to one sibling, usually the eldest, and they are usually not affected until age 17 or thereabouts, though there have been exceptions to these rules. One source has claimed that those susceptible may succumb to the mushroom madness whether they have eaten the mushrooms or not.

The fungi are taken without ritual, usually cooked in a number of ways, generally roasted in an earth oven or stewed in a pot with vegetables. B. reayi is usually cooked with the leaves of a shrub called 'kosgagl', or 'mosong kumu'. Large amounts of the mushrooms must be eaten to have any effect. Some are said to affect only one sex; others affect both. Different species are often consumed in a mixed collection, creating more confusion for ethnobotanists and pharmacologists! Amongst men, the intoxication is known as 'komugl tai'. They are seen to be tense and excited, with shivering or trembling of the extremities; they also suffer from double vision and intermittent aphasia, while running wildly through the village and surrounding forest. They usually arm themselves, and people tend to stay out of their way to avoid injury. People are not held accountable under tribal law for damages or injuries inflicted whilst komugl tai. Women who eat the mushrooms become 'ndaadl', a condition usually brought about by 'nonda mosh' [R. agglutinata and R. maenadum], and they become "delirious and irresponsible", bragging amongst themselves of their sexual exploits. Those who are unmarried may initiate sexual encounters with single and married men alike, whilst married women are expected to stay faithful to their husbands. On the morning of the second day, the women sometimes order their husbands to decorate them in their best feathers and weapons, while dancing in the formations of the men's sub-clans, something they would never be allowed to do when not ndaadl. Amongst the nearby Sina-Sina, mushroom madness is also known; the fungi responsible are known as 'kirin'. With one type of mushroom ['nonda namanotio'; still not identified], the madness [in this case called 'kegliotopogam'] may last 2-4 days, though one type known as 'nonda kandagegl' is known to cause a madness called 'wilopum', which may last 1-2 months, during which the person affected will live in the forest. These two conditions are feared amongst men. An episode of the madness apparently may be aborted by plunging into the nearest river (Heim 1963a, 1963b, 1965, 1967, 1973; Heim & Wasson 1965; Reay 1960; Schultes 1966; Singer 1958b). It should be noted that the term 'nonda' or 'nondo' applies to fungi in general. Researchers have found difficulty in properly collecting and identifying all of the mushroom species associated with the madness, as native systems of classification differ from strict botanical classification (Heim 1965).

Unidentified species from these three genera [Boletus, Heimiella, Russula] are crushed and eaten raw [usually up to 2 mushrooms] in the 3 final stages of initiation as an elder amongst the Bimin-Kuskusmin of West Sepik, New Guinea, along with an unidentified **Psilocybe**, probably P. kumaenorum, and many other substances [see *Endnotes*]. When found, patches of the mushrooms are anointed periodically with boar fat, cassowary faeces, and human semen; they have sacrificial meat placed around them shortly before picking for use. They may also be surrounded by crushed ginger [see *Endnotes*] and tobacco [see **Nicotiana**] to ward off pests and predators. Patches that become damaged or have a dead animal near them are assumed to have been contaminated by evil forces, and abandoned (Poole 1987).

Interestingly, Kuma men under the unfluence of nonda have been reported to perceive 'bush-demons' buzzing around their heads. These bush-demons as perceived through nonda are usually the size of wild bees, and were described as "tiny, two-dimensional, and often transparent" cartoonish creatures (Thomas 2001b). It has recently come to light that many bluing Boletaceae are sold and eaten in China, where it is well known that if not fully cooked before consumption, one will see 'the little men', and psychedelic experiences have been reported (Stijve 1997). It is also of interest that in Germany, B. luridus has been known as 'hexenpilz' ['witch's mushroom'] and 'hexenröhrling' ['witch's bolete'], suggesting association with magical practices (De Vries 1991).

Most researchers today believe the mushroom madness phenomenon to be a non-pharmacological one – that is, the apparent effects of the mushrooms are psychosomatic and constitute a complex social roleplay (Heim 1973; Ott 1993; Schultes & Hofmann 1980, 1992). Others suggest that any real effects come from other plants consumed with the mushrooms, particularly **Nicotiana** [of which handfuls are sometimes eaten with the mushrooms, by men], which are believed to be required to activate the mushrooms (Thomas 2001b). It seems premature to regard these fungi as entirely inactive, due to presumably wide variation in species consumed in combination, seasonal potency, interspecies chemical variation, and various positive reports of psychoactivity.

Roger Heim conducted a series of self-experiments with B. manicus, which is said to be one of the most powerful species in inducing the Kuma 'mushroom madness'. Heim consumed small quantities of dried, powdered B. manicus, less than 60mg in each experiment, though did not note the exact dose for each. The first bioassay revealed no activity. The second led to a sleep state in which he experienced fleeting brightly-coloured luminous visions. The third resulted only in slight stomach malaise (Heim 1965). Internet rumour suggests that B. erythropus [B. luridus var. erythropus] may be consumed in doses of at least 100g [fresh] for psychedelic effects, but it is very uncertain whether this is based in experience or supposition. Although B. satanas causes primarily gastrointestinal symptoms, some suspect it is also psychoactive (Toro 2004).

Many boletes exhibit blue staining when bruised, cut or aged, but this is not indicative of the presence of *psilocybin* or related products [see **Psilocybe**]. With these mushrooms, bluing results from the enzymatic oxidation of xerocomic acid, variegatic acid and gyrocyanin, producing hydroxyquinone derivatives. Some species exhibit black or bluish-black staining on bruising. Blackening in these species might be caused [as in the bolete Strobilomyces floccopus] by enzymatic oxidation of *L-DOPA* [see also **Hygrocybe**]. However, intense staining from the oxidation of variegatic acid [such as in B. erythropus] can result in blackish-violet tones (Gill & Steglich 1987).

Some people have been led by their curiosity to the point of intentionally consuming bluing boletes. One psychonaut consumed a 1-2cm cube of fresh flesh from a bluing bolete picked in Denmark, Western Australia; the same specimen was apparently inactive if cooked. He "became quite paranoid for a couple of days" after consumption. "He became concerned about the possibility of an attack by a tiger that may have escaped from a zoo passing through town, or of being struck by lightning. On the one hand he knew that these events were usually not things to worry about, but on the other hand, they were 'possible' and therefore 'real' concerns. He was able to talk himself out of being too paranoid, but acts such as walking through the forest at night, or being outside with a storm brewing, were accompanied by a considerable rise in adrenaline levels" (Santa pers. comm. 2001). Another psychonaut consumed 4 raw bluing boletes [size or weight of specimens not noted] harvested in Australia [location not noted], without any effects at all. The specimens had golden caps, and yellow-orange tubes below (Ramon pers. comm. 2001).

Boletus edulis is edible (Simonetti 1990), though many other species are considered inedible or toxic, especially when raw. Boletus spp. with red-mouthed tubes [such as B. frostii, B. luridus, and B. satanas] are considered particularly suspect. Symptoms often simply involve vomiting and diarrhoea, though episodes of paralysis have been reported. B. granulatus is often regarded as edible, though some people have suffered toxicity from consuming it (Benedict 1972; Heim 1963b). Russula emetica is well-known for its emetic properties, and R. virescens is also said to be toxic. R. squallida caused death in a guinea pig after 3 days, though it had no effect on rabbits (Ford 1910/1911b).

B. calopus has been shown to contain muscarines [36% muscarine and 64% epi-muscarine; see **Amanita** and **Inocybe**] (Stadelmann et al. 1976).

B. edulis has yielded *phenethylamine* and *tyramine* (Lundstrom 1989), as well as c.8.8% amino acids [including arginine, asparagine, leucine, *glutamine*, lysine, threonine, *tryptophan* and valine] (Zhuk & Tsapalova 1973).

B. erythropus has yielded *tryptamine* (Turowska et al. 1970), as well as 16.6-16.8% mannitol (Heim 1965) and variegatic acid (Gill & Steglich 1987).

B. luridus has been shown to contain <0.002% muscarines [8% muscarine and 92% epi-muscarine] (Stadelmann et al. 1976; Worthen et al. 1965), as well as 15.4-17.7% mannitol (Heim 1965).

B. luteus has yielded *phenethylamine* (Lundstrom 1989).

B. manicus has been shown to contain 3 unidentified indole bases [0.022-0.05% combined], as well as 0.002-0.005% *tryptophan* (Heim 1965, 1973) and 9.8-10.1% mannitol (Heim 1965).

B. nigro-violaceus has been shown to contain <0.005% of an unidentified indole substance; calcium oxalate was also found (Heim 1965).

B. satanas, which is comparable to B. manicus (Heim 1965), has been shown to contain muscarine (Worthen et al. 1965), as well as 19.3% mannitol (Heim 1965).

B. zelleri has been shown to contain *tyramine*, N-methyl-*tyramine*, *hordenine*, and 3 unidentified alkaloids (Lee et al. 1975).

A Boletus sp. harvested near Mt. Hagen, PNG, known as 'namanama', and claimed to be implicated in the 'mushroom madness', was analysed and found to contain 2.5% amino acids [alanine, arginine, *glycine*, histidine, leucine, isoleucine, *methionine*, valine, threonine, 0.04% L-2-amino-4-methyl-5-hexenoic acid], and sterols [ergosterol, as well as 2 unidentified steroids] (Gellert et al. 1973; Rudzats et al. 1972). The term 'namanama' used by these researchers may be a derivation of 'ngam-ngam', a Kuma word applied to some of the Boletus spp. associated with the madness, including B. reayi and three unidentified species (Heim 1965).

In addition, B. frostii, B. miniato-olivaceus and B. subvelutipes contain unidentified alkaloids (Worthen et al. 1965).

As mentioned above, some Russula spp. are known to be toxic, causing poisoning said to be similar to that caused by muscarine, and are often pungent-tasting; mild-tasting species are said to be edible (Bresinsky & Besl 1989).

R. cyanoxantha has been shown to contain *choline* (Turowska et al. 1970).

R. delica has yielded protoilludane sesquiterpenoids, stearoylplorantinone B [0.004%] and stearoyldelicone [0.009%], from intact specimens; the sesquiterpenes plorantinone A, B, and C [degradation products of the above sesquiterpenoids] were obtained from injured specimens (Clericuzio et al. 1997).

R. emetica has been shown to contain muscarines [41% muscarine, 59% epi-muscarine] (Stadelmann et al. 1976) and mannitol. The ethanol extract of fresh specimens showed muscarine-like activity (Balenović et al. 1955). From Japanese specimens, 0.4-0.7% lipids were extracted, with 22,23-dihydroergosterol as a major component (Yonezawa & Mitsuhashi 1969).

R. ochroleuca has yielded L-γ-glutamyl-2-amino-3-hexanone, an aminoketone (Welter et al. 1976).

Nothing seems to be known of the chemistry of Heimiella spp.

Boletus manicus has a pileus up to 13cm across, hemispheric-globose becoming convex or irregularly subhemispheric, very thick, dry, glabrous, matt, white or pallid or slightly greyish; margin incurved, funiculiform; surface covered by an irregular pile of narrow hyphal ends 3-10µ wide, some walls to 1µ thick. Stipe 9-15cm x 20-30mm, 30-55mm at base, rooting, attenuate upwards, white with red reticulation, pale yellowish towards apex, base fuscous vinaceous. Tubes to 5mm, adnexed (free or scarcely adnate), not ventricose, orange-yellow, cyanescent; pores small, round, orange-yellow then red-orange or crimson. Flesh thick, firm, pale yellow, slightly cyanescent. Smell strong, almost repulsive; taste bitter. Spores 9-11.6(-13.5) x 4-5µ, olive ochre in mass, smooth, oblong, hyaline, amygdaliform. Fr. Aug.-Sep.

Found on the ground in forest; New Guinea, Minj, 1500-1700m (Corner 1972; Heim 1963a).

Heimiella anguiformis has a dry pileus 4-8cm across, convex or umbonate, ruguloso-cerebriform, dry, dark- to fawn-brown or tinged orange; margin exceeding the tubes, membranous; surface of pileus rugulose, covered with a pile of moniliform hyphal ends, the pyriform cells 10-40µ wide and finally detaching. Stipe 12-20(-30?)cm x 7mm above, to 15mm at base, attenuate upwards, sinuous, glabrous, light yellow, pink upwards, fuscous and subsulcate downwards, otherwise smooth. Tubes to 15mm, sinuate, ventricose, citron-yellow to orange and olivaceous; pores concolorous. Flesh light citron-yellow, unchanging, rather tough. Smell sour. Spores 18-21 x 10-12.5µ, spore body 12.8-16.5 x 9.3-11.3µ, brown in mass, amygdaliform, base rounded, apex subacute, reticulate in the exospore, without a smooth adaxial patch.

In **Castanopsis** forest, New Guinea, 1500-1800m (Corner 1972; Heim 1963a).

Russula nondorbingi has a viscid, subglobose to convex (eventually convex to applanate) pileus 56-72mm across, slightly umbilicate, glabrous, light grey, deeper-coloured in centre, paler at margin, margin acute and smooth becoming short-sulcate, flesh firm. Stipe 58-90 x 15-28mm, white or whitish with small brown spots, glabrous, subrugulose, solid, then spongy-holey, equal or tapering upward; veil none. Gills cream or whitish, equal, simple, crowded, later close, varying from attingent-subfree to adnate-subdecurrent, but very narrowly attenuate at apex of stipe, to 6.5-7.5mm broad, distinctly anastomosing. Spores 10-13.5 x 8.7-12.7µ, almost globose and yellowish in larger spores, more so than in smaller spores, medium- and small-sized spores more subglobose and hyaline, echinate with isolated spinules 1.5-2µ long; spore print colour unknown.

In tropical forest; Minj, New Guinea (Singer 1958b).

BOOPHANE [Boophone, Buphane] and some relatives

(Amaryllidaceae)

Boophane disticha *(L. f.) Herb.* **(B. toxicaria** *Herb.***; Amaryllis disticha** *L. et Pat.***; Haemanthus toxicarius** *Thunb., Jacq. et Gawl.***)** – buphane, giftbol, seeroogblom, incotho, leshoma, sore-eye flower, Cape poison bulb, candelabra flower
Ammocharis coranica *(Ker-Gawl.) Herb.* – incotho
Brunsvigia radulosa *Herb.* **(B. cooperi** *Baker***)**

The bulbous African herb B. disticha has been used as an intoxicant, and also has several other recorded usages, such as in veterinary medicine. It has been used to poison hunting arrows, and as a suicide poison in the Orange Free State [administered by enema]. It is grown outside of the huts of the Manyika in order to bring good luck and rain, and to ward off nightmares when sleeping. The Xhosa use dried scales from the bulb as a dressing for circumcision wounds. The scales and the leaf have also been used as a dressing for wounds by Europeans in the area, due to the analgesic and pus-excluding actions of the scales, and the styptic action of the leaf. The bulb is used traditionally in Zimbabwe to "arouse ancestral spirits". It is also consumed [mixed with food and other ingredients] by Basuto boys for their initiation and circumcision, to "fill them with the spirit of their ancestors", and to enter manhood with this strength. The dose must be carefully measured, as the bulb of B. disticha is considered very toxic and frequently causes fatalities due to respiratory paralysis. The bulb has also been consumed as a 'recreational' hallucinogen in parts of southern Africa, and its effects are apparently similar to those of **Datura** and related plants. Even simply smelling the flowers is reputed to cause headache and drowsiness (De Smet 1995, 1996, 1998; Laydevant 1932; Usher 1974; Watt & Breyer-Brandwijk 1932, 1962).

An unidentified Boophane sp. is used in Natal to treat hysteria, asthma, and other disorders. Zulu women roll their snuff on dried bulb scales from the same plant, in order to "improve the snuff" (Watt & Breyer-Brandwijk 1962). In Zululand, A. coranica is used to treat mental illness when B. disticha is not available. The outer scales of the bulbs of the plant are partially burnt, before being made into headrings for tribal chiefs, in much of southern Africa. The related Brunsvigia radulosa is also considered narcotic (Koorbanally et al. 2000).

These plants contain a variety of 'Amaryllidaceae alkaloids' limited in their known occurrence to plants of this family (Harborne & Baxter ed. 1993; Martin 1987), as well as the genus **Dioscorea** (Mulholland et al. 2002). See also **Narcissus**, **Pancratium**.

B. disticha bulbs [fresh] have yielded 0.31% alkaloids – 19.4% buphanidrine, 18.6% undulatine, 16.9% buphanisine, 14.1% buphanamine, 11.1% nerbowdine, 7.2% crinine, 5.4% distichamine, 1.2% crinamidine, 0.6% acetylnerbowdine, 0.4% lycorine and 0.3% buphacetine. Other studies have found buphanine [similar to *hyoscine* in effect; on hydrolysis gives buphanitine] and haemanthine [similar in action to buphanine], as well as furfuraldehyde, acetovanillone, chelidonic acid, pentatriacontane, laevulose, ipuranol, a phytosterol, copper, and fatty acids. Dry bulbs have yielded up to 4% alkaloids; outer dry layers of bulb contain no alkaloids. Bulbs grown in shade are said to be more potent. The aerial portions appear not be toxic, as they are grazed harmlessly by animals (De Smet 1996; Watt & Breyer-Brandwijk 1932, 1962). Arrow poison made

from B. disticha, on a Bushman arrow over 60 years old, had retained so much potency that 100-300µg [s.c.] killed mice within 20-30 minutes (De Smet 1998).

A. coranica bulbs have yielded lycorine, 1-O-acetyl-lycorine, crinamine [hypnotic sedative; respiratory depressant and powerful transient hypotensive in dogs – LD50 10mg/kg], 6-OH-crinamine, buphanisine, epi-buphanisine, buphanidrine, ambelline, coranicine [an uncharacterised alkaloid], hippadine, hamayne, caranine, acetylcaranine, cycloeucalenol, cycloeucalenone, epi-vittatine, 24-methylene-pollinastanone, 24-methylene-cycloartan-3β-ol, 6α-OH-powelline and 1-O-acetyl-9-O-demethylpluviine (Buckingham et al. ed. 1994; Koorbanally et al. 2000).

Brunsvigia radulosa bulbs [fresh] harvested in summer have yielded brunsvigine, brunsvinine, and crinamine; in late autumn, lycorine replaces brunsvinine (Dry et al. 1958).

Boophane disticha is a bulbous scapose herb, with an annually-produced fan of leaves from the base. Leaves strap-shaped, not narrowed to base, distichous; leaf sheaths unspotted. Inflorescence a dense terminal umbel of numerous dull red flowers, pedicellate, bisexual, regular, at apex of a leafless stem, subtended by 2 or more membranous bracts; pedicels longer than perianth-tube, lengthening and spreading in fruit, becoming stiff and straight, so that the entire fruiting inflorescence can break away and roll over the ground, distributing seeds; perianth with the tube shorter than the lobes, of 6 equal segments; stamens 6, long. Ovary inferior or superior of 3 carpels with axile placentation; ovule solitary in each cell. Fruit a capsule; seeds few or numerous, often angular or winged.

Locally common in rocky grassland, 1500-2500m; S. Africa, upland Kenya (Agnew 1974), Zimbabwe (De Smet 1996).

BORONIA

(Rutaceae)

Boronia latipinna *J.H. Willis* – Grampians boronia
Boronia muelleri *(Benth.) Cheel*
Boronia pinnata *Smith*
Boronia rivularis *C.T. White* **(B. thujona var. 'a')**
Boronia safrolifera *Cheel*
Boronia thujona *Penfold et Welch*
Boronia spp.

Plants of this genus have been popular horticulturally as ornamentals, partially due to their pleasant fragrance, for which they are also used in perfumery. Some contain a variety of interesting compounds with psychoactive potential.

B. latipinna leaf yielded 0.9% essential oil, terminal branchlets yielded 1.4%, consisting of 60.6% bornyl acetate, 6.7% *camphor*, 9.5% camphene, 5.8% β-*pinene*, 0.6% *safrole*, 0.3% *borneol*, 0.1% humulene and others (Brophy et al. 1986).

B. muelleri essential oil has yielded *elemicin*, *pinene* and geraniol (Ghisalberti 1997).

B. pinnata flowers have yielded *elemicin* from their essential oil, as well as methyl anthranilate and anthocyanin malvidin 3,5-dimonoside; essential oil from the leaves has yielded limonene and d-α-*pinene* (Ghisalberti 1997; Shaw et al. comp. 1959).

B. rivularis essential oil has yielded *safrole* and l-limonene (Ghisalberti 1997).

B. safrolifera leaf essential oil has yielded *safrole*, *methyleugenol*, and d-α-*pinene* (Ghisalberti 1997).

B. thujona leaf and branch essential oil has yielded α- and β-*thujone* (Ghisalberti 1997; Shaw et al. comp. 1959).

Boronia thujona is a shrub or small tree 1-4m tall, glabrous, unarmed; branchlets with 2 grooves separated by decurrent leaf bases. Leaves aromatic, opposite, rarely subopposite, pinnate with 3-15 leaflets; leaflets narrow-elliptic to linear-oblong, 5-30 x 1-6mm, apex acute, margins finely glandular-crenate and revolute to recurved, lower surface slightly paler, lateral leaflets opposite, terminal leaflet often shortest; rachis 9-40mm long, slightly winged; petiole 7-17mm long. Inflorescences axillary, cymose or paniculate, 2-6-flowered; flowers bisexual; pedicels 5-15mm long; sepals 4(-5), free; petals 4(-5), free, not persistent in fruit, 6-9mm long, imbricate, bright pink; stamens 8(-10), free, erect or pyramidally arranged; carpels 4(-5), +- free, lacking a sterile apex; styles fused, arising terminally or subterminally from carpels; stigma scarcely differentiated from style or capitate or grossly swollen and almost sessile; ovules 2 in each carpel. Fruit of 1-4 cocci, cocci not transversely ridged, with rounded apices, glabrous; seeds released forcibly from dehiscing cocci, dull or shiny, black. Fl. Aug.-Nov.

In wet and dry sclerophyll forest, in damp shady spots on sandstone; from the Sydney region to the Budawang Ranges, NSW [Australia] (Harden ed. 1990-1993).

BOSWELLIA

(Burseraceae)

Boswellia carteri *Birdw.* **(B. sacra** *Flueck.***)** – African olibanum, oliban, frankincense tree
Boswellia thurifera *Roxb. ex Flem.* **(B. glabra** *Roxb.***; B. serrata** *Roxb. ex Colebr.***)** – Indian oliban, frankincense tree, salai

The delicious incense of 'frankincense', the oleo-resin from B. carteri, B. thurifera, or related species, has been used by Middle-Eastern cultures since time immemorial. A prosperous trade route for this commodity was centred around Yemen for many years. In the first century AD, Pliny wrote of the fact that it was a capital offence for a camel transporting frankincense to turn from the trade route – he also described the security measures at a major processing centre in Alexandria, where the workers were strip-searched before being allowed to leave the workplace. 'Myrrh', a stronger incense [from Commiphora spp.], commanded three times the price of frankincense, but the popularity of the latter was such that it enjoyed a demand five times greater. Ancient Egyptians used it in perfumes, cosmetics, and as an incense for temple rites; it was also highly esteemed by the Persians, Babylonians, Assyrians, Hebrews, Greeks and Romans. It was said to have been one of the gifts given to the baby Jesus, as well as being an ingredient of the holy incense given to Moses by God. In England today, the Lord Chamberlain makes an offering of frankincense during the feast of the Epiphany on Jan. 6. The incense is believed to be a purifier, used to drive out evil spirits, and its scent is said to be a manifestation of the 'presence of the divine' (Abercrombie 1985; Duke 1983; Lawless 1994).

In TCM, a decoction of B. thurifera resin [3-9g] is taken to treat chest and stomach pain, painful menstruation, amenorrhoea, nocturnal emission, epilepsy, poor circulation, boils and abscesses. An alternative means of ingestion is to let a piece of the resin dissolve in the mouth. In Ayurvedic medicine, it is used externally for carbuncles, and internally for lung infections and gonorrhoea; it is used in Indian folk medicine to treat CNS-disorders and rheumatism (Reid 1995; Watt & Breyer-Brandwijk 1962). Oleo-resins of both B. carteri and B. thurifera have been used in folk medicine to treat tumours (Pernet 1972). Frankincense vapours clear the head, and are considered warming, restorative, revitalising, uplifting, sedative and tonic; taken internally, frankincense is also an analgesic, emmenagogue, astringent, antiinflammatory, antiseptic, carminative, expectorant, digestive, and circulatory stimulant, also stimulating muscle-growth (Lawless 1994, 1995; Reid 1995). One psychonaut reported being "hardly able to walk", with perceived "opioid" effects, after heavy use of frankincense essential oil in a vapouriser, in a closed room (theobromus pers. comm.). See also the Catholic altar-boys below!

B. carteri oleo-resin has yielded 5-10% essential oil, containing *pinene*, dipentene, limonene, *thujone*, phellandrene, cadinene, cymene, p-cymol, myrcene, terpinene, camphene, olibanol, verbenol, verbenone, bornyl acetate, octyl acetate, incensyl acetate, octanol, linalool and incensole; as well as 60-65% resins [α- and β-boswellic acid], 20% gum [containing arabinose, galactose, galacturonic acid], and 5-8% bassorine, a polysaccharide (Battaglia 1995; Lawless 1995; Pernet 1972). Investigating the possible cause of habituation of some Catholic altar-boys to inhaling frankincense fumes, it was hypothesised that *THC* could be formed in the fumes, and possibly also from chewing or digesting the resin (Martinetz et al. 1989). However, this was not actually proven, and later research failed to detect *THC* in the pyrrolysis products of resin samples (Safayhi 2001). See also *citral* entry in *Chemical Index*.

B. thurifera oleo-resin has yielded an essential oil containing *estragole*, geraniol, terpineol, α-thujene, p-cymene, β-*pinene*, (+)-limonene, linalool, elemol and cadinene; as well as arabinose, rhamnose, glucose, galactose, fructose, digitoxose, xylose, polyuronic acids, glucuronic acid and galacturonic acid. The non-phenolic fraction showed analgesic, sedative and antitumour activity (Kar & Menon 1969; Pernet 1972; Rastogi & Mehrotra ed. 1990-1993).

Boswellia thurifera is a deciduous, middle-sized tree with a spreading, flat crown; bark c.1.2cm thick, greenish, ash-coloured, peeling off in thin, smooth flakes; young shoots and leaves pubescent with simple hairs. Leaves imparripinnate, crowded at ends of branches; leaflets 8-15 pairs, opposite or nearly opposite, sessile, lanceolate, +- deeply crenate, apex generally obtuse. Flowers bisexual, in small racemes; calyx small, 5-7-cleft; petals 5-7; stamens 10-12, inserted at base of red annular, fleshy disc; anthers 2-celled, dehiscent longitudinally. Ovary free, 3-celled, ½ immersed in the disc, 2 collateral ovules in each cell, hanging side by side from the top of the central angle. Fruit a 3-valved drupe, the valves separating from the dissepiments, which remain attached to the axis, dehiscent; seeds 3, enclosed in heart-shaped stones attached to the inner angle. Leaves fall Mar.-Apr., new foliage sprouts in Jun. Fl. when tree is leafless.

In deciduous forests, often gregarious, forming open forests with Sterculia urens; sub-Himalayan tract, from the Sutlej east and throughout the drier parts of the w. Peninsula to within 16-32km of the w. Ghats.

Easily grown from cuttings (Brandis 1906).

Frankincense resin [in this instance referring to that from B. carteri] is collected all year, except during rainy periods. A top layer of bark is scraped away, and globules of white resin ooze out; resin from the first two scrapings of one spot is discarded – it is the third cutting that produces what is regarded as 'real' incense. The best comes from Yemen and southern Arabia, with cheaper types coming from India and Somalia (Abercrombie 1985).

BRACHYCHITON

(Sterculiaceae)

Brachychiton diversifolius *(G. Don.) A. Terracc.* **(B. diversifolium** *(G. Don.) R. Br.***; B. populneum** *R. Br.***; B. populneus** *(Schott) R. Br.***; Sterculia diversifolia** *G. Don.***)** – nanungguwa, burdaga, marndaja, pirtpa, kurrajong, northern kurrajong

This tree, related to **Cola** and **Theobroma**, is utilised by indigenous groups in northern Australia. The seeds are eaten raw or cooked [sometimes with honey], though they are covered with irritating hairs; these hairs are usually removed in the process of roasting the seeds on hot coals. The roots of young plants are also eaten raw or cooked. The inner bark is made into an eyewash, and is also chewed to alleviate thirst and fatigue on long journeys. The outer bark is used to make rope, string and belts; the Ngarinyman prefer to use the inner bark for their fibre requirements. The wood is used to make fire sticks and some types of spears. The gummy bark exudate may be rubbed into cuts and sores to promote healing, and the inner bark is used to make bandages. The Ngarinyman use B. megaphyllus, B. spectabilis, and B. viscidulus [all known as 'jarrinkal'] in the same ways as they use B. diversifolius (Aboriginal Communities 1988; Brock 1988; Smith et al. 1993).

The seeds have caused intoxications in sheep and cattle, referred to as 'scrub-cramps', and observed as locomotor disturbance when affected animals were forced to move (Webb 1948).

The most interesting aspect of this plant, however, is that the seeds were shown to yield c.1.8% *caffeine* (Bock unpubl.; Turner 1903), which makes them potentially a stronger stimulant than some coffee [see **Coffea**].

Mature seeds of B. paradoxum [Sterculia ramiflora] from Chillagoe, Queensland [harv. Jun.], tested positive for alkaloids (Webb 1949). See also Sterculia in *Endnotes*.

Brachychiton diversifolius is a tree 7-15m tall, with a well-formed conical crown, semi-deciduous, glabrous except for flowers; bark tight, round, dark grey, finely fissured. Leaves alternate, smooth, ovate to elongate heart-shaped, 4.5-15 x 5-10.5cm, green, apex long-pointed, young leaves highly variable in size and shape, often 3-5-lobed, mature leaves ovate to lanceolate or 3-lobed. Inflorescence an axillary panicle; flowers unisexual, broadly campanulate, hairy and greenish-yellow or creamy-white externally, spotted red-brown and yellow within, 1.2-1.5(-2)cm high x 1.2-1.5cm wide, usually 5(-6)-lobed, valvate or induplicate-valvate; petals absent; anthers 10-30, subsessile on androgynophore, 2-locular; carpels 5, free, raised on short gynophore; staminodes 10-30 at base of carpels; styles cohering initially, later separating; stigmas ligulate, radiate. Fruit smooth, oblong to ovoid woody follicles, (4-)5-9.5 x 2.5-3.5cm, 5 or fewer by abortion, stipitate, short-pointed apex, dark grey to black, splitting open when ripe, prickly-hairy inside; seeds numerous, 2-seriate, yellow, with prickly hairs, surrounded by honeycomb-like compartments. Fl. Jun.-Sep.(-Oct.), fr. (Sep.-)Oct.-Dec.

Open forest and woodland, on a wide variety of well-drained soils, extending to sparse savannah woodlands in dry regions, or rocky hillsides; n. Qld, WA, NT, NSW, Vic. [Australia]. Cultivated as an ornamental (Brock 1988; Jessop ed. 1981; Stanley & Ross 1983-1989).

BRASSICA

(Cruciferae/Brassicaceae)

Brassica alba *Rabenh.* – white mustard, siddhartha, sufedrai

Brassica juncea *L.* – brown mustard, common Indian mustard, rajika, sarson

Brassica spp. – wild turnip, wild radish, wild mustard

Many Brassica spp. are common weeds all over the world, and their seeds may be made into mustards. The pungency that gives the characteristic taste of mustard develops when the seeds are crushed in water (Bremness 1994; Low 1991b). Some cultivars of B. oleracea are also common vegetables, such as B. oleracea cv. botrytis [cauliflower], B. oleracea cv. capitata [cabbage], B. oleracea cv. gemmifera [Brussels sprouts], and B. oleracea cv. cymosa [broccoli].

Mustard seed is associated with Aesculapius, the Roman god of healing. It is used in love and fertility potions, and some Italian peasants sprinkle the seeds on the doorstep as a protective agent. The seeds are also said to be effective in increasing mental powers (Cunningham 1994). Because they are believed to "promote virility", mustard seeds have been forbidden to monks (Rätsch 1990). In Tuscany, Italy, small pieces of wild B. oleracea ssp. robertiana ['cavolo di San Viano'] leaf are sometimes eaten to provide a good omen (Pieroni & Giusti 2002). The Cherokee use three species [B. hirta, B. napus and B. nigra] as tonic stimulants and appetite stimulants, as well as to treat fever, dropsy, palsy and asthma (Hamel & Chiltoskey 1975). The Chinese use B. juncea to treat colds, abscesses, ulcers, rheumatism, lumbago and stomach problems (Bremness 1994). It is said that the Hindus used mustard seed to 'travel through the air' (Cribb 1981; Cunningham 1994). In India, seeds of B. alba are used as a nerve stimulant, which is an emetic and narcotic poison in large doses; they also treat epilepsy and hysteria (Nadkarni 1976). In Tanzania, B. juncea leaves and flowers are smoked to 'get in touch with the spirits'; the effects are said to be **Cannabis**-like, but weaker (Burkill 1985-1997).

Mustard seeds stimulate the circulation, warm and stimulate the digestive system, treat bronchitis, and may reduce inflammation applied topically as a counter-irritant; mustard oil is also strongly antibacterial and antifungal, but may blister the skin (Bremness 1994; Low 1991b; Mabey et al. ed. 1990). Seeds contain the highest concentration of mustard oils; important constituents are the glycoside sinigrin, and the enzyme myrosinase [thioglucosidase], which react with water to release allyl isothiocyanate [a strong irritant], potassium bisulfate and glucose (Hall 1973; Harborne & Baxter ed. 1993; Rastogi & Mehrotra ed. 1990-1993).

Specifically, B. juncea has also yielded glucobrassicins, cyclobrassin sulfoxide, progoitrin, napoleiferin, 3-butenonitrile, phenylacetonitrile, 3-phenylpropionitrile, 3-phenylpropionamide, 5-isothiocyanato-1-pentene and 25-methyl-24-methylenecholesterol (Buckingham et al. ed. 1994; Rastogi & Mehrotra ed. 1990-1993; Wu & Sheng 1999). Benzyl-isothiocyanate and phenethyl-isothiocyanate inhibit enzyme P-450 [see *Neurochemistry*] (Teel & Huynh 1998).

The psychoactive effects of some Brassica spp., which have not been scientifically investigated, might possibly be partly due to circulatory stimulation, which could provide a 'circulatory rush' giving rise to a sensation of moving through air. Some of the compounds found in B. juncea and other B. spp. may produce potentially psychoactive byproducts on degradation. On hydrolysis, the glucobrassicins produce 3-indolemethanol, 3-indoleacetonitrile, 3,3'-diindolylmethane, and 4-OH-indolemethyl derivatives. Progoitrin and napoleiferin on hydrolysis produce goitrin derivatives; on pyrolysis they might produce compounds similar to sulphur analogues of muscazone [see **Amanita**] (theobromus pers. comm.; Wu & Sheng 1999).

Brassica juncea is an annual herb to 1m tall, with branches almost erect, glabrous. Leaves glaucous; basal leaves lyrate-pinnatisect with 1-2 pairs of lobes, to 20cm long, sparsely bristly; upper leaves reducing to +- entire, glabrous, +- petiolate. Inflorescence elongating from a flat corymb; flowers actinomorphic, bisexual, nectariferous; sepals 4, free, in 2 whorls; petals 4, free, usually clawed, cruciform, 7-9mm long, pale yellow; stamens usually 6 in 2 whorls, outer 2 filaments shorter than 2 inner ones; anthers dehiscing longitudinally. Gynoecium of 2 fused carpels; ovary superior, 2-locular, false septum dividing ovary typically present and persistent after seed dispersal; style single; stigma usually 2-lobed. Siliqua terete to somewhat flattened, partly contracted between seeds, spreading, 2-6cm x 2-4mm, +- 4-angled, lateral veins on valves anastomosing, beak 4-10mm long, narrower than stigma; pedicel 7-20mm long; seeds numerous in valve region, 1 row per loculus.

Native to Europe and Asia – a weed of agricultural lands; in Australia, found in Qld, NSW, SA & WA (Harden ed. 1990-1993).

BRUGMANSIA

(Solanaceae)

BRUGMANSIA X CANDIDA 'BUYÉS'

Brugmansia x candida *Persoon* **(B. arborea** *(L.) Lagerheim***; B. aurea** *Lagerh.***; Datura arborea** *L.***; D. candida** *(Pers.) Saff.***)** – tecomaxochitl, floripondio, floripondio blanco, floripondio amarillo, almizclillo, máma maikiwá, buyes, po:b piH, borrachero, borrachera de agua, munchira, tonga, misha, misha rastera blanca, cimora oso, cimora galga, cimora toro curandero

Brugmansia x insignis *(Barbosa-Rodr.) Lockwood ex Schultes* – toa-toé, sacha toé, danta borrachera, unt maikiwá, pehí, muhu pehí, seme pehí, sese pehí, tãkiyaí pehí, misha rastrera

Brugmansia sanguinea *(Ruiz et Pavón) D. Don* **(B. bicolor** *Lindl.***; B. bicolor** *Pers.***; D. sanguinea** *Ruiz et Pavón***)** – puca campancho, huaca, yerba de huaca, huacachaca ['plant of the tomb'], grave plant, misha toro, misha rastrera, tongo, tonga, borrachero, borrachero rojo, guamuco, guamuco borrachera, guamuco floripondio, chimite maikiwá, dóctor maikiwá

Brugmansia suaveolens *(Humb. et Bonp. ex Willd.) Bercht. et Presl* **(D. suaveolens** *H. et B. ex Willd.***)** – toé, flor de toé, floripondio, floripondio blanco, borrachero, misha colambo, tsuak, ain-vai, maikua, tsuakrutin maikua ['medicine maikua'], tuktur maikua ['doctor maikua'], ukunch maikua ['bone maikua'], yawa maikua ['dog maikua'], baikua, bikut, míkiut maikiwá, tsuak, fleur trompette

Brugmansia versicolor *Lagerheim* – misha del Inca

Brugmansia vulcanicola *(Barclay) Schultes* – yas

Brugmansia (Datura, section Brugmansia) spp. – borrachera, buyés borrachera, siva ghanta, dhodre phul, dhature phul, angel's trumpet, tree datura

These tree relatives of **Datura** have been cultivated as ornamentals and magical plants in S. America since pre-Columbian times. They reproduce only in cultivation through cuttings and planted seed, no truly wild forms being known. Many specimens exist as cultivars, and species such as B. x candida have many varieties with different names (Bristol 1969). Opinions also differ on the synonymy of some of these species, which is confused by their variability, and the existence of many cultivars and hybrids. In particular, B. arborea, B. aurea and B. x candida are sometimes considered separate species, and B. suaveolens is sometimes not considered to be a true species at all. They are, however, very similar both in appearance and chemistry, and for the sake of simplicity I will follow the classifications above and leave the definitive taxonomy of this genus for others to debate.

The Sibundoy Valley of the Colombian Andes is the centre of Brugmansia use, and indigenous people there grow the trees as private possessions. Their use also spreads south to Chile. The striking red-flowered B. sanguinea was sacred to priests of the Temple of the Sun at Sogamoza, Colombia. The Guambiano of s. Colombia say of B. vulcanicola – "How pleasant is the perfume of the long, bell-like flowers of the Yas, as one inhales it in the afternoon…But the tree has a spirit in the form of an eagle…The spirit is so evil that if a weak person stations himself at the foot of the tree, he will forget everything…feeling up in the air as if on the wings of the spirit of the Yas." The spirit jealously guards the plant where it lives, and is said to viciously pursue anyone who would try and fell it, ruining the offender's crops and plaguing their livestock. Apart from external application to rheumatic pain, Brugmansia spp. are often used for their hallucinogenic properties in divining, whereby an infusion or pressed juice of crushed seeds, stems or stem raspings, leaves and/or flowers is drunk. Leaves are usually taken in pairs. Sometimes the plant parts are added to chicha beer [see *Methods of Ingestion*], or are drunk with aguardiente [a distilled cane alcohol] or tobacco-water [see **Nicotiana**]. Fortifying recreational alcoholic beverages with Brugmansia is generally considered antisocial as it can lead to fighting and social disorder. Species and varieties are recognised as having differing potency or toxicity, and less toxic types are preferred for shamanic work. They may be taken with a sober assistant – like **Datura**, the intoxication induced by Brugmansia can be long-lasting, unpredictable and difficult to manage. The Jivaro administer the seeds to unruly children, so that their ancestors may punish them and show them the right way to live. They also give it to boys at the age of 6, to acquire an 'eternal soul' ['arutam wakani']. An infusion of 3-6 leaves of B. x insignis is sufficient to produce a hypnotic state of mild inebriation, to facilitate divination. Ground leaves and flowers of B. x candida are sometimes fed to hunting dogs to improve their senses (Bennett 1992; Bristol 1969; Schleiffer 1973; Schultes 1969c; Schultes & Hofmann 1980, 1992; Schultes & Raffauf 1990).

In Mochica, Peru, B. x candida is sometimes brewed together with San Pedro [see **Trichocereus**] (De Rios 1977). This is also the case in Huancabamba, Peru where B. x candida, B. sanguinea and other unidentified Brugmansia spp. are occasionally added to the brew for cases of difficult divination. Even amongst shamans of the area, many Brugmansia cultivars are considered too strong and dangerous to take internally, instead applying them externally for both medicine [inflammations, aches and pains, skin problems etc.] and divination. For example, rather than drinking the plant with San Pedro, some shamans may tie a couple of leaves to their head and absorb the drug that way, whilst drinking the San Pedro. However, some weaker cultivars are indeed taken internally, such as B. versicolor, of which an alcohol tincture is used as a sedative and analgesic. As with many potentially dangerous drugs used in n.e. Peru, the effects may be stopped by drinking 'arranque' or 'corte', a mix of water, sugar, corn [Zea mays - see *Endnotes*], white rose petals and **Citrus** aurantiifolia ['limón agrio'] juice (Davis 1983; De Feo 2003; Rätsch 1998).

B. suaveolens leaves are sometimes added to ayahuasca brews [see **Banisteriopsis**] by the Siona, Sharanahua, Shuar, Quichua and Ingano; leaves, stems, seeds and/or leaf ashes of other spp. [such as B. x insignis] have also been added to the brew. Often only 2 leaves are added. Shuar shamans consider B. suaveolens "to be the most powerful and the most dangerous hallucinogen" which can cause insanity with repeated use. This applies to all Brugmansia spp. (Bennett 1992; Luna & Amaringo 1991; McKenna et al. 1995; Ott 1994; Rivier & Lindgren 1972; Schultes 1957; Schultes & Raffauf 1990; Uscategui 1959). Besides being added to ayahuasca, in Peru B. suaveolens is also sometimes taken as a plant teacher, in a 1 month diet. For this purpose, one method of preparation consists of cooking the core of the stem in a double-boiler until it becomes rubbery. It is then consumed as it is (Bear & Vasquez 2000; Luna 1984). The Shuar also occasionally consume the raw juice from green bark of B. suaveolens to find their soul or 'arutam', or to see into the future. The plant is also used medicinally, to treat weakness and menstrual pain and to allay infections (Bennett 1992).

The Mixe of Oaxaca, Mexico, drink a diluted hot-water maceration of 3 B. x candida flowers [or 6 in total if there is no effect] at night for divinatory purposes (Lipp 1990). In Mexico, B. x candida is also used as an intoxicant, local analgesic and purgative, whilst B. suaveolens is used as a local analgesic and antipyretic (Diaz 1979). Interestingly, shamans in Nepal have taken to using Brugmansia spp. which have naturalised there; flowers and leaves are smoked or burned as incense, sometimes with **Cannabis**, for shamanic travel to the underworld or to visit the 'nagas' [see **Naja and Ophiophagus**]. Flowers are also used as offerings to Shiva (Müller-Ebeling et al. 2002).

In the West, intoxications from Brugmansia spp. ingestion are not uncommon. The ingestion is usually intentional, by young people seeking new [and free] psychedelic experiences, due to the fact that these plants are commonly grown as ornamentals and are thus easily available. These experiments sometimes result in temporary hospitalisation until symptoms subside [often with i.v. physostigmine administration to reverse anticholinergic effects], and people trying these plants alone often endanger themselves with bizarre behaviour and their lack of physical or mental control. In one case, "an 18-year-old boy was found wandering the streets naked and masturbating. He was confused, delirious, agitated, belligerent, eating tree bark, and complained of terrifying visual hallucinations". Symptoms closely follow those of **Datura** ingestion, due to similar chemistry; the typical anti-cholinergic syndrome is observed, featuring delirium, hallucinations, confusion, agitation, memory impairment, blurred vision, dilated pupils, dry mouth, hyperthermia, flushing, occasional tachycardia, and sometimes convulsions with very large doses. Death can result in overdose from respiratory and circulatory paralysis, though more often, death is due to misadventure whilst intoxicated. In one unfortunate incident, a boy "was found dead, lying face down in a shallow puddle of water". In most cases, there is full recovery after several days at the most (Hall et al. 1977, 1978b; Popkin et al. 1976). Every time I have ingest-

ed Brugmansia spp. [see below], I have felt absolutely fine the next day. Maybe I've just been lucky, and I have further limited my chances of disaster by ceasing my experiments with these plants many years ago.

I have experimented with what was believed to have been B. x candida [growing ornamentally] on several occasions. All experiments used flowers taken from the same tree within a 2 month period. The initial experiments involved drinking a flower decoction in increasing concentrations over a period of 1 week [3 separate ingestions, of 1, 2, and finally 3 flowers].

The first was without effect; the second induced a dry mouth, very mild sensory alterations and incoordination lasting several hours. The third experiment was fully active, and thankfully, was the only one conducted in a relatively safe environment. Effects were noted within 20-30 minutes after ingestion; shortly after, I experienced very dry 'cotton-mouth', gagging in the throat, and difficulty in breathing. Attempts to vomit were unsuccessful, and these uncomfortable side-effects diminished after another 20 minutes. After this point, the drug was in full effect for at least another 6-8 hours, after which I was put to bed by friends [still heavily affected], though in the condition I was then in, time could not reliably be measured. The course of events during the full intoxication could neither be adequately recorded; often I seemed to be existing in at least two places at once, and could not tell fully what I was doing at any time. Visual hallucinations were vivid, though not dominating the experience, which was more coloured by distortions of time, space and thought, as well as heavy confusion and delirium; my behaviour was bizarre, irrational and benignly uncontrollable [mainly in that I had little control over my actions]. Despite this, the portion of the experience following the initial breathing difficulties and 'gagging' was not unpleasant – rather, it was very interesting, but highly confusing. Sleep was sound, and I awoke the next morning free of after-effects or difficulty in focussing visually [many people speak of being 'blind' for several days afterwards]. There was little memory of the previous night, though certain brief events can still be recalled – the exact order in which they occurred, however, can not.

On another occasion, c.1 flower was eaten raw with pumpkin soup; this experiment was done under foolhardy circumstances with no forethought. I experienced the dry mouth, gagging and breathing difficulties mentioned above, as well as nausea, with little psychic component other than distress and mild confusion (pers. obs. 1993).

The dried leaves may also be smoked for mild effects, though care should be taken to not smoke too much; a headache emerging is a good sign to go no further (pers. comms.; pers. obs.). Some people have tried infusing the crushed seeds or leaves in water and leaving the mixture to ferment in the sun for up to several days before consumption – this is said to reliably result in a less toxic, more manageable experience (Wise pers. comm.). This may also be a reason why Brugmansia is sometimes drunk with alcohol – perhaps alcohol lessens the toxicity of these tropane alkaloids? Drinking the plant juice with tobacco-water would also be expected to alter some of the effects, due to the cholinergic pharmacology of **Nicotiana** alkaloids. Still, caution is advised with these plants.

B. x candida has yielded 0.23-0.55% total alkaloids from aerial parts, of which 31-60% may be *hyoscine*, with usually lesser amounts of *hyoscyamine*; other alkaloids present are *atropine*, noratropine, norhyoscine, meteloidine and oscine. Roots yielded *atropine*, noratropine, *hyoscine*, norhyoscine, meteloidine, oscine, tropine, pseudotropine, 3α-tigloyloxytropane and 3α,6β-ditigloyloxytropane (Bristol et al. 1969; Henry 1939). As hybrids between B. aurea and B. x candida, aerial parts yielded 0.65-0.72% *hyoscine* and 0.17-0.19% *hyoscyamine*; the B. x candida parent in this case yielded only 0.25% *hyoscine* and 0.04% *hyoscyamine* (El-Dabbas & Evans 1982). *Hyoscine* content in leaves decreases as they mature (Griffin & Lin 2000). The coumarins *scopoletin* and aesculetin have been found in aerial parts [0.0002% combined, w/w] (Kala 1958).

B. sanguinea flowers have yielded 0.34-0.89% *hyoscine* as well as 0.03-0.25% other alkaloids [flowers yielded 0.345% *atropine* in one test]; stems yielded 0.27% *hyoscine* and 0.05% other alkaloids; leaves yielded 0.07-0.97% *hyoscine* and 0.03-0.57% other alkaloids; roots yielded 0.12-0.28% *hyoscine* and 0.19-0.33% of a mixture of *hyoscyamine* and *atropine*; seeds yielded 0.16-0.172% alkaloids, consisting mostly [78%] of *hyoscine*, as well as apohyoscine, *hyoscyamine*, tropine, pseudotropine, *choline* and 2 unidentified alkaloids (Evans et al. 1965; Leary 1970).

B. suaveolens leaves from Brazilian plants have yielded 0.09-0.16% alkaloids, with the variations being unrelated to season – *hyoscine* may constitute up to 80% of total alkaloids, with lesser amounts of norhyoscine, apohyoscine, *atropine*, noratropine, meteloidine, teloidine, 6β-tigloyloxytropan-3α,7β-diol, 3α-tigloyloxytropan-6β-ol and 3α,6β-ditigloyloxytropan-7β-ol; roots yielded 0.13-0.21% alkaloids, consisting of *hyoscine*, *atropine*, meteloidine, cuscohygrine, tropine, 3α-acetoxytropane, (+-)-3α-tigloyloxytropan-6β-ol, 3α,6β-ditigloyloxytropan-7β-ol and 6β-(α-methylbutyryloxytropane); calyces yielded 0.29% alkaloids, and corollas yielded 0.35% alkaloids – in the corolla, norhyoscine was a major component (Evans & Lampard 1972).

Brugmansia x candida is a large shrub or small tree 3-5m tall, often spreading clonally, all parts densely pubescent with simple, erect, crisped hairs. Leaves simple, alternate, entire, rarely coarsely dentate or shallowly lobed, ovate or oblong-elliptic, 15-25[-40]cm long, 8-12cm wide or more, apex acute to acuminate, base oblique; petioles to 6cm long. Flowers pendulous, solitary; pedicels 3-5cm long, stout in fruit; calyx tubular, spathe-like, split on one side, lobes not clearly separated, 1-4-toothed, 1.5-3cm wide, to 12cm long; corolla white or pale apricot, 25-30cm long, trumpet-shaped, 5-lobed, tube slender, slender basal part wholly enclosed by calyx, gradually flaring to the limb, the limb flaring to broadly triangular apices, with recurved terminal cusps 2-9cm long; stamens 5, inserted below middle of corolla tube; filaments 4-5cm long; anthers distinct, linear, c.2.5cm long, dehiscing longitudinally. Ovary 2-celled; style slender, 17-19cm long; stigma oblong, 2-lobed, 5-7mm long, included in corolla throat. Fruit an oblong-cylindric to fusiform pod or capsule, rarely formed, 4-valved, up to 20cm long, 2cm wide, pendulous, lacking a persistent calyx, smooth; seeds numerous, angular, D-shaped, laterally compressed, 6-10mm long, testa thick and corky, embryo curved.

Native to Peru; widely cultivated as an ornamental. The most common cultivar is 'buyés'; the most toxic cultivars are reputedly 'salamán' and 'munchira', which are uncommon and have mutated leaf forms [as do some other cultivars] (Bristol 1969; Wagner et al. 1990).

With seed germination, bottom heat may be beneficial but is not always required; seeds germinate easily with no special treatment. Most plants rarely set seed. Cuttings root easily in water; in the Sibundoy, branch cuttings over 50cm long are often simply stuck in the ground to strike. The best portions to use for cuttings are stems which are thick and quite vigorous, as opposed to stems with woody growth. Water young plants frequently. Grow outdoors in a large tub or in a permanent position, protected from wind in rich, well-drained soil. In summer, water once a week with organic liquid fertiliser. In cold areas, plants go dormant in winter, and may be brought indoors (Bristol 1969; Grubber 1973; pers. obs.).

BRUNFELSIA

(Solanaceae)

Brunfelsia australis *Benth.* **(B. hopeana var. australis** *(Benth.) J.A. Schmidt***; B. paraguayensis** *Chodat***)** – yesterday today and tomorrow, Paraguay jasmine, francissia

Brunfelsia chiricaspi *Plowman* – chiricaspi ['cold tree' or 'fever tree'], chiricsanango ['cold medicine'], sanango, covi-tsontinba-ko, borrachera ['intoxicant']

Brunfelsia grandiflora *D. Don* **(B. tastevinii** *Benoist***; B. grandiflora ssp. schultesii** *Plowman***)** – borrachero, chiricsanango, chiriqsanango, chiriguayusa, chiricaspi picudo, chiricaspi salvaje, chiricaspi chacruco, chinikiasip, sanango, hu-ha-hai, yai-hu-ha-hai, chi-pi-ri-tsontinba-ka

Brunfelsia pauciflora *(Cham. et Schlect.) Benth.* **(B. calcyina** *Benth.* **var. floribunda** *Raffill***; B. calycina var. macrantha** *(Lem.) Bailey et Raffill***)** – yesterday today and tomorrow

Brunfelsia uniflora *(Pohl) D. Don* **(B. hopeana** *(Hook.) Benth.***)** – manacá, umbura puama, vegetable mercury, jerataca, Paraguay jasmine, white tree, good night

In southern Colombia and adjacent Ecuador, the Kofan, Siona, Shuar, Runa and Ingano [and probably other groups also] sometimes add the leaves of B. chiricaspi to their ayahuasca brews [see **Banisteriopsis**], it being considered the strongest species of Brunfelsia in use [more on B. chiricaspi below]. Addition of Brunfelsia spp. to ayahuasca is said to make the brew stronger, and make a sound 'like rain in the ears'. The Quechua name for the plant, 'chiricaspi', means 'cold tree' referring to the chills and tingling sensations that are felt after ingestion of the bark. It is said to act as a tonic over time, giving one strength and resistance to cold. Bark, stems, leaves or roots of B. grandiflora and/or B. grandiflora ssp. schultesii are also sometimes added [the former sometimes being taken with yoco (see **Paullinia**), though B. chiricaspi is preferred. This species, as well as B. grandiflora ssp. schultesii, are also used by some of the same tribal groups in the Colombian and Ecuadorian Putumayo as intoxicants ['borracheras'] without any other plants. In Peru, the roots are sometimes taken under a 1 month diet, as a plant teacher. It is said that old, thick roots are toxic, and that only roots c.1-1.5cm diameter should be used. A dose may consist of 2-3 roots (Bear & Vasquez 2000; Luna 1984; McKenna et al. 1995; Pinkley 1969; Plowman 1973, 1977; Schultes 1966, 1972, 1979; Schultes & Raffauf 1990). The Shuar infuse B. grandiflora stems and leaves and drink the resulting beverage for curing. This reportedly gives the shaman "strong feelings" making it easier to diagnose the sickness of the patient (Bennett 1992).

B. uniflora root constitutes the Brazilian medicinal drug 'manacá', which is used as an emetic, purgative, diuretic, antirheumatic, antisyphilitic and abortifacient. This plant is also occasionally used for shamanic purposes, and is known to cause delirium, tremors, salivation, vertigo, anaesthesia, swollen tongue, 'turbid vision', and partial paralysis of the face. It gained its name from the Tupi of Brazil, who honoured its beautiful flowers by naming it after the most beautiful girl in the tribe, Manacán. The root has been used in arrow poisons, and the Cambéba use its juice in the preparation of their 'curupá' snuff [see **Anadenanthera**]. The plant

has also occasionally been added to 'vinho de jurema' [see **Mimosa**]. In Candomblé [Brazil], the fragrant flowers ['macaçá'] are used in ritual baths, and as an offering to the goddesses Oxum, Nama, and Yemanjá. B. chiricaspi is also used to treat fever, rheumatism and arthritis. Its ingestion initially results in chills and cold sweats, followed up to 6 hours later by loss of coordination, inability to move [symptoms lasting up to 48 hours], visual disturbances, vertigo, spinal and body tingling, tremors, stomach ache, nausea, weak vomiting, urtication, frothing at the mouth, swollen lips and 'heavy tongue'. The plants are little used today as intoxicants, due to their unpleasant side-effects. It should be noted that use of B. grandiflora has sometimes been mistakenly reported as B. maritima [B. latifolia] or B. bonodora (Duke & Vasquez 1994; Narby 1999; Plowman 1973, 1977; Schultes 1966, 1979; Schultes & Raffauf 1990; Voeks 1997).

B. australis has been responsible for poisoning dogs who ate the berries of the plant – intoxicated dogs exhibited tremors, instability, lethargy, staring, frothing at the mouth, vomiting and other frequent excretions. This period was followed by collapse and convulsions, with rigidity but later relaxation; a hypersensitivity to stimulus remained. B. australis is often sold in horticultural circles as either B. bonodora or B. latifolia, which are both separate species, the latter being synonymous with B. maritima. B. pauciflora is also grown horticulturally (Bailey & Bailey 1976; Bor & Raizada 1954; McBarron 1983; McBarron & De Sarem 1975).

B. brasiliensis [as B. ramosissima] has yielded 0.1% *scopoletin* (Mors & Ribeiro 1957); leaves have been shown to contain brunfelsine and manacine [alkaloids of unknown structure]; seeds have yielded 1.14% brunfelsine, and no manacine, though manacine had earlier been reported from the seeds (Plowman 1977).

B. grandiflora has yielded c.0.1% *scopoletin* from unspecified parts (Mors & Ribeiro 1957); root bark has yielded *scopoletin*, as well as brunfelsamidine [pyrrole-3-carboxamidine], a convulsant (Lloyd et al. 1985). B. grandilfora ssp. schultesii tested positive for alkaloids; the parts analysed were not specified (Evans 1979), but may have been foliage.

B. nitida leaves have been found to contain 5 calystegines [see **Convolvulus**] (Bekkouche et al. 2001).

B. pauciflora [as B. calycina var. macrantha] has yielded *scopoletin* (Mors & Ribeiro 1957; Plowman 1977). B. pauciflora [as B. calcyina var. floribunda] has caused lethal and nonlethal poisoning in dogs; the active principles seem to act in the manner of a spinal convulsant, such as *strychnine* [not found in the plant], and are water soluble and very stable (Spainhour et al. 1990).

B. uniflora root acts as a CNS-depressant in rats; it has yielded 0.0033% *scopoletin* (Iyer et al. 1977) and cuscohygrine [mandragorine] (Plowman 1977). Other alkaloids have been found in the plant, such as hopeanine (Gellert et al. 1980), hopamidine [1H-pyrrol-3-amidine; inhibited rat-paw oedema induced by cobra venom – see **Naja**] from the leaves [0.015%], stems, and roots (Birkner et al. 1987), and the convulsants manacine and manaceine. Heated with water, manacine breaks down to manaceine and a substance that was thought to be aesculetin [see **Aesculus**] (Plowman 1977).

Brunfelsia chiricaspi is a shrub or small tree 1-3m tall; trunk to c.5cm diam. near base; bark thin, cracked lengthwise, roughish, greyish-brown; branches few, lax, spreading, naked; branchlets subterete, 5-6mm diam., glabrous, light brown to ochraceous, shiny, outer bark thin and splitting longitudinally, shedding in thin flakes; internodes c.1-3cm long. Leaves scattered along branchlets or somewhat crowded, elliptic to lanceolate, rarely obovate, 20-30 x 7-12cm, apex obtuse with short, subfalcate acumen or acuminate, base cuneate to obtuse, glabrous, smooth, subcoriaceous, dull, dark green above, paler beneath, lateral nerves 8-10, straight, spreading, arcuately anastomosing 2-8mm within margin; petiole short, stout, subterete, 5-10mm long, canaliculate above, glabrous, dark brown, roughish. Inflorescence corymbiform, terminal or axillary, 4-7(-20)-flowered, flowers puberulent or glabrous; bracts lanceolate, concave, 1-2mm long, glabrous; pedicel slender, terete, erect, 6-13mm long, glabrous; calyx tubular-campanulate, slightly inflated, 10-13mm long, 4-6mm diam., subcoriaceous, glabrous, teeth short, broadly triangular, acute to blunt with short glandular acumen, in fruit coriaceous, striately nerved, dotted with lenticels, to 13mm long; corolla tube twice as long as calyx, cylindric, straight, fleshy, slightly dilated and curved at apex, 22-25mm long, 3mm diam., glabrous, limb 25-30mm diam., glabrous, sky-blue to violet, fading to white, thickening prominently at mouth, fleshy, 5-angled, white, lobes subequal, the uppermost slightly larger, rounded, abruptly narrowed at base, strongly deflexed at anthesis; stamens inserted in upper part of corolla tube; filaments subligulate, curved at apex, lower inner pair 2.5mm long, upper outer pair 3.5mm long, reaching the mouth; anthers rounded-reniform, to 1.5mm long, light brown. Ovary ovoid-conical, gibbous at base, 2mm long, c.15-ovuled; style filamentous, curved at apex, equalling the filaments; stigma bifid, forcepiform, obtuse, upper lobe larger. Capsule subglobose, c.10mm long, 8mm diam., dry at maturity; seeds few, ellipsoid-reniform, 6 x 2.5mm, reticulate-pitted.

In forest; Colombia (Plowman 1973).

BUBBIA

(Winteraceae)

Bubbia sp. – kikisira

An unidentified Bubbia sp. from Papua New Guinea is sometimes used by Gimi shamans ['aona bana'] to divine the cause of illness. The bark is mixed with tobacco [see **Nicotiana**], and the mixture is smoked to enter a "dreamlike state" in which he may encounter his 'aona' ['vital force' or 'soul'], which will tell him what he needs to know (Bock unpubl.; Glick 1967).

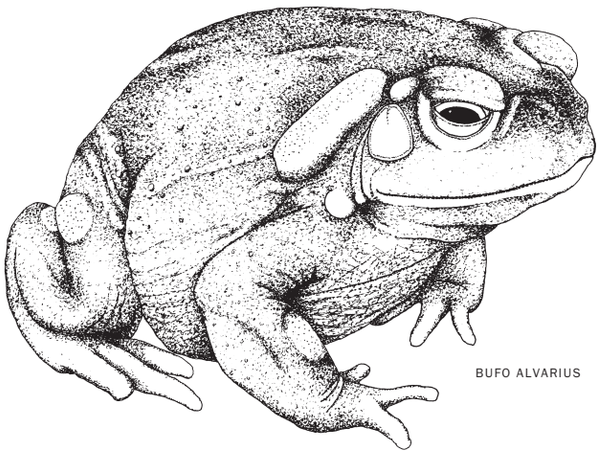
Stem bark of a Bubbia sp. from Papua New Guinea [harv. Feb.] gave positive tests for the presence of alkaloids (Fong et al. 1972).

Bubbia spp. are small shrubs or trees, often very variable; stipules none. Leaves alternate or rarely whorled, pellucid-punctate, aromatic, entire, pinnatinerved, petioled. Inflorescence a terminal cluster, each peduncled, few- to many-flowered, each lateral flower with 1 bracteole; flowers bisexual; sepals 2-6, regular, valvate, +- cup-like or short and dentate; petals in bud protruding past sepals, in 2-several series, imbricate, often soon caducous; stamens 1-many, in 1-several series, hypogynous; stigmas apical, sessile. Carpels 1-many, in a single whorl or rarely biseriate, free, with 1-many ovules; styles usually none. Fruit a capsule, pulpate, calyx persistent; seeds with copious endosperm.

At least 19 species have been recorded in Papua New Guinea, from a genus of 32 species (Van Royen 1979-1983).

BUFO

(Bufonidae)



BUFO ALVARIUS

Bufo alvarius *Girard* – Colorado River toad, Sonoran Desert toad, giant toad, Girar's toad, sapo grande
Bufo bufo ssp. bufo *L.* **(B. vulgaris** *Laurenti***)** – common European toad
Bufo bufo ssp. gargarizans *Cantor* **(B. bufo ssp. asiaticus** *Stejneger***; B. gargarizans** *Cantor***)**
Bufo marinus *L.* **(Chaunus marinus** *(L.) D.R. Frost et al.***; Rhinella marina** *(L.) Chaparro et al.***)** – cane toad, marine toad, giant toad, neotropical toad, aga toad
Bufo melanostictus *Schneider*
Bufo viridis *Laur.* – European green toad
Bufo spp. – toads, sapo

In Meso-American mythology, the toad is symbolic of the Earth Mother, the fertile giver and taker of life; the Aztec Tlaltecuhtli is one embodiment of this concept. Quetzalcoatl the bird-serpent, and Tezcatlipoca, sorcerer-jaguar, were said to have found her floating in the sea at the beginning of creation, whence they tore her body in two to form the sky and the earth; the remains of her body gave rise to the first food plants, in return for the death that eventually awaits all mortals. The association with birth and death springs in part from the toad's prolific breeding capabilities [also, male toads are sometimes able to revert to the female sex in order to reproduce under hardship], and the cannibalistic behaviour seen when a mother may eat her young. The change from egg to tadpole to toad is also symbolic of metamorphosis, itself representative of the endless cycle of life and death.

Toad remnants [usually of B. marinus], as well as carved artefacts such as statues, axe heads and bowls with toad representations, have been found in Mayan and Olmec burial sites dating back to 1250-900BC. Mayan art shows the toad as the servant of the rain gods. Likewise, with some tribes in the Orinoco basin of Amazonia, the toad is seen as the bringer of rain; there, toads are sometimes kept captive under pots in or-

der to obtain rain if needed (Degraaf 1991; De Rios 1974, 1990; Furst 1976; Hamblin 1979; Kennedy 1982; Morgan 1995).

In southern Veracruz, Mexico, B. marinus has been used as an unusual psychotrope for love magic or divination by shamans in the past. The venom from 10 toads was collected without harming them [or their parotoid glands are used], and mixed to a thick paste with plant ashes, 5 grains of sprouted corn, and limewater; this was boiled until its foul smell had passed, before being added to corn beer and strained. This liquid was mixed with corn meal and fermented in the sun for several days. It was then dried with heat, and rolled into a dough which would be reconstituted with water and drunk when required. One researcher who ingested this preparation noted sweating and hypertension within 30min of consumption, followed by a chilling sensation, muscle twitching, headache, immobility and delirium, lasting 3-5hrs (Davis 1988; Furst 1976). B. marinus and other **Bufo** spp. have reputedly also been added to the 'balché' brew of Central America [see **Lonchocarpus**] (Kennedy 1982; Rätsch 1992), and a live toad [species not noted] was observed to be added to a 'chicha' brew [see *Methods of Ingestion*] prepared by the Pakomam Maya of Guatemala in the 17th century (Kennedy 1982). B. marinus has been added to some Haitian zombi potions [see *Methods of Ingestion*] (Davis 1988).

Likewise, European witches have reputedly added **Bufo** spp. to some of their intoxicating magical brews. In rural England, a decoction or 'casserole' of a toad and 'certain' mushrooms [picked in full moonlight and not touched with the bare hands – see also **Psilocybe**] in spring water was said to be drunk [5 drops] as an aphrodisiac or love potion. Toad blood was said to be drunk for the same purpose in central Europe. Some European alchemists also used toads in various magical recipes. For example, "Five toads are shut up in a vessel and made to drink the juices of various herbs with vinegar as the first step in the preparation of a marvellous elixir for the purposes of transformation". The Taoists of China have a legend of the 'gama sennins' or 'toad-wizards', wise men who lived as mountain hermits with a giant toad, which taught the secrets of magic and herbalism, as well as how to make pills that could turn the gamma sennin into a toad. Earlier Chinese myths speak of toads that could conjure up visions of the Taoist 'Islands of Paradise' (Degraaf 1991; Kennedy 1982; Morgan 1995).

Toad preparations were prescribed to treat fever, dropsy and incontinence in numerous European pharmacopaeias of the 17th and 18th centuries (Chilton et al. 1979). Today, venom of B. bufo ssp. bufo, B. bufo ssp. gargarizans and/or B. melanostictus is still used in TCM as 'ch'an su'. Small doses [22-37mg] are used to treat heart problems, and externally as a surface anaesthetic, detoxicant and anodyne, and to treat sinusitis, toothache, bleeding gums, and inflammation. As an anaesthetic, it is sometimes applied as an alcoholic extract [30% concentration] comprising 9g ch'an su, 9g aconite root [see *Endnotes*], 16g **Datura** and 6g peppermint, a preparation that would presumably be very dangerous if taken internally. The venom alone is toxic, and can cause nausea, vomiting, abdominal pain, diarrhoea, irregular heart beat, vasodilation, dizziness and numb extremities. It has been sold in the US as a topical aphrodisiac, under names such as 'love stone', 'black stone' and 'rock hard', and has caused deaths when taken internally (Brubacher & Hoffmann 1996; Brubacher et al. 1995; Huang 1993; Keys 1976). Toad brains ['ch'an nao'] may be used to cure "nightblindness and to clarify the vision", according to some Chinese Materia Medicas (Kennedy 1982). In Nepal, some shamans use B. melanostictus venom for shamanic travel; it is taken simply by squeezing some onto the palm and licking it up (Müller-Ebeling et al. 2002).

Toad venom has a long history of use in poisoning – toads were apparently used for such murderous purposes by Roman poisoners, and much later in Italy toads were still noted to be in such use. These latter-day poisoners would sometimes prepare a poisonous salt by placing a toad in a sack containing ordinary salt, and shaking. Thus some of the toad venom would be secreted due to such irritation and become mixed with the salt, which was then used "for slow, chronic poisonings" (Chilton et al. 1979). In 19th century Amazonia, 'natives' were claimed to prepare an arrow poison from B. agua venom, probably synonymous with B. marinus (Abel & Macht 1911), though this appears to be supposition as the amphibians so used were not identified. The use of venomous frogs in that part of the world for such purposes is much better known [see **Phyllomedusa**].

Apparently, in parts of Somalia and Nigeria, weary travellers may pick up an available toad and rub it on their forehead for refreshing themselves and alleviating fatigue (Morgan 1995).

B. marinus was introduced to Queensland [Australia] in 1935 to control the 'cane beetle' [Phyllophaga vandinei], which was infesting sugar cane crops. The toads ignored the beetles, which lived mostly above the reach of the toad anyway, and have since spread to become a major pest threatening native and domestic fauna (Tyler 1994). However, many here still love the toads [many more hate them with vigour], and some Australians have even attempted their use as psychedelics, though this practice is not common today. It should be noted that possession of B. marinus venom is illegal in Australia [particularly in Queensland], and is seen as being equivalent to *bufotenine* [a prohibited substance]. This is unusual, given that B. marinus venom is usually low or deficient in its content of that alkaloid. The means of administration in Australia has usually been to either decoct toad skin in water to be drunk, or to simply lick the venom glands of the toad. Although *bufotenine*-like psychotropic symptoms have been reported from this, the practice is also highly dangerous due to toxic elements of the venom. Symptoms such as nausea, vomiting, sweating, burning in the mouth, salivation, convulsions, hypotension and hypertension, and tachycardia accompany the experience, which is usually very unpleasant (Hitt & Ettinger 1986; Lewis 1989; Pantanowitz et al. 1998; pers. comms.). Smoking the dried venom does not seem to produce toxic side-effects in moderate amounts, and it would seem that the toxins do not survive the heat. With hand-collected venom that I have experimented with, central effects were usually mild at best, and consisted of a calm, non-emotive 'stoned' state lasting about 30-60 minutes, as well as a sense of pressure in the head (pers. obs.).

B. viridis dried venom has been experimented with in the form of a snuff, causing local anaesthesia, sneezing, sweating, mild tachycardia, salivation, mild 'hallucinogenic' effects ['trails'], and later, burning sensation in nostrils and deep sedation; the bulk of the effects lasted about 1 hour. Other routes of administration were also used [licking the venom glands, ingesting venom dried on paper, rubbing venom glands across the forehead], and all produced mild effects with pupil dilation and mild colour enhancement. Overall, though, effects were not deemed as pleasant (Morgan 1995). Others have obtained positive entheogenic effects with smoked venom from a **Bufo** sp. in conjunction with tantric practices (Rätsch pers. comm.).

Most interestingly, B. alvarius has been used in recent times for its potent psychedelic venom, in the southern US. It is usually collected by squeezing the various venom glands on the live toad; the venom is dried, shaved off into small flakes and smoked in one deep inhalation. A piece the size of a paper match-head is usually sufficient to induce a powerful experience of the same nature as *5-methoxy-DMT* [*5-MeO-DMT*], its main constituent (Most 1984; Weil & Davis 1994). Illicit use of the venom has attracted the attention of police in the US, and some rare individuals who chose to use the venom as a sacrament and were reported to the authorities, have been arrested. Although *5-MeO-DMT* is currently still legal in the US [though not in Australia], *bufotenine* is not, and this has been used as a basis for prosecution [nearly all toad venoms, and some frog venoms, contain at least some *bufotenine*]. The toads have also become more difficult to obtain from pet stores in the US, presumably because of such illicit uses (pers. comms.).

Venoms from **Bufo** spp. usually consist of chemicals from several classes – the tryptamines [such as *bufotenine* (*5-OH-DMT*), bufoviridine (*bufotenine* O-sulfate), bufothionine (dehydro-*bufotenine* O-sulfate), dehydro-*bufotenine* and bufotenidine (N,N,N-trimethyl-*serotonin*; cinobufagin), a local anaesthetic 90x more potent than *cocaine* (Kennedy 1982)], the *phenethylamine*s [such as *dopamine* and *epinephrine*], and the cardioactive steroids [bufogenins or bufagins, bufadienolides, and bufotoxins]. B. alvarius is unique in containing *5-MeO-DMT*. The pharmacology of some of these alkaloids is discussed further in **Arundo**. Bufadienolides have also been found in some toxic plants, such as hellebrine in the seeds of Helleborus odorus (Kiβmer & Wichtl 1986).

These venoms should never be orally consumed except under expert supervision, and care should be taken to avoid contact with the eyes, mouth, nostrils and other openings in the skin after handling venom. Venom can be extracted without harming the toad, as follows – grip the toad firmly but gently in one hand, with its belly facing your palm. The parotoid glands [and any other venom glands present] may be squeezed at the base between thumb and forefinger. If the toad is distressed, venom may squirt for up to 1m or more, so some prefer to hold a sheet of glass above the toad to catch the venom; otherwise, the venom will simply ooze to the surface, and can be scraped off very gently from the amphibian with a blunt tool or spatula. Sometimes a popping sound is heard when 'milking' a toad. Each gland is composed of 50-60 lobules [in B. marinus], each discharging venom via a single duct, each duct being sealed with a small plug of tissue; when pressure in the gland is high enough, the plug will burst, resulting in this audible sound. The venom is then dried naturally and stored in an airtight container until use. Toads may yield more venom after a rest period of 30-40mins; after this, glands require 4-6 weeks to recuperate (Meyer & Linde 1971; Tyler 1994; pers. exp.).

As an interesting sidenote, hedgehogs seem to be immune to **Bufo** venoms. They are known to attack the toads, first biting and chewing the parotoid glands, then licking the venom over their spines, before eating the toad; this anointing of venom is believed to be a defensive technique (Brodie 1977).

B. alvarius venom glands yielded 5-16% *5-MeO-DMT* and <0.01-0.5% *bufotenine*; non-glandular skin yielded 0.05-0.4% *5-methoxy-DMT*, 0.017-0.22% *bufotenine*, 0.001-0.0023% 5-MeO-*N-methyltryptamine*, 0.004% 5-MeO-indoleacetic acid [5-MIAA], 0.0015-0.002% bufoviridine, 0.003-0.004% N-methyl-*serotonin*, 0.0011-0.0012% 5-OH-indoleacetic acid [5-HIAA], 0.0004-0.0006% *serotonin* and 0.0004-0.0008% 5-OH-tryptophol, as well as small amounts of several unidentified amines. 5-MeO-tryptophol is also found in the pineal tissue of the toad, as the major

metabolite from deamination of the endogenous 5-methoxy-tryptamines (Erspamer et al. 1965, 1967). Each toad may yield c.400mg of dried venom per milking (Meyer & Linde 1971).

Fresh skin of B. bufo ssp. bufo yielded 0.0145-0.045% *bufotenine*, 0.0287-0.0353% bufothionine, 0.0087-0.013% dehydrobufotenine, 0.0044-0.0064% bufotenidine, N-methyl-*serotonin*, and traces of *serotonin*. The dried venom yielded 0.3-0.33% *bufotenine* and 0.53-0.62% bufotenidine, as well as bufotalin, bufotalidin [hellebrigenin], bufotalinin, marinobufagin and telocinobufagin. Each toad may yield c.13mg dried venom per milking. B. bufo ssp. formosus fresh skin yielded 0.015% *bufotenine*, 0.0375% bufothionine, 0.014% bufotenidine, 0.0025% dehydrobufotenine, 0.0065% *serotonin*, and 0.006% N-methyl-*serotonin* (Cei et al. 1968; Deulofeu & Rúveda 1971; Meyer & Linde 1971). B. bufo ssp. gargarizans venom was found to contain 0.001-0.01% each of bufotenidine, *serotonin* and N-methyl-*serotonin*, as well as *epinephrine*, arenobufagin, bufalin, bufarenogin, bufotalidin, bufotalin, desacetylbufotalin, cinobufagin, desacetylcinobufagin, cinobufotalin, desacetylcinobufotalin, gamabufotalin, resinobufogenin and telocinobufagin (Daly & Witkop 1971; Meyer & Linde 1971).

B. marinus skin yielded 0.003-0.0671% *serotonin*, 0.004-0.051% N-methyl-*serotonin*, 0-0.003% *bufotenine*, 0.22-0.6% dehydrobufotenine, 0.003-0.0465% bufothionine, *dopamine*, N-methyldopamine, *norepinephrine*, *epinephrine* [c.4-7% of venom] (Cei et al. 1968; Daly & Witkop 1971; Deulofeu & Rúveda 1971; Märki et al. 1962), bufalin, argentonogenin, bufotalidin, gammabufotalin, hellebrigenol, marinobufagin, resibufogenin, telocinobufagin and marinobufotoxin. Each toad may yield c.580mg dried venom per milking (Meyer & Linde 1971). B. marinus ssp. horribilis [from Veracruz, Mexico] skin yielded 0.3% dehydrobufotenine, 0.05% *serotonin*, 0.03% N-methyl-*serotonin*, 0.004% bufothionine, 0.003% *bufotenine* and 0.0025% bufotenidine. B. marinus ssp. poeppigi skin yielded 0.014-0.11% dehydrobufotenine, 0.016-0.097% *serotonin*, 0.01-0.04% N-methyl-*serotonin*, and 0.001-0.03% bufothionine (Cei et al. 1968). Surprisingly, small amounts [1.53-4.49 pmol/g] of *morphine* have been found in B. marinus skin (Oka et al. 1985). As B. agua, early studies of the venom found 4.48% *epinephrine* [estimated total 6.72%] and c.36% bufogenins [estimated content] (Abel & Macht 1911).

B. melanostictus yielded around 90mg venom per animal, consisting of 0.001-0.01% *bufotenine*, 0.001-0.01% dehydrobufotenine, 0.1-1% bufotenidine, 0.01-0.1% *serotonin*, bufalin, bufotalidin, bufotalin, marinobufagin and resibufogenin (Daly & Witkop 1971; Meyer & Linde 1971).

B. viridis skin yielded 0.1-1.0% *bufotenine*, 0.01-0.1% bufotenidine, 0.01-0.1% bufoviridine, 0.001-0.01% *serotonin*, 0.001-0.01% N-methyl-*serotonin*, 0.001-0.01% dehydrobufotenine, 0.001-0.01% bufothionine (Cei et al. 1968; Daly & Witkop 1971), arenobufotoxin, marinobufotoxin, telocinobufotoxin, hellebritoxin, arenobufagin, marinobufagin, telocinobufagin, hellebrigenin and bufotalinin (Shimada et al. 1986); viridobufagin and viridobufotoxin have also been found. Each toad may yield c.27mg dried venom per milking (Meyer & Linde 1971). Females apparently contain more *bufotenine* in their venom than males (Morgan 1995).

'Chan su' [from one of a number of species - see above] contains *bufotenine*, bufotenidine, desacetylbufotenidine, bufadienolide, cinobufaginol, resibufogenin, cinobufotoxin, bufotalin, many other bufogenins, *epinephrine* and cholesterol (Brubacher et al. 1995; Huang 1993).

Bufotenine is also found as a major venom constituent in B. arenarum, B. boreas, B. calamita, B. fernandezae, B. hemiophrys [also high in dehydrobufotenine], B. major, B. marmoreus, B. paracnemis, B. perplexus, B. pygmaeus [also high in dehydrobufotenine], B. spinulosus [also high in dehydrobufotenine], B. trifolium and B. variegatus. B. debilis, B. haematiticus, B. ictericus, B. major and B. punctatus are rich in dehydrobufotenine. African species [such as B. berghei, B. funereus, B. kisoloensis, B. mauretanicus and B. regularis] seem to contain only *serotonin*, and no other tryptamines (Cei et al. 1968; Daly & Witkop 1971).

Bufo alvarius males are 80-156mm long, females 87-178mm; stout, with a broad, flat head with raised eyes, low crescent-shaped crests curving around rear of eye like fleshy folds; body smooth and leathery, scattered with pale orange warts, skin colour ranging from dark brown, to olive or grey-green; belly cream-coloured; 1-4 prominent white warts at corner of mouth; large parotoid glands on shoulders c.2.5 x 1cm, each with 50-60 lobules, subreniform, spreading down at shoulder; femoral glands on outside of each hind leg between knee and thigh, tibial glands between knee and ankle, as well as glands on forearms. Nocturnal, living in underground burrows during daytime; at night, gathering near springs, streams, water pools, puddles, and irrigated fields. Most active in breeding season, May-Jul. Voice seldom used; a quiet chirping sound.

Near rivers and streams, as well as around water troughs in Sonoran Desert; s. California, through Arizona and Colorado into n.w. Mexico (Cannon & Hostetler 1975; Wright & Wright 1995).

BURKEA

(Leguminosae/Caesalpiniaceae)

Burkea africana *Hooker* – Rhodesian ash, wild seringa, wild syringa, wilde sering, umu nene

The wood of this African tree, the only member of its genus, is hardy and of good quality, and has been much used in construction. In central Africa, a leaf decoction is rubbed on the head to relieve headache. Bark and leaf decoctions are used as mouthwashes to treat scurvy and trachoma. The Zezuru of s. Rhodesia chew the bark to break and moisten it, before placing it on septic sores; they also use the leaves to treat gastric complaints. The Ila throw the pulverised fruit and bark into water to stupefy fish, making them easier to catch. The stem of the plant yields a soluble, translucent yellowish to brownish-red gum, which is used to treat dysentery; the fruit is used for the same purpose in Natal. In n. Nigeria, the twigs are used as chew-sticks for oral hygiene (Allen & Allen 1981; Watt & Breyer-Brandwijk 1932, 1962). Also of interest to us are the chemical constituents of the stem bark.

B. africana stem bark has yielded the indole alkaloids *tryptamine* (Correia da Silva & Paiva 1973; Ferreira 1974a), *harman*, *tetrahydroharman*, *harmalan*, and Burkea alkaloid E [which is possibly *harmalan* N-oxide]; 3 other alkaloids were detected, which have not been identified. Also found in the stem bark were β-sitosterol (Ferreira 1974b, 1974c), 5-OH-piperidine-2-carboxylic acid, and tannins (Allen & Allen 1981; International… 1994). The plant has also yielded fisetinidol-(4-α→β)3-O-galloylcatechin, fisetinidol-(4-β→6)ampelopsin, fisetinidol-(4-α→2')robinetin, fisetinidol-(4-β→6)robinetindol, fisetinidol-(4-α→6)taxifolin, and 3-galloylrobinetinidol (Buckingham et al. ed. 1994).

Burkea africana is a tall shrub to deciduous tree 10-21m tall, with a 2m girth and stout, knotted branchlets, straight bole of 6-7m or more, flattened crown; bark corrugated and blackish. Leaves light and silky, young parts reddish-tomentose, leaves bipinnate, 2-5-jugate, jugae opposite; leaflets alternate up to c.12, petioluled or sessile, elliptic-ovate, ovate-lanceolate or elliptic-oblong, obtuse or emarginate at apex, unequal-sided at base, up to 5 x 3.5cm, at first silky, at length glabrous and +- glaucous beneath; petioles often rusty-tomentose; stipules filiform, early caducous. Flowers in panicles of slender spikes to 30cm long, small creamy-white fragrant flowers crowded with the leaves at ends of branchlets; axis pubescent; bracts small; calyx campanulate, 1.5mm long, lobes 5, ciliate, rounded, oblong, equal; petals 5, subequal, obovate or elliptic, obtuse, imbricate, glabrous, +- twice as long as calyx; stamens 10, subequal, shorter than petals; filaments linear, uniform, oblong-oblanceolate, longitudinally dehiscent, connective pointed, bearing an inflexed sessile apical gland. Ovary sessile or shortly stipitate, densely villous, superior, 1-celled; ovules 1-2; style short, thick; stigma terminal, truncate or concave. Pods elliptic- to oblong-lanceolate, flat, compressed, reticulate, brittle, subcoriaceous, c.6 x 2.3cm, shortly appressed-pubescent, persistent after new leaves appear; 1-seeded, seeds compressed, suborbicular.

Dry sandy soil in savannahs and woodlands up to 1500m; mainly in Zambia, present throughout Africa as north as Ethiopia and west to Nigeria (Allen & Allen 1981; Hutchinson & Dalziel 1954-1972).

CAESALPINIA

(Leguminosae/Caesalpiniaceae)

Caesalpinia bonduc *(L.) Roxb.* **(C. crista** *L.***)** – putikaranja, katkaranj, katkaliji, sagur-ghota, khayahe-i-iblis ['devil's testicle'], bonducella nut, Molucca bean, fever nut, physic nut, senna

Caesalpinia digyna *Rottler* – vakeri-mul, vakeriche-bhat, umul-kuchi, nuni-gatcha, nooniglika, senna

Caesalpinia echinata *Lamarck* **(Guilandina echinata** *(Lam.) Spreng.***)** – cumaseba, su-mu

Caesalpinia gilliesii *(Wall. ex Hook.) D. Dietr.* **(C. gilliesii** *(Wall. ex Hook.) Benth.***; Erythrostemon gilliesii** *(Wall. ex Hook.) Klotzsch***; Poinciana gilliesii** *Wall. ex Hook.***)** – bird of paradise bush, yellow bird of paradise, desert bird of paradise, Barbados pride, pride of China, Mimosa of Japan, blazing Poinciana, Brazilwood, flower fence

Caesalpinia pulcherrima *(L.) Sw. non G. Don.* **(Poinciana bijuga** *Lour.***; P. elata** *Lour.***; P. pulcherrima** *L.***)** – peacock flower, paradise flower, Spanish carnation, Barbados pride, dok fanf, fang ham, krishnachuda, sidhakhya, sidhanasha, guletura, caballero

Caesalpinia sappan *L.* **(Biancaea sappan** *(L.) Tod.***)** – false sandalwood, sappan wood, bois sappan, sappanga, pattanga, parthangi, chappanam, bakan, brasiletto, gango

Caesalpinia sepiaria *Roxb.* **(C. benguetensis** *Elm.***; C. crista** *Thunb. non. L.***; C. decapetala** *(Roth) Alston***; C. decapetala var. japonica** *(Sieb. et Zucc.) H. Ohashi***; C. decapetala var. japonica** *(Sieb. et Zucc.) Isely***; C. sepiaria var. japonica** *(Sieb. et Zucc.) Gagnep.***; Biancaea decapetala** *(Roth) O. Deg.***; B. sepiaria** *(Roxb.) Isely***; Reichardia decapetala** *Roth***; Mezoneurum bengetense** *Elm.***)** –

peacock flower, wait-a-bit, mysore thorn, thorny Poinciana, bahama sappan, black bonduc, yun-shih, puakelekino, chillara, karanj, kando, puto, mala bung, mala mukhi

'Yun-shih', C. sepiaria, has enjoyed a history of use in Chinese medicine – the seeds as an astringent, anthelmintic, antipyretic and antimalarial; and the root to 'assist removal of a bone in the throat'. The root is a purgative and emmenagogue. The flowers, and possibly also the seeds, have more mystical properties. They are said to "enable one to see spirits, and when taken in excess, cause one to stagger madly. If taken over a long period, they produce somatic levitation and effect communication with the spirits." They are also said to be able to drive away evil spirits, and "when put in water and burned, spirits can be summoned…the seeds are like lang-tang [**Hyoscyamus**], if burned, spirits can be summoned; but this method has not been observed" (Kirtikar & Basu 1980; Li 1978). In Japan, roots have been used in folk medicine to treat neuralgia (Ogawa et al. 1992). In Nepal [as C. decapetala; Müller-Ebeling et al. considered it a synonym of C. pulcherrima, yet I could find no other litertaure that supports this view], shamans use the seeds for shamanic travel, although in small doses they are sometimes used as a spice or food with pickles and curry. The flowers are used as an offering to Shiva, and the plant is regarded as being protective. The seeds are said to "cleanse the entire human system" (Müller-Ebeling et al. 2002), hinting at possible purgative and emetic properties (pers. obs.).

C. sappan wood ['su-mu', 'su-feng-mu'] is used in TCM to control pain, improve circulation, and control bleeding. It has tranquillising and soporific properties, and is paralytic in high doses; it has been shown to antagonise the stimulant effects of *brucine* [see **Strychnos**] (Hsu et al. 1986). In India, it is used as an astringent and emmenagogue (Nadkarni 1976). In Indo-China, C. pulcherrima is used as a tonic, stimulant and emmenagogue; in the Philippines, a flower infusion is used to treat asthma, bronchitis and malaria (Kirtikar & Basu 1980). In Peru, bark from the related C. echinata has been added to ayahuasca brews [see **Banisteriopsis**] (Ott 1994). Ritual pipes for use in healing are also made from this species in Peru (Luna & Amaringo 1991).

The leaves of C. bonduc are known as 'senna' in Nigeria, and are infused as a purgative [see **Laburnum**, **Cassia**] (Nwosu 1999). The seed oil is used there as an anticonvulsant; in s. Vietnam, the leaf oil is used similarly. The plant is also sometimes used to treat malaria (Lassak & McCarthy 1990; Watt 1967). In India, the pressed oil from the tender leaves is used as an anticonvulsant, as well as to treat "palsy and similar nervous complaints". In Burma, C. digyna root is pounded and soaked in water, and drunk to relieve fevers; the drink is reported to have an "intoxicating" effect (Nadkarni 1976), though the exact nature of this intoxication was not made clear. A root bark decoction of this species is used in Nigeria to treat senile dementia (Nwosu 1999). C. bonducella seeds are used in Tanzania to treat diabetes mellitus, though experiments with rabbits did not reveal any effect on blood glucose (Moshi & Nagpa 2000).

C. bonduc roots yielded 0.00284% cassane-furanoditerpenes, bonducellpins A-D (Peter & Tinto 1997). The plant has also yielded homoisoflavones, peltogynoids, caesalpins, a benzoquinone and a chalcone (Che et al. 1986).

C. bonducella seeds yielded α- and β-caesalpin, as well as unidentified protein fractions (Qudrat-i-Khuda et al. 1961).

C. gilliesii has yielded 0.63-0.7% alkaloids from leaves, and 0.4-0.45% from stems; flowers contained 4 different alkaloids (Abdulla-Zade & Agamirova 1965). Stem-bark and roots [summer collections] tentatively tested positive for the presence of *5-methoxy-DMT* and other compounds (Trout ed. 1997d). In another assay, no alkaloids were found in stems, leaves, and flowers combined [harv. Mar., New Zealand] (White 1951). The seeds have yielded the amino acids 3-OH-proline [main], γ-methyl-*glutamic acid* and γ-methylene-*glutamic acid* [traces] (Watson & Fowden 1973). Caution may be advised with this and other Caesalpinia spp. – in a case of sober plant-human communication, a reliable friend was surprised to be 'told' by an ornamental C. gilliesii specimen that it was a 'hallucinogen' that would kill him if he did not learn how to use it correctly (Trout pers. comm.).

C. pulcherrima flowers, buds and roots [summer collections] tested strongly positive for the presence of *5-methoxy-DMT*, though results are still tentative, and the presence of large quantities of unidentified alkaloids was also noted. Flower petals contained no *5-methoxy-DMT*, but did contain small amounts of an unidentified indole (Trout ed. 1997d; Trout pers. comm.). Stems have yielded the peltogynoids pulcherrimin [0.00015%] and 6-MeO-pulcherrimin [0.00012%], the homoisoflavonoids bonducellin [0.00072%] and 8-MeO-bonducellin [0.000009%], the chalcone 4'-methylisoliquiritigenin [0.0007%], and 0.000006% 2,6-dimethoxybenzoquinone (McPherson et al. 1983). Roots have yielded the diterpenoids vouacapen-5α-ol [0.008%], 6β-cinnamoyl-7β-OH-vouacapen-5α-ol [0.0059%] and 8,9,11,14-didehydrovouacapen-5α-ol [0.00017%], as well as 0.006% β-sitosterol (McPherson et al. 1986). Seeds contain traces of γ-methyl-*glutamic acid* and γ-methylene-*glutamic acid* (Watson & Fowden 1973). In separate tests, whole plant and leaf material gave positive tests for HCN (Watt & Breyer-Brandwijk 1962).

C. sepiaria contains an alkaloid of unknown structure (Schultes & Hofmann 1980); leaf and stem from Brisbane, Queensland [Australia], harvested in April, tested positive for alkaloids (Webb 1949). Seeds contain small amounts of pipecolic acid, 4-OH-pipecolic acid, m-carboxy-*phenylalanine* and γ-ethylidine-*glutamic acid* (Watson & Fowden 1973). Stems have yielded 0.0015% pulcherralpin [a cassane-diterpene ester] (Che et al. 1986). The closely related C. sepiaria var. japonica has yielded [from roots, w/w] the cassane-diterpenoid caesaljapin [0.024%], triterpenoids betulinic acid [0.00012%] and lup-20(29)-en-3β-ol [0.004%], and the phenolics sappanchalcone [0.0011%], 3-deoxysappanchalcone [0.00032%], catechin [0.00037%], methyl gallate [0.00015%] and 3-OH-1-(4-OH-3-MeO-phenyl)-1-propanone [0.00042%]; bark has yielded chalcones and homoisoflavones (Ogawa et al. 1992).

Caesalpinia sepiaria is a climber or shrub with sprawling branches, forming large, impenetrable thickets; stem stout, woody, armed with strong, sharp, hooked yellowish prickles; young branches finely downy, and as with leaf rachis, bearing recurved prickles as above. Leaves 23-38cm long, with 3-15 pairs of subequal pinnae, pinnae 5-7.5cm long, with slender pubescent rachis; leaflets 5-12 pairs per pinna, subsessile, oblong-elliptic, 1-2.2 x 0.4-1.1cm, apex rounded, base rounded and somewhat oblique, glabrous or faintly puberulous above, glaucous and slightly pubescent beneath, pale green; stipules deciduous, obliquely ovate, entire, 8-20mm long. Flowers perfect, yellow, 25-30mm diam., in simple axillary and/or terminal racemes 15-30cm long; pedicels 1.3-2cm long, densely pubescent, articulate near flower; bracts 1cm long, ovate-lanceolate, caducous, densely pubescent; calyx 1-1.25cm long, deeply 5-cleft, densely pubescent, upper sepals oblong, obtuse, pubescent on both sides, lower concave or boat-shaped; corolla 1.3-2.2cm diam., petals suborbicular, clawed, spreading, imbricate, bright yellow, upper one veined or blotched with red, the lower c.1.3cm diam., the upper 6mm diam.; stamens 10, free, declinate, filaments densely wooly in lower half; anthers uniform, dehiscing longitudinally. Ovary sessile or subsessile; ovules few; style filiform, sometimes clavate at apex; stigma terminal. Seed pods dehiscent, slightly swollen, straight or slightly recurved, linear-oblong, with long beak, not stalked, somewhat turgid, 6.5-11.5 x 2-3cm, smooth, reticulately veined, especially on lower half; seeds 4-9, ellipsoid, laterally flattened, narrowly winged, 8-12 x 6-8mm, greenish or black, mottled.

Native to tropical Asia, grows along roadsides and disturbed areas; naturalised in Hawaii (Kirtikar & Basu 1980; Wagner et al. 1990).

CALEA

(Compositae/Asteraceae)

Calea zacatechichi *Schlechtendal* – zacatechichi, zacachichi, thlepelakano ['leaf of God'], hoja de dios, hoja madre ['mother's leaf'], zacate de perro ['dog's grass'], bitter grass, prodigiosa, garañona

The flowers of C. zacatechichi have been tentatively identified adorning parts of the statue of the Aztec deity Xochipilli [see **Turbina**] (Wasson 1973). The herb is used by the Chontal of Oaxaca, Mexico, for medicinal purposes. It may be used to treat fevers, diabetes, nausea and diarrhoea, acting as a purgative, antiperiodic and astringent. Its shamanic use amongst the Chontal is less common. To divine the cause of an illness, or locate lost objects or people, a tea of the dried [some prefer fresh], crushed leaves is prepared. A handful, or c.60g, is steeped in boiling wa-

ter [grain alcohol extracts the active compounds more efficiently], and after cooling and straining is drunk slowly, previous to reclining in a dark and quiet position [sometimes with more leaves under a pillow] to smoke a cigarette of the leaves and await the effects. These mostly occur in the sleep that soon follows. The herb can cause slight enhancement of the senses, mild thought discontinuity, rapid 'influx of ideas', and later sedation, and brief sleep with vivid dreams. A feeling of well-being is often reported, which may last for a day or more. The consumer often may become more aware of their pulse and heartbeat, voices or whispers may be heard, and sometimes visual imagery is reported from behind closed eyes. In controlled tests, an increase in the frequency, lucidity and recall of dreams was noted, as well as slowed EEG patterns and an increase in reaction time. Paradoxically, REM sleep was reduced, and the dreaming seems to occur as 'lively hypnagogic images' in slow-wave sleep (Diaz 1979; Emboden 1979a; Jiu 1966; Mayagoitia et al. 1986; Rätsch 1992; Schultes 1969c).

Many westerners experimenting with this plant report no effects, or consider it too mild to be worthwhile – however, it works well for some who give it their attention, and it certainly has its adherents (pers. comms.). Some varieties seem to be much more potent than others – from a 10:1 vodka tincture made from fresh leaves of one strain, as little as 10 drops were required to elicit strong effects (theobromus pers. comm.).

Apparently, there are both active and inactive varieties of this plant, which may actually be distinct species. Although Diaz (1979) promised taxonomic study on this point, I am not aware of any such work having been published to date. Active varieties contain a group of terpenoids called germacranolides.

C. zacatechichi has yielded caleicin I & II, caleins A-F, 0.02% 1-β-acetoxyzacatechinolide, 0.01% 1-oxo-zacatechinolide [all germacranolides], caleochromenes A & B, acacetin, O-methylacacetin, zexbrevin, calaxin, ciliarin, 2,8,10,16-heptadecatetraene-4,6-diyn-1-ol, 2,9,16-heptadecatriene-4,6-diynal, and traces of an undefined alkaloid (Bohlmann & Zdero 1977; Buckingham et al. ed. 1994; Diaz 1979; Herz & Kumar 1980; Mayagoitia et al. 1986; Quijano et al. 1979).

C. urticifolia from Honduras has yielded sesquiterpene lactones similar to some of those found in C. zacatechichi (Herz & Kumar 1980); it is not known whether they have psychoactive properties.

Chemotaxonomic studies suggest that a revision of the genus Calea and its close relatives is needed (Bohlmann et al. 1981).

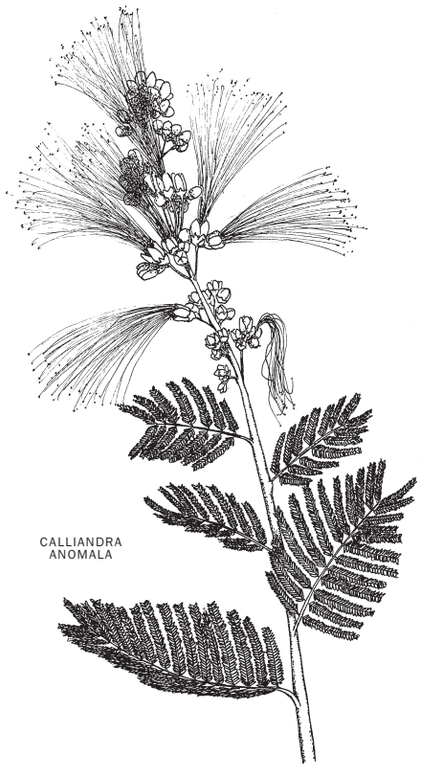
Calea zacatechichi is an erect-stemmed shrub or bush, stems several feet long, terete, subtrichotomous, glabrous beneath, ashy-grey, epidermis lenticellate, above with branches subfastigiate and patently-spreading, purplish and pubescent. Leaves rigid-membranaceous, decussate, subtriplinerved, venose, rugose, ovate, acute, strongly crenate, base shortly cuneate, above hispid and scabrous, below pale and pubescent, c.1.9-3.8 x 1.2-1.9cm; petiole hispid-puberulous, 4-7mm long. Inflorescence small, terminal cymes, irregular, usually arranged simply; capitula c.4mm high, 12-flowered, discoid, with rounded blade and thickened margin, flowers usually paired in each female capitula, whitish, subequal; involucre cylindric, leaflets concave, lutescent, margin scariose undulate, obtuse, entire, erect, rotundate-elliptic to slightly oblong-elliptic, c.4mm long, plurinerved; bracteoles scariose, inner leaflets not very short, obovate, clasping the flowers, plurinerved, subtruncate, erose-denticulate, equal when fruiting and mature; corolla glabrous, disc strongly 5-fid, lacinia reflexed, rays tongue-shaped, elliptic, obsolete, tube short. Fruit an achene with pappus, base long turbinate, terete, hirsute, to c.3mm long, blackish-dark brown. Fl. Aug.

On exposed hills (Schiede 1834); Mexico to Guatemala and Costa Rica (Schultes & Hofmann 1980).

This plant has proven difficult to grow from seed (DeKorne 1994), though fresh seed may give better results. May be propagated from cuttings. Do not allow the plants to dry out as they will wilt rapidly; some find standing the pot [if the plant is potted] in several cm of water helps minimise watering troubles (theobromus pers. comm.).

CALLIANDRA

(Leguminosae/Mimosaceae)



Calliandra angustifolia *Spruce ex Benth.* **(C. sodiroi** *Harms***; C. subnervosa** *Benth.***)** – bobinsana, bobinzana, chipero, quinilla blanca, poi-fa'-ko, sin-sin-ño

Calliandra anomala *(Kunth) Macbr.* **(C. grandiflora** *(L'Hér) Benth.***; C. grandiflora fo. pubescens** *Micheli***; C. kunthii** *Benth.***; Acacia callistemon** *Schltdl.***; Anneslia albescens** *Br. et R.***; An. bella** *Br. et R.***; An. chihuahuana** *Br. et R.***; An. colomasensis** *Br. et R.***; Inga anomala** *Kunth***; Mimosa grandiflora** *L'Hér***)** – cabeza de angel, cabellos de angel, pambonato, pombotano, tlacoxiloxochitl, angel's hair, red powder puff

Calliandra antifebrile *(Gris.) Johnson*

Calliandra pentandra – samiki

Calliandra spp. – powder-puff trees

C. anomala was used by the Aztecs as a psychotropic medicine. The root was chewed, or peeled and ground with water and honey, to treat coughs, eye diseases, dysentery, diarrhoea, swollen anus and indigestion. The branches are still used in Mexico to treat malaria. Shallow, narrow incisions were made in the bark early in the morning, and the resin collected a few days later. When dry, it was powdered and mixed with ash to be used as a hypnotic, soporific snuff. In Mexico and other parts of C. America, the root may be added to 'tepache' [a fermented drink made from 'pulqué', in turn made from **Agave** spp.; see *Methods of Ingestion*] to retard fermentation (Allen & Allen 1981; Emboden 1979a; Tani et al. 1998; Tyler 1966; Usher 1974). A dog has died from a dose of 90g of C. anomala snuff – it is recommended that humans take not more than 120g at a time (Rätsch 1998).

Some inhabitants of the Rio Pastaza area [through Ecuador and Peru] lightly decoct C. angustifolia roots as a stimulant, "taken for strength when [a man] must swim a river or fight" (Schultes & Raffauf 1990). In Peru, C. angustifolia is sometimes used as an additive to ayahuasca brews [see **Banisteriopsis**]. A recipe reportedly used by one ayahuasquero called for 3.5kg **Banisteriopsis** caapi vine, 500g **Psychotria** viridis leaves, 3 **Brugmansia** suaveolens leaves, 10-20 **Nicotiana** tabacum leaves, and 4 C. angustifolia flowers. It was not reported how many serves this was intended to provide (Gnostic Garden 2001). C. angustifolia is said to increase the purgative properties of ayahuasca. An unidentified Calliandra sp., known as 'samik', is sometimes added by the Shuar of Ecuador in place of 'chacruna' [see **Psychotria**], producing a visionary brew. C. pentandra [an elusive species name for which I can find no author or description] is also known as 'samik', and might represent the same plant. C. pentandra (Luna 1984; Luna & Amaringo 1991; Ott 1994; Rätsch 1998) and C. antifebrile have also been used in ayahuasca. C. calothrysus has been known as 'yajé' [see **Banisteriopsis**], though it is not known to have been associated with the brew (Trout ed. 1998).

The Yagua of Peru have been known to snuff the dried, powdered seeds of C. angustifolia mixed with the seeds of 'pashaco' [see *Endnotes*], and sometimes with 'toad' venom [see **Phyllomedusa** and **Bufo**]. The addition of 'bobinsana' [C. angustifolia] to pashaco gives the snuff its visionary power, which pashaco seeds lack on their own (Bear & Vasquez 2000). In Nigeria, C. portoricensis root and stem are used as an anticonvulsant and treatment for gastrointestinal disorders; the stems are also chewed as an analgesic (Akah & Nwaiwu 1988). The Mexican C. houstoniana ['tabardillo'] is said to paralyse the heart (Jiu 1966).

C. angustifolia has yielded *harman* (Rätsch 1998); leaves contain pipecolic acid, trans-4-OH-pipecolic acid, cis-5-OH-pipecolic acid and trans-trans-4,5-dihydroxypipecolic acid. These compounds have insecticidal properties, and are present at roughly 1% combined (Romeo 1984).

C. anomala has yielded *harman* from the root bark, as well as possibly *DMT*, though other tests found no *DMT* above the detection limit of 0.1%. Root also contains calliandrin [a resinous glycoside], tannins, fats, and an essential oil (Rätsch 1998). Branches yielded triterpene saponins [Calliandra saponins A-O] (Tani et al. 1998). Seeds [as C. grandiflora] were shown to contain mainly S-(β-carboxyethyl)-cysteine, as well as 5-OH-pipecolic acid, and smaller amounts of S-(β-carboxyisopropyl)-cysteine and pipecolic acid (Krauss & Reinbothe 1973).

C. haematocephala leaves have yielded 0.0118% [w/w] *tyramine* (Wheaton & Stewart 1970), 2S,4R-carboxy-2-acetylamino-4-piperidine (Marlier et al. 1979), pipecolic acid, trans-4- and trans-5-OH-pipecolic acid, trans-cis-4,5-dihydroxypipecolic acid and trans-4-acetylaminopipecolic acid [the pipecolic acids present at roughly 1% combined] (Romeo 1984).

C. pentandra has yielded *leptaflorine* (Shulgin & Shulgin 1997) and *harman* (Rätsch 1998). C. sp. 'samik' [probably C. pentandra] was analysed in the form of a sample of prepared ayahuasca [also containing **Banisteriopsis** sp.], and was shown by UV-HPLC to contain a compound which may have been *DMT* (Luna & Amaringo 1991, quoting pers. comm. from J.C. Callaway).

C. portoricensis root yielded 1.9% alkaloids, stem yielded 1.2% – at least some of these appear to be quinine-like alkaloids. Also found were glycosides, sterols, saponins, flavonoids, triterpenes and tannins (Akah & Nwaiwu 1988).

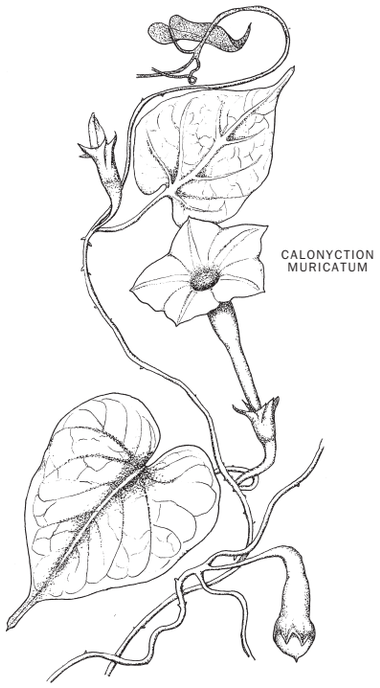
Chemistry of these plants is otherwise obscure.

Calliandra angustifolia is a glabrous tree, c.4.5-6m tall; branches spreading, long, rigid. Leaves dense, bipinnate; pinnae 1-paired; leaflets 1-paired, narrowly oblong, strongly oblique, terminal leaflets 2.5-5.1cm long, coriaceous, shiny, sub-2-nerved, with many minor tertiary nerves; stipules short, membranous, rigid, acute. Inflorescence composed of compound glomerules or heads; peduncule 4-8mm long, rigid; flowers sessile; calyx c.2mm; corolla c.6.5mm long; stamens more than 10; filaments coalesce basally into a tube prolonged above apex of floral cup. Fruit a subwoody legume, c.7-8cm x 6-8.5mm, flattish, slightly bulged over seeds, tapered towards base, margin strongly thickened, valves scarcely veined (sharply recurved after dehiscence), elastically dehiscent, persistent; seeds (1-)2-6, small and flattish.

Eastern Peru; abundant on banks of Huallaga and Mayo rivers (Bentham 1875; Correll & Johnston 1970 [for additional genus information]).

CALONYCTION

(Convolvulaceae)



Calonyction muricatum *G. Don* **(Ipomoea muricata** *Jacq.***; I. turbinata** *Lag.***)** – lakshmana, gariya, barikbhauri, tukhm-i-nil, kaladana ['black seed']

'Lakshmana' is a very important plant in Ayurvedic medicine, mostly for use as an aphrodisiac, having been named after Lakshmi, the beautiful goddess of love and luck. It is also used as a yoga medicine, and is considered to be food for the kundalini energy [see *Influencing Endogenous Chemistry*]. Those practicing tantric yoga make an ointment using lakshmana herbage and a bezoar stone [silicate of magnesia and iron – a type of soapstone], which is massaged into the '3rd eye' area on the forehead to create "irresistable love magic" and "mystical insights". The herb is also considered a tonic elixir of longevity. The root is considered a universal poison antidote, and is carried in many forms as a charm against snakebite (Nadkarni 1976; Rätsch 1992). Otherwise, the plant juice is used to destroy bugs, and the seed is said to have the same properties as those of **Ipomoea** hederacea, ie. purgative. The Munda of Chota Nagpur take a couple of the powdered, bitter seeds to treat fever (Chopra et al. 1965; Kirtikar & Basu 1980; Nadkarni 1976). As 'kaladana', the seed has been used in Pakistan as a purgative, though the identification as C. muricatum was doubted for some time (Abou-Chaar 1970; Abou-Chaar & Digenis 1966). 'Kaladana' is also used to refer to the purgative seeds of **Ipomoea** nil, and sometimes to black seeds of other plants (Austin 2000).

C. muricatum seeds have yielded 7.53% lipids and 0.0192-0.49% indole alkaloids [53% *lysergol*, 37% *chanoclavine*], as well as a new alkaloid, ipomine [1β-ipalbidinyl-(6'-O-p-coumaryl)-β-D-glucopyranoside]; leaves yielded kaempferol [MAOI (Sloley et al. 2000)], 4'-MeO-kaempferol, 7-MeO-kaempferol, p-OH-benzoic acid, vanillic acid and β-resorcylic acid. The plant has also yielded up to 3.7% behenic acid [said to be a CNS-stimulant (Rätsch 1992)], julandine, and muricatin, with lysine, histidine, threonine, valine, leucine, isoleucine, palmitic acid, stearic acid, oleic acid, palmitoleic acid and linoleic acid in the seed oil (Abou-Chaar 1970; Abou-Chaar & Digenis 1966; Nair et al. 1986; Rastogi & Mehrotra ed. 1990-1993).

Calonyction muricatum is a large twining herb, stems often muricate. Leaves 7.5-15 x 6.3-12.5cm, broadly ovate, acuminate, glabrous, entire, base deeply cordate with rounded basal lobes; petioles 7.5-15cm long. Peduncles 1-5-flowered, variable in length; bracts caducous; pedicels usually much thickened upwards in fruit; sepals 5, 1.3-1.6cm long, smooth, elliptic-oblong, aristate, subequal in length, 3 outer sepals much broader than the 2 inner ones; corolla salver-shaped, tube 2.5-5cm long, narrow, cylindric, 5-7.5cm long, rose purple, hairy within; stamens 5, exserted. Ovary 2-celled; ovules 4; style filiform; stigma 2-globose; anthers not twisted; pollen grains spinulose. Fruit a 4-valved capsule, 1.3-1.7cm diam., globose, apiculate; seeds 4, 1cm long, glabrous, black.

Himalayas from Kangra to Sikkim up to 1530m, Upper Gangetic Plain, Bengal, Bihar, Orissa, Bombay, Deccan Hills, upper Burma, Ceylon; possibly naturalised in China and Japan (Chopra et al. 1965; Kirtikar & Basu 1980).

CALYCANTHUS

(Calycanthaceae)

Calycanthus occidentalis *Hooker et Arnot*

C. occidentalis, which has interesting chemistry, is related to 'California allspice', C. floridus, the aromatic bark of which is used as a cooking spice, and as a medicine to ease muscle cramps and toothache. The leaves of C. floridus may also be used to treat fevers (Bremness 1994). The Cherokee use it to make eyedrops to treat poor eyesight, as well as using the plant as an emetic, and to treat hives and bladder complaints (Hamel & Chiltoskey 1975). C. glaucus [C. fertilis] is also known as California allspice [as well as 'sweet-scented shrub' and 'bubby']; its seeds have been reported to have killed cattle (Gordin 1905), with symptoms compared to those of *strychnine* poisoning (Anon. 1888a). In parts of eastern US, it is used to regulate menstruation (Usher 1974).

C. occidentalis has been shown to contain the β-carboline alkaloids *harmine* [0.0197%] in aerial parts (Lutomski & Nowicka 1969; Lutomski et al. 1968b), and *harman* in the leaf [leaf contained 0.000004% alkaloids calculated as *harman*] (Lutomski & Malek 1975b), as well as the indoles calycanthine [0.8% from seeds], folicanthine [0.14% from leaves] (Hodson & Smith 1957; Manske & Marion 1939) and calycanthoside (Buckingham et al. ed. 1994). Calycanthine [not the same as calycanthin, a glucoside] is a spinal stimulant and cardiac depressant in cats and rabbits; 5mg/kg [i.v.] induced *strychnine*-like "violent tetanic spasms". In frogs, it had a weak curare-like paralytic activity at doses of 5-10mg [injected into the anterior lymph-sac], with the 10mg dose causing spasms as above; 15mg caused death within a few days (Gordin 1905). Calycanthine also has uterine-stimulant activity (Harborne & Baxter ed. 1993). When reacted under heat with selenium in a stream of nitrogen, it degrades to *norharman*, skatole, β-ethyl-indole, lepidine, and an unidentified base; when benzoylated and oxidised in acetone with potassium permanganate, it forms benzoyl-*N*-*methyltryptamine* (Manske & Marion 1939).

C. floridus seeds have yielded c.1% alkaloids (Manske 1950), including calycanthine and isocalycanthine (Henry 1939); isocalycanthine is believed to be an artefact of extraction. Leaves have yielded 0.34% folicanthine (Hodson & Smith 1957).

C. glaucus seeds have yielded c.2% calycanthine and isocalycanthine, as well as 39-47% fixed oils; bark, leaves and flowers [but not seeds] contain an essential oil (Anon. 1888a; Gordin 1905; Henry 1939).

Calycanthus occidentalis is an aromatic, erect branching deciduous shrub 1-3m tall, foliage pleasantly aromatic when bruised. Leaves opposite, entire, 7-10cm long, ovate to oblong-lanceolate, acute at apex, rounded or cordate at base, firm in texture, dark glossy green and scabrous, very short-petioled. Flowers solitary, pedunculate, terminal; sepals and petals several, 2-6cm long, linear-spatulate, reddish-purple, emitting the odour of wine; stamens many, inserted on receptacle in several rows, the inner sterile; pistils many, enclosed in the hollow receptacle. Ovary 1-celled; 1-2-ovuled; style filiform; sterile filaments densely villous. Fruiting hypanthium ovoid, slightly constricted at apex, 25-35mm long; achenes numerous, smooth, oblong, 7-8mm long, villous. Fl. May-Sep.

In moist places, along streams and borders of lakes and ponds; Upper Sonoran and Arid Transition zones [Sonoran Desert], California, in north coast ranges and Sierra Nevada foothills (Abrams 1940-1944).

CAMELLIA

(Theaceae)

Camellia assamica *(J. W. Mast.) H. T. Chang* **(C. sinensis var. assamica** *(J. W. Mast.) Kitam.***; Thea assamica** *J. W. Mast.***; T. chinensis var. assamica** *(J. W. Mast.) Pierre***; T. viridis var. assamica** *(J. W. Mast.) Choisy***)** – cha-gaca
Camellia assamica var. kucha *Chang et Wang* – kucha
Camellia irrawadiensis *Barua*
Camellia ptilophylla *Chang* – cocoa tea
Camellia sinensis *(L.) Kuntze* **(C. thea** *Link.***; C. theifera** *Griff.***; Thea sinensis** *L.***)** – tea, thea, cha, chaha, chavika, chai
Camellia taliensis *(W. W. Sm.) Melch.* **(Thea taliensis** *W. W. Sm.***)**

The 'tea' bush, C. sinensis, is an ancient plant thought to have originated in China or Assam (Rätsch 1992). Its use is recorded from China as early as 2700BC, and the plant has been applied there as a tonic and ritual stimulant drink. Buddhists utilised it to keep them awake during lengthy meditations, and Taoists valued it as an ingredient of elixirs of immortality [see *Methods of Ingestion*]. In Tibet, tea is given to revive weary horses, and early herbals have always claimed [in various terms] that it could relieve fatigue, strengthen the will, delight the soul and repair eyesight. Tea cultivation gradually spread to other regions, being grown in Japan by c.800AD, and the consumption of the beverage made from the leaves gradually evolved into what is now known as the 'tea ceremony'. Such a ceremony is rigorously prepared for by the host, and is held in a room that is sparsely but tastefully decorated. The mood of the tea ceremony is one of silent contemplation and artistic appreciation. Tea was introduced to English society c.1840, after which the British established tea plantations in India and Sri Lanka. The popularity of the drink spread rapidly from there, and it is now consumed worldwide. The related C. assamica is used in India as a tea substitute; this species is considered to be the parent species of the cultivated plant, C. sinensis. The leaves of tea are 'gently exhilarating' if infused for a long time; overdoses are said to have a "degenerative effect on the nervous system analogous to what follows even the moderate dose of alcohol". It has even been said that "at times...the disorder of the mental faculties under the influence of strong tea, amounts nearly to insanity" (Emboden 1979a; Huang 1993; Nadkarni 1976; Okakura 1964; Schapira et al. 1975). For most people, however, tea acts as a mildly stimulating and relaxant beverage.

An early method of preparing tea in the Yangtse-Kiang Valley of China was to steam the leaves, crush them in a mortar, press them into a cake and boil it in water with rice, ginger [see *Endnotes*], salt, orange peel [see **Citrus**], milk, onions and other spices. Later, the only extra ingredient was salt – this was added to the water when it began to simmer, and the tea added when it began to boil. When a rapid boil commenced, a ladle of cold water was poured into the brew [to 'revive the youth of the water'] and the beverage consumed immediately. In the Sung Dynasty, tea was prepared in the 'whipped tea' fashion, in which the ground leaves were whipped in hot water with a bamboo whisk (Okakura 1964; Schapira et al. 1975). Tea is now usually prepared by pouring boiling water on the dried tea leaves and letting them infuse in a covered pot [or in a cup, if using teabags] for 1-5 minutes. Sometimes milk and/or sugar or honey are added, usually only to black tea [see below].

In western countries, 'chai' often refers not to simple tea itself, but to 'masala chai', a spiced tea blend popular in n. India. Masala chai is based on black tea [usually cheaper grades], with spice additives varying, but usually including 'cardamom', cinnamon bark [see **Cinnamomum**], cloves [see **Syzygium**] and black pepper [see **Piper 1**]. Sometimes ginger [see Endnotes] and other spices are also added. Masala chai is usually boiled in water, with milk added near the end of brewing, and sugar or honey added before serving (pers. obs.).

Tea leaves have been smoked on occasion – 'haysan tea' [see below] was much smoked in cigarettes by women earlier last century (Chopra et al. 1965; Emboden 1979a). Some desperate **Cannabis** smokers have been known to use black tea mixed with pipe residue and strained solids from bong-water [often referred to as 'dregs'], to help make such resinous gunk more readily smokeable. For this purpose, the powdered tea and residual matter are lightly heated in a frying pan, mixing all the while with a spatula, in order to dry and mix the two more effectively. The frying process is stopped when fumes are first observed arising from the mixture, which can then be mixed with a small amount of tobacco [see **Nicotiana**] if desired, and smoked through a water-pipe. This tastes quite filthy and is probably very unhealthy, but is psychoactive (pers. obs.).

Leaves are harvested in early spring from plants at least 4-5 years old, and for quality teas the tender young shoots, buds and immature leaves are plucked. Harvesting may take place often throughout the year, but those picked in early spring are considered the best. Stems and other impurities are removed before processing. How they are then processed determines what type of tea will result, the main types being green, black, and semi-fermented ['oolong'] teas. [However, beyond this, Chinese connoisseurs recognise up to 330 different kinds of tea (Huang 1993) – see also Von Bibra (1855) for descriptions of some of them].

Japan produces only green tea, and some also originates from China. Freshly harvested leaves are quickly roasted in a pan over a fire to remove excess moisture, and thus, prevent fermentation. The leaves are then rolled into sticks or balls; these are fired again, before being sifted and graded according to quality. Those rolled into balls are known as 'gunpowder' or 'imperials', and those rolled lengthwise are known as 'hyson' or 'haysan'. In Japan, the fresh leaves are steamed before the firing stage.

Oolong ['black dragon'] or semi-fermented tea is produced in Formosa [Taiwan]. Picked leaves are partially dried and fermented in the sun on bamboo trays, while repeatedly being rolled and crushed by hand.

The leaf soon changes to a darker colour, and while still moist it is dried in bamboo baskets over burning charcoal. A popular variant on this is 'jasmine tea', or 'jasmine oolong tea' [see **Jasminum**], grown in the Foochow Province of China. The semi-dried leaves are spread on the ground and covered with several layers alternating with jasmine blossoms and tea leaves. This is left to sit for several hours before the whole mass is heated to dryness, and the jasmine flowers removed.

'Black tea' or 'pu-erh tea' is manufactured in India, Sri Lanka, Java and Sumatra, as well as China, the best being that grown in the Keemun district. Fresh leaves are first withered on racks in specially designed lofts for 24 hours. They are then rigorously rolled and crushed – this is now done by machines. The fermentation room is structured to be a cool and moist environment, free from direct sunlight – here, the leaves are spread out to a depth of c.1.25cm, and fermented for 4-4.5 hours, until the leaf is a rich golden brown and has acquired the characteristic aroma, which is absent from unfermented tea leaves. They are then dried by firing, and sorted according to grades – usually divided into broken and unbroken, and further categorised into types such as 'orange pekoe', 'souchong', 'broken orange pekoe', and the 'dust' grades. Tea quality is often judged by the size of the leaf, the tightness of the curl of the whole dried leaf, aroma, colour, flavour etc. A less common and cruder variant is 'brick tea', produced chiefly in w. China, and used in parts of Russia and Tibet. Small twigs and coarse leaves are heated in an iron pan for a few minutes, bundled, and taken to the factory. Here it is fermented, sun-dried, graded, steamed and pressed in brick-shaped moulds for 3-4 days until dry (Dowell & Bailey 1980; Schapira et al. 1975; Williams 1937).

Tea is a CNS-stimulant, astringent [due to tannin content], diuretic, digestive and sudorific. Overdose of tea can cause symptoms such as nausea, vomiting, trembling, weakened pulse, paleness, headache, hallucinations and nightmares. New studies show tea may help reduce tooth decay, due to antibacterial and anticaries actions, as well as showing success in treating bacterial dysentery. Green tea has also shown antitumour and antioxidant activity, partially due to the polyphenolic catechins present, as well as the non-polyphenolic fraction, containing pheophytins A and B; it may also boost the immune system and inhibit MAO-B (Bremness 1994; Higashi-Okai et al. 2000; Huang 1993; Mazzio et al. 1998; Miketova et al. 1998; Nadkarni 1976; Simonetti 1990). Theanine, an amino acid which is abundant in Japanese green tea, has been shown to increase brain concentrations of *serotonin* and *dopamine* in the striatum, hypothalamus, and hippocampus, as well as stimulating *dopamine* release in the striatum (Yokogoshi et al. 1998). Tea has also shown antimutagenic activity against various mutagenic chemicals, with oolong and 'pouchong' [a type of black tea which is packaged in light yellow paper (Von Bibra 1855)] teas being most active (Yen & Chen 1996).

Green teas retain more of their ascorbic acid [vitamin C] content than fermented teas. Catechin content is highest in green teas, and lowest in fermented teas. In fermentation, the catechins are oxidised by the enzyme polyphenol oxidase and then polymerised to result in formation of theaflavins, thearubigins and other compounds. In the phenolic fraction, gallic acid content is increased from fermentation, as it is released from its bound form in catechin gallates. However, some studies found green tea to contain greater levels of phenols than black tea; others have found them to be similar in content; others have found black tea to contain greater levels than green tea. On average, fermented teas contain more *caffeine* than green teas, with oolong tea and Ceylon black tea sometimes bearing the highest levels [as well as highest levels of phenolic compounds] (Khokhar & Magnusdottir 2002; Lin et al. 1998; Yen & Chen 1996). The fermentation apparently slightly increases *caffeine* levels through breakdown of nucleic acids (Suzuki et al. 1992). The great chemical variation of different teas makes it difficult to generalise about yields or types of compounds likely to be present in any given sample, unless perhaps one is a true 'tea expert'. It is worth noting, however, that commonly-available commercial teas in non-Asian countries [especially those pre-packaged in tea bags] are generally of much lower quality [both chemically and subjectively], compared to the teas consumed by connoisseurs (eg. see Khokhar & Magnusdottir 2002; Lin et al. 1998).

Although tea, on average, contains more *caffeine* by weight than coffee [see **Coffea**], it is usually less stimulating due to the smaller weight of tea used in the average brew (pers. obs.). One cup of tea brewed with black tea bags may contain 8-67.4mg *caffeine*, or 9-19mg with green tea bags; up to 150mg per cup has been found, from tea of unspecified type [probably black] (De Camargo & Toledo 1999; Gilbert et al. 1976; Karch 1996). 'De-caffeinated' teas still contain small amounts of *caffeine* [c.0.27% of dried leaf, in one sample]. Infusing tea for a longer time than is usual [c.10min. rather than 1-5min.] gives greater extraction of catechins (Khokhar & Magnusdottir 2002).

C. assamica var. kucha [cultivated in Guangzhou, China; harv. Oct. and May] expanding buds yielded c.2.7% *caffeine*, 1.45% *theobromine* and 2.8% theacrine [1,3,7,9-tetramethyluric acid]; young leaves yielded c.0.55% *caffeine*, 0.35% *theobromine* and 2.75% theacrine; mature leaves yielded c.0.7% *caffeine*, 0.12% *theobromine* and 1.25% theacrine; old leaves from near the base of the tree yielded c.0.1-0.5% theacrine, with *caffeine* absent or present only in traces (Zheng et al. 2002).

C. irrawadiensis leaves have yielded up to 0.02% *caffeine* and 0.53-0.81% *theobromine* (Nagata & Sakai 1985).

C. ptilophylla leaves have yielded *theobromine* as the major alkaloid (Zheng et al. 2002).

C. sinensis leaves may yield 1-5% purine alkaloids, most of which [c.3.5% of leaves, even up to 4.5% in some] is *caffeine* [green tea has yielded 1.15-2.01% *caffeine*; oolong tea 2.43-2.44%; black tea 1.5-4%], with modest amounts of *theobromine* [0.1-0.17%; 0.2-0.4% in black tea; up to c.0.96% in green tea], *theophylline* [c.0.02% in black tea, up to c.0.13% in green tea], methylxanthine, xanthine, adenine and a guanine-derivative; as well as *phenethylamine*, *DMPEA*, theanine [γ-glutamylethylamide], methyl salicylate, c.30% fixed oil, 9.5-21% tannins [tannic acids], catechins [c.3-30%, lowest values in black teas], mineral salts, saponins, cis-3-hexanal, gallic acid, angelic acid, cinnamic acid, glucuronic acid, linoleic acid and tiglic acid (Gilbert 1986; Huang 1993; Khokhar & Magnusdottir 2002; Kirtikar & Basu 1980; Lewis & Elvin-Lewis 1977; Lin et al. 1998; Lindner 1956; Lovenberg 1973; Lundstrom 1989; Nadkarni 1976; Nagata & Sakai 1985; Power & Chestnut 1919a; Rastogi & Mehrotra ed. 1990-1993; Simonetti 1990; Yokogoshi et al. 1998). Theacrine [see above] also occurs in traces (Zheng et al. 2002). The pericarp of the fruit has yielded 1-2% *caffeine* [w/w] and 0.05-0.1% *theobromine* (Suzuki et al. 1992). One study reported finding up to c.17% *caffeine* in Chinese green tea, and c.16% *caffeine* in a black tea made from a Taiwanese C. sinenis hybrid called TTE 12. In this study, the average yield of *caffeine* from a wide variety of teas was c.7-8%. [Many of the figures given in this paper were not incorporated into the yields of C. sinenis alkaloids given above, due to their great difference compared to other research]. Chinese green teas contained more *theobromine* and *theophylline* than did Japanese green teas, which in turn contained more catechins. In general, however [and in conflict with other research], this study did not find a very significant difference between alkaloid content of non-fermented, semi-fermented and fully-fermented teas (Lin et al. 1998).

C. taliensis leaves have yielded 2.28% *caffeine* and 0.14% *theobromine* (Nagata & Sakai 1985).

Camellia sinensis is a shrub or small tree, glabrous or slightly pubescent. Leaves evergreen, alternate, serrate, coriaceous or membranaceous, glossy, +- ovate. Flowers axillary, solitary, in peduncles with a few distinct bracts, sometimes a second flower in the axil of one of them, sessile or shortly stalked; sepals 5-6, round, very obtuse, unequal; petals usually 5, white, obovate-obtuse, glabrous or pubescent on the back; stamens numerous, glabrous, adherent to base of petals, the innermost 5-12 free. Ovary villous, 3-5 celled; ovules 4-5 in each cell, pendulous; styles 3, glabrous, connate beyond middle. Capsule woody, usually short, loculicidal, depressed, 3-cornered, 3-seeded; seeds mostly solitary in each cell, wingless, testa hard and shining.

India to Japan (Chopra et al. 1965; Kirtikar & Basu 1980).

Tea is best grown at a high altitude, with temperatures from 18-25°C., and wind protection. Soil should be rich, loamy and well-drained. Can be grown from cuttings. Seeds that sink in water are planted c.10-20cm apart, 2cm deep, and covered with thatch to prevent sunburn. Tea is often grown under the shade of legumes. Regular pruning is later required to maintain a good-yielding bush (Simonetti 1990; Williams 1937).

CANANGA

(Annonaceae)

Cananga odorata *(Lam.) Hook. f. et Thomson* **(Canangium odoratum** *(Lam.) Baill.***; Uvaria odorata** *Lam.***)** – ylang-ylang, perfume tree, alangigan, anangiran, tangit, burak

'Ylang-ylang' ['flower of flowers'] is a popular aphrodisiac perfume obtained from the flowers of C. odorata. It is commonly available as an essential oil, and in perfumes, soaps and skin lotions. In Indonesia, the flowers are spread on the bed of newlyweds for the honeymoon. The effects of the oil have been compared to those of **Narcissus** oil, acting as a CNS-depressant and regulating heart action – aromatherapists say it may also be calming, antidepressant, aphrodisiac, euphoric and narcotic. Used in excess, ylang-ylang can cause headaches and nausea. The best oil is considered to come from C. odorata var. genuina – C. odorata var. macrophylla is known simply as 'cananga', and yields an inferior quality oil. Different quality essential oils are collected at different stages of fractional steam distillation [or fractional steam and water distillation], with the first portion being of the highest quality [known as 'ylang-ylang extra']. Best grade ylang-ylang steam-distilled oils are almost colourless, with a slight yellowish tint, though a high-grade oil which is very dark is extracted from the flowers with petroleum ether (Battaglia 1995; Bremness 1994; Lawless 1994, 1995; Rätsch 1990; West & Brown 1920).

C. odorata flowers have yielded up to 0.45% essential oil, containing linalool, geraniol, *pinene*, cadinene, p-cresol, methyl benzoate, benzyl benzoate, benzyl acetate, benzyl valerianate, methyl paracretol, methyl salicylate [see **Gaultheria**], *eugenol*, isoeugenol, *safrole* (Erickson 1976; Lawless 1995; West & Brown 1920) and *isosafrole* (Harborne & Baxter ed.

1993). Best quality oil may contain 25.1% benzyl acetate, 8.7% methyl benzoate, 2.2% benzyl benzoate, 16.5% p-cresyl methyl ether, 13.6% linalool, 5.3% geranyl acetate, 1.7% caryophyllene and 7.4% other sesquiterpenes; in contrast, lowest quality oil may contain 9% caryophyllene, 4.3% benzyl benzoate, 3.7% benzyl acetate, 1% methyl benzoate, 3.5% geranyl acetate, 1% linalool, 0.5% p-cresyl methyl ether and up to 97% other sesquiterpenes (Battaglia 1995). Eupolauridine, sampangine and 3,7,11-trimethyl-2,4,6,10-dodecatetraene have also been found in the plant. The alkaloids liriodenine and ushinsunine have also been reported from the genus (Buckingham et al. ed. 1994).

Cananga odorata is a tall tree, trunk straight; bark smooth, ashy; shoots glabrous. Leaves alternate, 12.7-20.3 x 5-7.6cm, ovate-oblong, finely acuminate, base rounded, margins waved, puberulous beneath, especially on veins, veins furrowed; petiole c.1.3cm. Flowers odorous, large, 7.6cm long, usually 3-nate, yellow, solitary or fascicled on short axillary peduncles, drooping; peduncles solitary or several from old scars; pedicels c.2.5cm, recurved, hoary, with a few basal bracts and a median scaly bract; sepals 3, ovate or triangular, valvate; petals 6, 8-9mm, 2-seriate, subequal, narrow, linear, base broad, silky when young, long, flat, valvate; stamens linear; anther cells approximate extrorse, connective produced into a lanceolate acute process. Ovaries many; style oblong or none; ovules numerous, 2-seriate; stigmas subcapitate. Carpels c.12, 1.3-1.7cm, ovoid or obovoid, black, glabrous, long-stalked, berried, 6-12-seeded; seed testa crustaceous, pitted, sending spinous processes into the albumen.

In moist or seasonal forests; Java, Philippines, India, Indonesia, Burma – cultivated throughout India and the tropics (Bremness 1994; Hooker 1954-1961); 700m and above.

Seeds have a low germination rate. Flowers are usually harvested at night from May to June, when mature and yellow; their essential oil is usually collected by steam distillation (West & Brown 1920). Battaglia (1995) noted that the flowers may sometimes be mauve or pink, but that yellow flowers are best for essential oil extraction.

CANARIUM

(Burseraceae)

Canarium album *(Lour.) Räusch*
Canarium commune *L.* – Java almond tree, jangali badam, canari, badamee, elemi
Canarium cumingii *Engl.*
Canarium luzonicum *A. Gray* – elemi
Canarium madagascariense *Engl.* – ramy
Canarium microcarpum *Willd.* – elemi
Canarium spp. – elemi

Trees of this genus, particularly C. commune and C. luzonicum, yield a pale yellow resin from incisions in the bark, called 'gum elemi', which is distilled to make 'oil of elemi' [also known as 'manila elemi', or 'brea']. The gum has a sharp lemon scent, and is used in the manufacture of soaps, as well as being used as an incense, and applied topically to persistent ulcers; the oil is similarly used in soaps, perfumes and cosmetics. The seeds treat beri-beri, and their oil is used in cooking; the fruit is laxative, and is considered fattening. In India, the seeds and their oil are used medicinally, and are considered stimulant in action. In Indonesia, the leaves are used to treat vertigo, and the bark for malaria. In Cambodia, the tubers of the trees are used as a stimulant, diaphoretic and styptic; they are taken internally to treat vertigo, chronic bronchitis, inflamed uterus, headache, and jaundice; and externally for neuralgia, rheumatism and liver complaints (Bremness 1994; Bruneton 1995; Kirtikar & Basu 1980; Nadkarni 1976; Pernet 1972).

In Madagascar, C. madagascariense bark is used as a disinfectant fumigant, and a stem decoction is sometimes prepared to cause fatal poisoning (Pernet 1972). The seeds of C. pimela are used as a sedative and nutrient in Hainan, China. The fruit of C. album has similar properties, and is also used raw as an antidote for intoxication, alcohol poisoning, fish poisoning, diarrhoea, and swollen sore throat (Perry & Metzger 1980). The Hmong of n. Thailand bathe in a wash of C. subulatum, as a tonic treatment (Anderson 1993). In the coastal Rai region of Papua New Guinea, a Canarium sp. is used in magic to promote a successful garden (Paijmans ed. 1976).

'Oil of elemi' prepared from the oleo-resins of C. commune bark has yielded 65-75% resinous triterpenes [including amyrenol, α-manelemic acid, elemolic acid] and 15-25% essential oil [including 0.5-8% *elemicin*, 45-72% limonene, 10-24% α-phellandrene, 3-8% sabinene, 1-15% elemol, 0.4-2% α-terpineol, carvone, dipentene] (Bruneton 1995; Pernet 1972); fruit essential oil contains *anethole* (Nadkarni 1976).

C. cumingii oleo-resin contains *elemicin* and amyrenol; leaves yielded camphene, cymol, dipentene and formic acid.

C. madagascariense oleo-resin contains *elemicin*, citronellol, dipentene and phellandrene. An extract of the aerial parts showed cardiac activity.

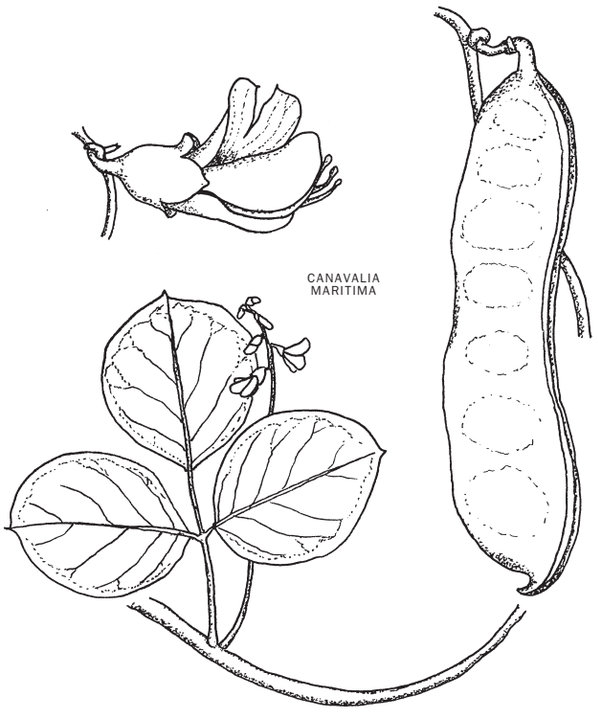
C. microcarpum has yielded *elemicin* and elemol (Pernet 1972).

Canarium commune is a tall balsamiferous tree; extremities of branches tawny-puberulous or glabrate. Leaves alternate, distant, imparipinnate, of flowering branches 25-45cm; leaflets 7-9, ovate to oblong, elliptical, acuminate, glabrous, usually opposite, usually petioluled, often very unequal, the lowest rotund, remote from base, or sessile at base of leaf and stipuliform, upper leaflets 10-15 x 3-6.5cm; lateral nerves c.10-15 pairs; stipules elliptic or rotundate, auricled, often very early deciduous; petiolules 12-25mm long. Flowers hermaphrodite or polygamous, in axillary and terminal branched panicles, panicles puberulous, with spreading successively shorter lateral branches; buds enclosed in ovate or rotundate tomentose deciduous bracts; flowers variable in size, female 8-12mm long or more; calyx campanulate, broadly 3-lobed, valvate, persistent; petals 3, imbricate below, tomentose above, thick, usually longer than calyx; disc annular, entire or lobed; stamens 6-10, in males inserted around hairy rudimentary ovary; filaments free or connate at base with each other and the disc. Ovary ovoid, glabrous, thickened above, usually 3-celled; ovules 2 in each cell; style short or equalling ovary in length; stigma capitate, 2-4-lobed. Drupe ellipsoidal, subtrigonous, with a bony 1-3-celled stone; seed conform to the cell, testa membranous.

Tropical forests; native to Moluccas, introduced to India, Malay Peninsula (Kirtikar & Basu 1980), and also found in n. Australia.

CANAVALIA

(Leguminosae/Fabaceae)



Canavalia maritima *Petit-Thouars* **(C. maritima** *(Aubl.) Urb.***; C. obcordata** *(Roxb.) Voigt***; C. obtusifolia** *DC.***; C. rosea** *(Sw.) DC.***; Dolichos emarginatus** *Jacq.***; D. maritimus** *Aubl.***; D. obcordatus** *Roxb.***; D. obtusifolius** *Lam.***; D. roseus** *Sw.***; D. rotundifolius** *Vahl.***)** – coastal jack bean, sea bean, horse bean, bay-bean, frijol de mar, poiszombi, pois lan mer, pois liane, pois maldioc, graines ouari, mate de costa

Canavalia virosa *(Roxb.) Wight et Arn.* **(C. africana** *Dunn ex Hutch.***; C. ensiformis var. virosa** *(Roxb.) Baker***; C. ferruginea** *Piper***; C. polystachya** *Schweinf.***; C. virosa** *Naves ex Villar***; Dolichos polystachios** *Forssk.***; D. virosus** *Roxb.***)** – kath-shim, kudsumbar

The mashed roots of C. maritima have been used by indigenous north Australians, infused and rubbed on the body to treat aches and pains, rheumatism, colds, leprosy and broken bones (Lassak & McCarthy 1990). Apparently, sailors in the Gulf of Mexico sometimes smoke the dried, ground seed-pods of this plant [minus the seeds] as a 'narcotic' **Cannabis** substitute. It is also said to guard against the 'evil eye'. Although there is no record of ancient drug-use of this plant, seeds have been recovered from graves in Mexico [Oaxaca and Yucatan] and Peru, dating back to times between 300BC and 900AD. It is also reported from Java that the plant is narcotic. Likewise, in India, C. virosa is reported to be narcotic. However, the unripe seeds and pods of C. virosa are eaten in China, India, Arabia and Africa, presumably after cooking. In the West Indies, mature seeds of C. ensiformis are roasted and used as a coffee substitute [see **Coffea**] (Emboden 1979a; Nadkarni 1976; Ott 1993; Schultes &

Hofmann 1980; Watt 1967). The seeds are toxic when raw or improperly prepared; roasting for 15-45min. destroys most [not all] of the canavanine present [see below], and boiling in water for a similar period leaches most [again, not all] of the canavanine present into the water. However, heated seeds are still toxic to rats (Bell 1973). Canavalia spp. are generally grown across the globe for cattle forage and green manure, as well as for their nitrogen-fixing capabilities (Allen & Allen 1981).

C. ensiformis leaves [or leaflets] produce the amino acid canavanine, with levels increasing as leaves develop (Rosenthal 1972). Canavanine has insecticidal, phytotoxic and cytotoxic effects; it antagonises metabolism of the amino acid arginine, increases clumping of red blood cells and was shown to be toxic to mice at 200mg/g [oral] (Bell 1973; Harborne & Baxter ed. 1993; Rosenthal 1977). Leaflets have also yielded the flavonoids cajanin, genistein [MAOI (Hatano et al. 1991)], 2'-OH-genistein, maackiain, medicarpin, quercitrin, rutin and vestitol. Seeds have yielded the alkaloids betonicine, canavalmine, caneine, kitagine, spermine, spermidine, trigonelline, 1,4-butanediamine, 4,4'-diaminobutylamine, 1,5-pentanediamine, and 3-isoxazolidinone; the amino acids canavanine, 2,4-diaminobutanoic acid, 2-amino-4-OH-butanoic acid, 2-amino-5-OH-pentanoic acid, and hexahydro-3-imino-1,2,4-oxadiazepine-3-carboxylic acid; as well as lupeol, lupeoside, stigmasterol and β-sitosterol (International... 1994).

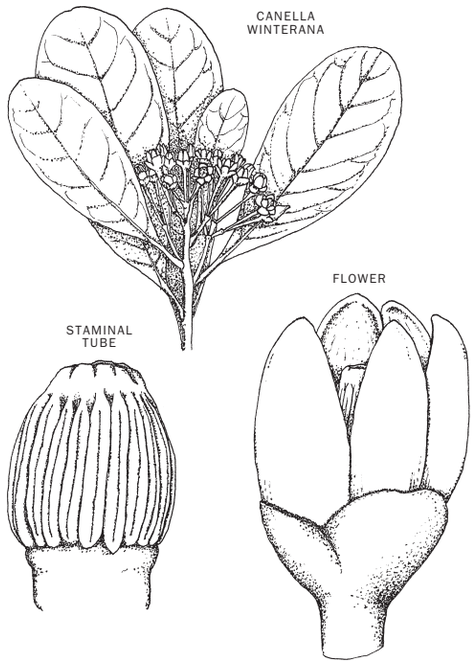
C. maritima seed pods have yielded L-betonicine, but no constituents known to be psychoactive have been found (Schultes & Hofmann 1980). The seeds have yielded 6.25% canavanine (Rosenthal 1977), and leaflets have yielded the flavonoids maackiain, medicarpin, and vestitol (International... 1994). Stem, leaf and fruit have tested positive for presence of alkaloids (Fong et al. 1972). A crude mix of unspecified leaf-alkaloids was shown, in very high doses [2g/kg oral], to exhibit low-level CNS activity, lowered arterial blood pressure, and an antiinflammatory effect in mice (CSIRO 1990).

Canavalia maritima is a climbing or trailing herb; stems 2-3m long, silky or glabrous. Leaves alternate, pinnately 3-foliate; leaflets circular to oblong, 4-12cm long, 3-10cm wide, leathery, glabrous at maturity, apex mucronate to retuse; stipules gland-like or minute, stipels usually not present. Inflorescences axillary c.8-flowered racemes; bracts minute, bracteoles +- circular, caducous; peduncle erect, 15-30cm long; calyx 2-lipped, c.12mm long; corolla mauve to white; standard rounded, reflexed, mostly 2-3cm long; keel incurved, sometimes beaked; stamens diadelphous; anthers uniform. Ovary many-ovuled; style beardless; stigma terminal. Fruit an oblong pod, +- compressed, 10-15cm x 25mm, c.6-seeded; seeds ovoid, c.18mm long, without obvious aril, poisonous. Fl. most of the year.

Mostly on sand dunes in coastal areas; Asia, Africa, Central America, Australia [WA, NT, Qld, north of Shellharbour in NSW] (Harden ed. 1990-1993).

CANELLA and DRIMYS

(Canellaceae)



Canella winterana *(L.) Gaertn.* **(C. alba** *Murray***; Laurus winterana** *L.***; Winterana canella** *L.***)** – wild cinnamon, white cinnamon, canella, canela, pepper cinnamon, Bahama whitewood, whitewood bark, false Winter's bark

(Winteraceae)

Drimys winteri *J.R. Forst. et G. Forst.* **(D. aromatica** *Descourt ex Baill., non F. Muell.***; D. chilensis** *DC.***; D. granatensis** *Mutis ex L. f.***; D. magnoliaefolia** *Kunth ex Eichl.***; D. paniculata** *Steud.***; D. polymorpha** *Spach ex Baill.***; D. punctata** *Lam.***; D. winterana** *Thell.***; Wintera aromatica** *Murr.***; Winterana aromatica** *Soland. ex Fothergill***)** – canelo, canelón, canellilo, boigue, boiye, boique, fune boighe, foie, foike, foige, foye, foikelawen, palo piquante, ciûla, shâahlku, shâlakuâhr, usskútta, wa-tsuts-ñee-ñoo-ssê, pepper bark, Winter's bark, Winter's cinnamon

Drimys winteri is highly venerated amongst the Mapuche [main survivors of the Araucano] of the southern Andes, Chile. To them it represents the world tree, with roots in the underworld, and above reaching towards the heavens. The tree, sometimes called 'iñ chao rayülelu' ['our flowery father'], is considered a manifestation of the divine, and its wood is used to make the drums ['kultrun'] of Mapuche shamans. Shamans ['machi', usually female] also have their own personal 'ritual pillar' ['rewe'] made from the wood, which they climb during ecstatic trance (Aukanaw 1983-2000; Plowman et al. 1971; Titiev 1951). The branches are burned during all shamanic ritual, to release the spirit of the tree and allow it to carry the machi to the otherworld. Divination with the plant was done in a dark hut with a leafless branch of it stuck in the ground, with a tuft of llama wool on the end. The scent of the wood alone is said to produce the desired effect. Spells or prayers were made effective by blowing tobacco smoke [see **Nicotiana**] over one of the trees, and the leaves of the tree may be rubbed on the body of a sick person to 'draw out the illness' [it is possible that the 'tobacco' reported to be used by the Mapuche is not **Nicotiana**, but rather **Lobelia** tupa (pers. obs.), which is an important visionary plant to the Mapuche (Rätsch 2001)]. Sometimes, a tree is planted during the festivities surrounding the naming of a child, so that the spirit of the tree will be an ally and protector throughout the life of that person (Rätsch 1992).

Rätsch (1992) reported this erroneously as referring to Canella winterana, which is not found in the Andes (theobromus pers. comm.). In the 16th century, Captain William Winter [a member of Captain Drake's expedition through the Straits of Magellan] was given the bark of D. winteri by natives to treat scurvy, during a land stop-over in s. Argentina. After noting its efficacy, the bark then became widely used in Europe as a medicine. Ever since, the true identity of what became known as 'Winter's bark' has been obscured, with C. winterana and/or Cinnamodendron corticosum often offered as substitutes (Felter & Lloyd 1898; Smith 1943). However, C. winterana is native to the West Indies, Florida, and southern Mexico, and Cinnamodendron corticosum is native to Jamaica (Adams 1972; Fawcett & Rendle 1926). Further confusion exists amongst plants known as 'canela' [Spanish] or 'canelo' [Portuguese], names which have also been used to refer to Miconia serialis, Ocotea spp., Nectandra mollis [see *Endnotes*], and **Cinnamomum** spp.

The Mapuche also recognise two varieties of D. winteri that are not held to be of sacred significance. 'Canelo de la paz' has leaves that are narrower and longer than the norm, and ash-grey beneath; carrying a branch of this plant symbolises peace. The similar 'canelo crespo' has ruffled leaves, and its bark [credited with powerful narcotic properties] is used to stun fish (Aukanaw 1983-2000; Titiev 1951).

D. winteri leaves and bark have a peppery taste, and are used to treat gastric disorders and diarrhoea; they have aromatic, aphrodisiac, stimulant, antispasmodic, antipyretic, tonic, and stomachic properties. About 2g of the powdered bark is considered a medicinal dose (Aukanaw 1983-2000; Felter & Lloyd 1898; Mendes et al. 1998; Titiev 1951). The leaves are also used in the Sibundoy Valley [Colombia] as a stimulant and tonic (Schultes & Raffauf 1990). As D. winteri does not naturally occur outside of Chile and Argentina (Moore 1983; Smith 1943), the use recorded in Colombia may represent cultivated or naturalised specimens, or perhaps a similar Drimys sp. that was mistaken for D. winteri. See also the closely-related **Tasmannia**.

The bark of C. winterana is used as a cooking spice and tobacco flavouring, as well as treating stomach upsets and restoring menstrual flow. It is commonly used as a substitute for cinnamon [see **Cinnamomum**] in Central and South America, and a bark infusion is drunk as an aphrodisiac and tonic (Chevallier 1996; Kioy et al. 1989; Usher 1974).

C. winterana stem bark has yielded up to 1.25% essential oil, containing *eugenol* [0.07% of bark], *myristicin* [0.012% of bark], *safrole*, *camphor*, 1-α-*pinene*, cineole, caryophyllene and canellal [0.04% of bark]; the essential oil has stimulating effects (El-Feraly & Hoffstetter 1980; Kioy et al. 1989; Rätsch 1992; Schermerhorn et al. ed. 1957-1974). The stem bark has also yielded 0.02% 3-MeO-4,5-methylenedioxy-cinnamaldehyde (El-Feraly & Hoffstetter 1980), 0.007% 3β,9α-di-OH-cinnamolide, 0.03% 9-α-OH-cinnamolide, 0.02% clovanediol, 0.06% warburganal, 0.096% mu-

kaadial, 0.008% heliocid, 3.5% mannitol and 0.035% β-sitosterol glucoside (Kioy et al. 1989, 1990).

D. winteri bark has yielded c.1.2% essential oil (Felter & Lloyd 1898); sesquiterpene drimanes, including polygodial [0.032-0.17%], 1-β-(p-MeO-cinnamoyl)polygodial [0.0017%], drimanial [0.024%], and mukaadial [0.001%]; and the flavonoids astilbin and taxifolin. The water/alcohol extract showed anti-asthmatic, anti-inflammatory, anti-allergenic, and analgesic properties. The analgesic properties were largely ascribed to the drimanes, with polygodial, 1-β-(p-MeO-cinnamoyl) polygodial, and drimanial all exerting marked pain-killing effects in mice; the first two were the most potent [being more potent than acetylsalicylic acid (aspirin) and acetaminophen (paracetamol)], with drimanial having approximately 1/3 the potency of polygodial (Cechinel-Filho et al. 1998; Malheiros et al. 2001; Mendes et al. 1998). Astilbin and taxifolin also have analgesic properties, and are likewise more potent than acetylsalicylic acid or acetaminophen (Cechinel-Filho et al. 2000). The leaves [harv. Mar.] have yielded 0.09% polygodial, 0.07% drimenol, 0.02% 3β-acetoxydrimenin, cryptomeridiol, cirsimaritin, astilbin, quercetin, quercitrin, and 0.19% safrol [a drimane sesquiterpene, not the same as *safrole* which is nevertheless sometimes spelled as safrol] (Sierra et al. 1986).

Canella winterana is a shrub or tree 2-10m tall; bark grey to white, deeply fissured into lozenge-shaped patches, aromatic. Leaves alternate, simple, entire, obovate to oblanceolate, rounded at apex, cuneate and decurrent on petiole at base, 2.5-7(-10) x 1.5-3(-4)cm, with pellucid glands, leathery, glossy or dull on upper side, paler beneath, nerves prominulous on both sides; petiole short; stipules none. Inflorescence a terminal cymose panicle; flowers bisexual; perianth bi-triseriate, actinomorphic; sepals 3, broadly imbricate, 2-3mm long, glaucous; petals 5 in one or more series, usually free, imbricate, 4-5mm long, crimson with yellowish mark at base within, fragrant; stamens 5-12, filaments connate; anthers bright red, 2-locular, extrorse, opening lengthwise. Ovary superior, 1-locular, with 2-6 carpels; placentas parietal each with 2 or more half-anatropous ovules; style short, persistent; stigma obscurely 2-lobed. Fruit a subglobose berry c.1cm long, turning red or purplish-black, placentas not evident in fruit, sweet and aromatic when ripe, 'hot like black pepper' [see **Piper**] when unripe and dry; seeds 1-4, filling the cavity of the fruit, black, hard, shiny, curved at one end, rounded on one side, 5mm long, 4-5mm wide, with oily endosperm. Fl. Apr.-Jul.; fr. Aug.-Feb. or all year.

Common in thickets and woodlands, in arid areas, to c.400m; Florida, Bahamas, Cayman Islands, West Indies on the drier islands, to Barbados (Adams 1972; Fawcett & Rendle 1926), and southern Mexico.

Drimys winteri is a shrub or small tree, to 20m tall; trunk to 1m diam.; branchlets brownish or dark cinereous, rugulose or sometimes smooth, subterete, 3-6mm diam. towards apex. Leaves coriaceous or thick-coriaceous, pale green to dark brown above when dried, glaucous or at least paler below and usually distinctly punctate, usually obovate-oblong to elliptic, (2.5-)6-15(-18)cm long, (1-)1.8-6.5(-7)cm wide, attenuate to obtuse at base and decurrent on petiole, obtuse or rounded and sometimes faintly emarginate at apex, margin slightly recurved, costa nearly plane or shallowly canaliculate above, prominent beneath, secondary nerves 5-15 per side, ascending or erect-patent, prominulous or immersed, obscurely anastomosing towards margin; petioles rugulose, canaliculate, 3-27 x 1-4mm, slightly swollen at base. Inflorescences usually clustered at or near branchlet apices, umbellate, fasciculate, or flowers single; peduncles up to 50mm long when present; pedicels 10-70mm long; sepals 2, reddish, caducous, membranaceous to submembranaceous, usually obscurely pellucid-glandular, sometimes copiously so, broadly ovate to suborbicular or reniform, 4-7mm long, 4-12mm wide, apex apiculate to rounded; petals 4-14, shiny, white, membranaceous, sparsely pellucid-glandular, oblong to narrowly-obovate, 6-20mm long, 2-6(-7)mm wide, apex obtuse; stamens 15-40, 2-4-seriate; filaments carnose, eglandular or nearly so, 0.8-3mm long, the connective eglandular or rarely with few very inconspicuous colourless apical glands, locules 0.5-1mm long. Carpels (2-)3-10, obovoid to ellipsoid, 2-3.5mm long at anthesis; ovules 9-18 on short or slightly elongate placentas; stigma lateral near apex or rarely subterminal, peltate, subsessile or short-stipitate, exceeded or equalled by the body of the carpel. Berry 5-9mm diam.; seeds 3-4mm, black, shiny, lunate. Fl. Oct.-Mar.

Often in lowland areas with abundant water supply [0-300m], though some varieties are found up to 2300m; Chile south of 36ºS, w. Argentina south of 38ºS, to Tierra del Fuego (Moore 1983; Smith 1943). Some Drimys spp. previously classified as synonymous with D. winteri exist north to Mexico (theobromus pers. comm.).

CANNABIS

(Cannabaceae)

Cannabis indica *Lamarck* **(C. sativa ssp. indica** *(Lam.) E. Small et Cronquist***)** – Indian hemp, Afghan hemp, hash plant, da ma, huo ma, bang, kif, quinib, kinnab, sharâneq, shâhdânag, taima, maconha, dagga, dakka [other common names as for C. sativa may also be applied in some instances, and vice versa]

Cannabis ruderalis *Janischewsky* **(C. sativa f. ruderalis** *(Janisch.) Chu***)** – Russian hemp, ye da ma

Cannabis sativa *L.* **(C. gigantea** *Hort.***)** – hemp, common hemp, ganja, ganjika, gajima, siddhi, siddhapatri, bhang, bhangi, bhango, hanga, kinnab, hinab, quinnib, cares, ben, til, jaya, ununda, vijaya, kendir, kenevir, xian ma, ye ma, canapa, cáñamo, chanvre, chanvrier sauvage, echter hanf, riesen hanf, marihuana, marijuana, pot, mull, green, weed, dope, grass, kief [many, many other names]

Cannabis is the most widely-used illicit drug in the world [although not illicit everywhere], and has been used by Eurasian cultures for thousands of years for religion, medicine and fibre. Its history is long, intricate and colourful, and due to this, and the many excellent books devoted wholly to the subject, this history of use will only be discussed briefly here.

In India, Cannabis is compared to Soma [see **Amanita**], and is said to be a 'liberator of sin'. It is widely used by saddhus in consecration to Shiva, who is said to be perpetually intoxicated by it. The rest of the populace consumed it more commonly when it was not restricted there. Indians know the herb in three main forms – 'bhang' [the large fan-leaves of the wild plant made into a drink with water, milk and/or butter/ghee (clarified butter), sometimes fortified and flavoured with spices such as black pepper (see **Piper**) and aniseed (see **Pimpinella**)]; 'ganja', the dried, flowering tops, often seedless ['sinsemilla' in Spanish], with some leaves and stems; and 'charas' or 'hashish', the compressed resin from the flowering tops. Cannabis is also sometimes made into a confectionery called 'majun' or 'majoon', of Middle-Eastern origin. There are many recipes for this, but basically it is a blend of Cannabis, ghee, milk and sugar, as well as a selection of intoxicating herbs such as **Strychnos**, **Datura** seeds, **Areca** nut and poppy seeds or opium [see **Papaver**]. A blend using *camphor*, cloves [see **Syzygium**], nutmeg and mace [see **Myristica**] was said to be good for inducing fantastic dreams; one using 'ambergris' [a secretion from sperm whales] and 'musk' [see *Endnotes*] was suggested for enhancing mood and sexual adventures (Chopra et al. 1958, 1965; Clarke 1998; Kirtikar & Basu 1980; Mills 2003; Nadkarni 1976).

Cannabis is used by shamans in Nepal, for ritual incense, sacred offerings, pleasure and trance, either eaten, smoked or snuffed; it is also used for its variety of medicinal effects (Müller-Ebeling et al. 2002). Other cultures and sects are known to have used Cannabis sacramentally or medicinally, such as the Zoroastrians, Assyrians, Scythians, Taoists, ancient Buddhists, ancient Germans, the Essenes, Islamic Sufis, Bantus, the Hottentot, Rastafarians, and many others. It is generally ascribed powers that can allow one to come into contact with spirits. Cannabis was the main ingredient [with olive oil] of the anointing oil used by Moses to talk to God. Patanjali, founder of classical yoga, wrote that it "refreshes the intellect...fills the mind with happiness...the spirit of hemp is the spirit of peace and knowledge. In hemp ecstasy, the flash of eternity transforms the haziness of matter into pure light". It is also valued by many as an aphrodisiac [though excessive use can be anaphrodisiac], and is used in Indian tantric practices (Aldrich 1977; Herer & Jiggens 1995; Preston 2002; Rätsch 1990, 1992; Robinson 1996). It is widely used in Africa as a medicine and inebriant. In southern Africa, Suto women smoke themselves into a stupor during childbirth (Watt & Breyer-Brandwijk 1932). Traces of cannabinoids [see below] found in Ethiopian pipes dating to c.1320AD suggest that Cannabis has been a smoking herb in Africa since before the introduction of tobacco, which is now also widely consumed on that continent [see **Nicotiana**] (De Smet 1998).

The ancient Chinese knew of the psychoactive properties of C. sativa, though they usually used it only for seed and fibre – it was said that taking the fruits ['ma-fên'] in excess would cause one to "see devils" and, if taken over time, to "communicate with spirits". Necromancers were said to use it with ginseng [see **Panax**] to see forward in time. It was also sometimes used to see spirits, the 'raw fruits' mixed in equal quantities with **Acorus** gramineus and Podophyllum pleianthum ['k'uei-chiu'; see **Mandragora**], made into pills of marble-size; one was taken facing the sun every day, and after 100 days the desired effect ensued. In medicine, the fruits [which presumably included flower-bracts, as the seeds are non-psychoactive] were usually used as an anaesthetic (Li 1978). Today in TCM, as 'huo ma ren', they are used in doses of 9-15g as a mild purgative to treat constipation in elderly or debilitated people (Huang 1993). The seeds are a popular and nutritious food in China.

The Rastafarians are best known as a modern 'sect' who smoke Cannabis almost constantly, as they believe it is a gift from God that allows them to attain wisdom, and commune with God and all living things (Chevannes 1994; pers. obs.).

Cannabis was once better known by most for the fibre it produces, called hemp [or 'true' hemp], which has long strands of great strength. It has been used with great success in the manufacture of quality textiles, fabrics, paper, rope, string, art canvas, biomass fuel and building materials. Hemp plants are selected for high-fibre and low-*THC* content. The seeds and their nutritious oil can be used as food, and as a base for paints, varnishes and lighting oil. Being such a highly useful plant, Cannabis in all its forms was made illegal in the US in 1937, followed shortly by most

other countries in the world following US pressure. Although the public campaign of misinformation perpetuated by the media and narcotics agencies made it seem that the threat was a highly dangerous [even deadly!] and addictive drug that caused psychosis, the real threat seemed to be to the paper and newspaper industry giant W.R. Hearst [and other timber-based industries], petrochemical giant Du Pont, and then-head of the Federal Bureau of Narcotic and Dangerous Drugs Harry Anslinger [keeping his job required finding drugs and drug-users to persecute]. Legislation was rushed through congress, without the American Medical Association [AMA] being properly consulted, and with no pro-Cannabis evidence of any kind admitted. Most of the evidence produced against the herb was either a distortion of the facts, or simply fallacious. Even today, much of the so-called 'scientific' evidence against Cannabis on grounds of physical and psychological health, is based on faulty, misleading or false data. Gabriel Nahas, who was responsible for producing much of the older evidence, adopted his basic premises on the drug from the propaganda of his employers [probably coupled with his own subjective bias], and based his methods of research upon those of Nazi scientists; he thus proceeded to construct experiments to prove the false assumptions already in place. His work is now decried in the scientific community, and he still only holds a good reputation with those who are unaware of his being exposed as a fraudster (Herer & Jiggens 1995; Robinson 1996; Solomon ed. 1970). It should be noted that Cannabis research is illegal without Government permission and funding, and that in the United States at least, no such research will be funded unless it intends to show that Cannabis is a harmful substance. This in itself is a rather obvious perversion of science – to decide the outcome before conducting the experiments! 'Just Say No'-style groups are also mostly Government funded and backed, and seem to spend more time spreading ignorant fear-based factual distortions and lies about Cannabis, than any more dangerous illicit substances, such as heroin.

Prior to all of this, some countries had placed restrictions of one kind or another on the sale of Cannabis and preparations derived from it. 'Hashish' [see below] was banned in Egypt in 1879, though it was commonly smoked there in water pipes, mixed with tobacco and molasses; wealthier Egyptians were accustomed to smoking it in cigarettes, drinking it in coffee, or eating it. Great Britain enjoyed considerable profits from its taxation and control of Indian opium [see **Papaver**] and Cannabis crops, and for years resisted calls from the Egyptian government to curtail the flow of the latter drug across their borders, and from wowsers at home who wished to see the stuff banned. After delegates from the US and other smaller countries at the 1925 League of Nations Opium Convention ganged up to push the matter, Great Britain eventually tightened up controls on import and export and effectively turned Cannabis into a prescription-only medicine at home, a situation which stood until the 1971 Misuse of Drugs Act made it fully illegal (Mills 2003).

It should also lastly be said that numerous major, exhaustive studies on Cannabis use have been commissioned by various governments. In all cases, said governments have rejected the unanimous results obtained by impartial researchers – that casual Cannabis use is not a significantly harmful practice in the majority of users, that it causes no long-term deterioration of health, intelligence or work capacity, and that prohibition of the herb is a futile exercise that is doing much more harm than good. Some of these studies have been done in countries with a high rate of chronic use, such as India [the Indian Hemp Drugs Commission Report, 1894] and Jamaica [Jamaican Study, 1975]. Other studies have included The Panama Canal Zone Military Investigations [1916-1929], the 1981 UCLA Coptic Study [of Jamaican Rastafarians in Florida, smoking 16 large 'spliffs' a day], the 1980 Costa Rican Study, Mayor Laguardia's 1944 Committee on Marijuana [New York City], The Baroness Wootton Report [U.K., 1968], Nixon's 1972 Blue Ribbon Report [The Shafer Commission], Canada's 1970 Le Dain Commission, the 1996 Victorian Premier's Drug Advisory Council Report [The Pennington Report, Australia], and the Canadian Senate Special Committee on Illegal Drugs [2002]. Even the World Health Organization's [WHO's] own report, completed in 1998, has been suppressed from publication because it shows that Cannabis is safer than alcohol (Chopra et al. 1958; Concar 1998a; Herer & Jiggens 1995; Mills 2003; Solomon ed. 1970). Even studies finding that Cannabis and some of its individual constituents may be useful in destroying tumours (eg. Galve-Roperh et al. 2000; Piomelli 2000) have been routinely ignored, and other existing studies showing medicinal usefulness have similarly remained obscure. This situation of information control is at its worst in the US, where during the Reagan era, such studies were systematically removed from libraries across the country and destroyed (Trout pers. comm.).

As I write, and as has occurred whenever it seems that Cannabis may be becoming more socially acceptable and/or tolerated, and suggestions for decriminalisation are made publicly, there is yet another flourish of Nahas-like anti-Cannabis 'science' in popular circulation. Again we are being told that smoking Cannabis causes psychosis and schizophrenia, despite strong evidence to the contrary [ironically, in the 19th century some British doctors used it successfully (sometimes with potassium bromide) to treat insanity (most effectively for manic patients), as well as migraine, menorrhagia and tetanus (Mills 2003)]. It should be stressed that Cannabis can indeed exacerbate pre-existing or latent schizophrenia in some people [though I know one schizophrenic person, and have heard of many others, for whom it helps keep symptoms at bay]. However, the overwhelming quota of perfectly sane and relatively healthy Cannabis users is adequate testimony to the relative innocuity of the herb in well-adjusted individuals. For such people, it is generally true that the only adverse effects would result from the act of smoking burning plant matter. This is, of course, avoided if the herb is prepared and eaten, or if Cannabis resin or a purified 'hash oil' is vapourised and inhaled. Incidentally, anti-Cannabis groups have made much mention in recent years of the higher potency of today's marijuana being of great concern. Despite average potencies generally being greatly exaggerated in such arguments, both common sense (pers. obs.) and laboratory experiments show that Cannabis of higher potency leads to less inhalation of tars, as less of the herb needs to be smoked to obtain a satisfactory effect, and of the herb smoked, there is less chlorophyllous matter (Matthias et al. 1997). Needless to say, even with such potent material, some users - especially young males - still will smoke large quantities all day long, often staring at a screen and eating junk food the whole time, and it is little wonder that some such people experience problems after a while, but no excuse to ban the drug for everyone. Also, many psychological problems experienced by people who abuse Cannabis are simply part of the spiritual journey that the user probably doesn't even know they're on, and could be worked through healthily in a society where such realms of consciousness were appreciated and understood to a greater degree [see *Questions and Answers*, *A Primer on Tripping*], rather than requiring psychiatric intervention. Recent reports of deaths from Cannabis overdose appear to have little scientific basis, jumping to conclusions where cause of death is not actually known, and/or a connection with Cannabis as a causative agent is not proven, only assumed. Even if such reports were accurate, Cannabis would still be safer than many legal drugs, alcohol and tobacco included. However, people with heart conditions should take special care, as smoking – Cannabis or anything else – may increase the risk of heart attack (pers. obs.; Sidney 2003).

Cannabis is often smoked in hand-rolled cigarettes ['joints', 'reefers'], very large joints ['spliffs', 'carrots', 'Cambridge carrots'], wrapped in a cigar leaf ['blunts'; in tobacconists in some countries, cigar leaf wrappings may be purchased in packets, exclusively for the purpose of rolling blunts], in a dry pipe, in a 'chillum' or 'chilam', or in a water pipe ['bongs', 'cones', 'pipes', 'billies'] [see *Methods of Ingestion*]. It is often chopped with tobacco [see **Nicotiana**] for use, though many prefer to smoke it by itself, sometimes even unchopped, simply putting a chunk in a pipe and lighting it. Oddly, in view of the large number of Cannabis smokers who mix with tobacco and like it that way, Rätsch (1990) stated that "tobacco is fully unsuited as an admixture, for its effects directly contradict those of marijuana".

With fine quality flowering tops ['buds', a term that is botanically incorrect in this application, but is widely used nevertheless], less than 50mg of herb may be required, depending on individual tolerance. Perhaps 300mg or so is often needed to make an average-sized joint, more if no tobacco or other mixing herb is used. Effects are felt within several minutes, often almost immediately. It may also be eaten, in which case the resins of the herb must be dissolved in a fat before consumption to be effective. Roughly 3-4 times the amount used for smoking is required, and effects are usually not felt until 0.5-2 hours after consumption, lasting 6-8 hours or so [depending on dose] (pers. obs.). The qualitative and quantitative differences in the eating experience are partly explained by the metabolism of *THC* via this route to the more potent 11-OH-*THC* (Clarke 1998).

A preparation much sought-after is 'hashish' ['hash', 'charas'], which consists of the pressed resin glands of the flower-heads and potent leaves, as noted above. These glands coat the surface of the plant, and are most concentrated in the female flowers; they contain the psychoactive terpenoids of Cannabis spp., often referred to collectively as cannabinoids. Hashish is produced in many countries famed for their export [mostly to Europe], ranging from n. Africa to s.e. Asia, and samples from different regions often have recognisable differences in appearance, smell, psychoactivity and method of manufacture. This resin is traditionally collected in one of two ways – hand-rubbing, involving literally rubbing the mature flower-heads of a live plant, and scraping the accumulated resin from the hands [after blowing away other plant debris]; or sifting, whereby the mature plants are harvested and thoroughly dried, before being lightly threshed over a silkscreen sieve, with a bowl underneath to collect the finest quality resin glands, visible in mass as a sandy-yellowish powder [or clear, resinous globules under a microscope]. The flower heads are never sieved for too long, to maintain a high quality of potency, as dried plant-matter can begin to crumble finely enough to pass through the sieve. Sifting can usually be done only in dry, relatively cool, and breeze-free conditions; this is perhaps one reason why it has always been a more popular method in the Middle-Eastern hashish-producing countries than in s.e. Asian hashish-producing countries, where hand-rubbing is often preferred [although sifting is sometimes practiced in India]. Hand-rubbing may be more convenient under some circumstances, but sifting produces

a better yield for less effort, and collects resin of a higher quality and purity if done properly. Once the resin is collected, it must be further processed to produce a quality hashish product for trade, or it can be smoked or vapourised as it is. Hand-rubbed resin is usually rubbed from the hands [which warms and softens it], pressed together, and hand-rolled vigorously for hours until a ball or other desired shape is formed with an even consistency, and smooth, shiny, unbroken skin. Sifted resin may be either hand-pressed, or poured into bags which are usually heated before pressing in a hashish-press, forming solid slabs. Poorly pressed hashish will usually deteriorate rapidly, often due to internal mould-growth and excessive drying. Hashish should be stored in a cool, dark, airtight space as for most other active substances. It may be smoked by inhaling the fumes from a smouldering ball or stick of the resin – once lit and any flames have died or been blown out, it should burn with a slow glowing ember like an incense stick. A popular method is the 'hot-knives' approach, which involves pressing a lump of hashish or resin-powder between two heated knives, and inhaling the vapours emitted through a bottomless bottle, inverted funnel, or similar device. Otherwise, it may be smoked in a pipe fitted with a metal screen, or may be crumbled, heated slightly, and mixed with Cannabis herb and/or tobacco [see **Nicotiana**] or other smoking herbs, and smoked in other ways. Hashish may contain on average up to 26% *THC* or more, 16.5% *cannabidiol* [CBD] and 9.1% *cannabinol* [CBN], though levels can be very variable (Cherniak 1995; Chopra et al. 1958; Clarke 1998; Nadkarni 1976).

Modern innovations in home hashmaking have resulted in some simple technology for collecting Cannabis resin. The Dutch Pollinator Company [www.pollinator.nl] have invented a small motorised tumbler, fitted internally with a fine mesh screen, called the Pollinator®, which collects resin on the inside walls of the unit due to centrifugal force. This was recently followed by the Ice-o-lator®, a specialised fine mesh bag device which operates on the principle that powdered Cannabis immersed in ice-chilled water will separate into plant matter and resin, allowing the resin to be retrieved and dried (Pollinator staff pers. comm. 2002). The finer grades of resin collected using such bags produce what has become known as 'bubble hash', a very pure and potent product so-called because it bubbles when heated (pers. comms.). The tumbler technique can also be adapted for hand-powered rather than motorised use. The water separation technique can be more crudely achieved by vigourously shaking very dry powdered, sieved Cannabis in chilled water and leaving to settle; plant matter should float to the top, and resinous material should collect at the bottom of the vessel (Clarke 1998).

In some countries today, the hash available on the street is sometimes a brown, oily, soapy substance which is highly adulterated with non-psychoactive contaminants, as well as possibly others such as animal tranquillisers; it is known as 'soapbar' in the UK, 'chocolate' in Spain and 'Chernobyl' in France (Preston 2002).

Several interesting Cannabis preparations have been observed within modern drug culture, as attempts to increase the potency of the herb. One involves boiling the herb in water for 1-3hrs, adding water as needed, before cooling and straining through cheesecloth; the liquid is set aside under refrigeration, while the remaining herb pulp is air-dried. The tea is consumed, followed by smoking of the herb, and the experience is said to be more psychoactive than usual (Segelman & Sofia 1973). If accurate, this may be due to the added activity of trace water-soluble constituents, such as the uninvestigated alkaloids [see below]. Another preparation is not so innocuous, and has been called 'AMP' – it is Cannabis that has been soaked in formaldehyde and dried. The preparation is more psychoactive than untreated Cannabis, but causes lasting psychomotor retardation, as well as tachycardia, salivation, sweating and tremors whilst intoxicated (Spector 1985). Solvents such as this might have occasionally been encountered as contaminants when 'Skunk' [see below] first became more widely available, as naïve customers would have been looking for 'stinky' flower heads with an aroma unlike Cannabis encountered previously [except perhaps for some high-quality Afghan C. indica] (pers. obs.). The sought-after 'Thai sticks', Thai C. sativa flower heads wrapped around a stem with bamboo fibre, are apparently laced with fresh opium juice from the first lancing of poppy pods [see **Papaver**], although many non-native consumers are unaware of this (Preston 2002).

Over the last couple of decades, great advances have been made in Cannabis cultivation, with innovations in indoor growing technology and breeding largely coming from Amsterdam [the Netherlands] and British Columbia [Canada]. Indoor cultivation, especially, has become a valued option in climates where outdoor cultivation would not produce quality plants, in areas where outdoor cultivation is too risky a venture, and in locales where no outdoor garden space is available for use. As a result, more potent strains and hybrids with larger flower heads and greater resin-production have been made more and more available. Needless to say, this is also thanks to the efforts of brave cultivators and breeders worldwide, wherever these plants are not tolerated. The popular 'Skunk' was one of the first 'super strains' to emerge in the 1980's [though developed by growers in The Netherlands in the late 1970's]. It was a plant c.60cm at maturity with one very large terminal inflorescence and several smaller ones, bred specifically for a short growing season [several months], high-yield and high-potency, to be grown indoors under high-powered grow-lights in a hydroponic system. The original Skunk ['Skunk #1'] was a hybrid between two C. sativa strains [50% 'Colombian Gold', 25% Mexican 'Acapulco Gold'] and a C. indica strain [25% 'Afghani']. More recently, a C. ruderalis 'Skunk' strain has been developed. Seeds of the notorious S. African C. sativa strain known as 'Durban Poison' [named from its origin] are now also available to cultivators through Dutch seed companies. The current variety of available strains is mind-boggling even for the Cannabis connoisseur, with varieties to cater for every taste in appearance, aroma, taste, qualitative/quantitative effect and other delicate characteristics (Dutch Passion 2002; pers. comms.; pers. obs.). They are truly beautiful flowers!

Cannabis is euphoric, hypnotic, sedative, mildly psychedelic, antidepressant, antispasmodic, analgesic, expectorant, antibiotic and appetite stimulant. It also relieves nausea and reduces saliva. It treats glaucoma by reducing intra-ocular pressure. Cancer patients find it invaluable in relieving the nausea, vomiting, and loss of appetite associated with chemotherapy. AIDS patients suffering the 'wasting syndrome' also benefit from this stimulation of appetite. However, too much may cause nausea and sometimes vomiting. People with spastic disorders may obtain remarkable relief due to the anticonvulsant and muscle-relaxant effects. It may also treat asthma – in some people it acts as a bronchodilator, but in a minority the condition is worsened [for these people, oral ingestion is preferred over smoking]. Cannabis can also supress some tumours, and relieve some types of chronic pain, such as migraine. In many cases where Cannabis is most useful medicinally, it provides therapeutic relief where all other available drugs have failed. The use of whole Cannabis herb is more effective than *THC* alone. Cannabis is also very non-toxic. As Grinspoon & Bakalar (1995) put it, "the ratio of lethal to effective dose is estimated as 40,000 to 1. By comparison, the ratio is between 3 and 50 to 1 for secobarbital and between 4 and 10 to 1 for ethanol." Although the cannabinoid resins are highly lipid-soluble, and remain in body fat for 48 hours or more after consumption, brain levels are relatively low. The cannabinoids are metabolised rapidly. There is no evidence that they cause breakage of chromosomes, immune-suppression in reasonable doses, or brain damage [one major component, *cannabidiol*, actually protects neurons from damage (Aesoph 1998)!].

The interactions between several important cannabinoids [*THC*, *cannabidiol* (*CBD*) and *cannabinol* (*CBN*)] are discussed further in the *Chemical Index*. It is worth noting that the amount of resin present does not necessarily dictate potency – this quality lies in the constituents of the resin and their relative proportions. Likewise, a sample of Cannabis high in *THC* is not necessarily more subjectively potent than another sample which may be low in *THC*, but richer in other related compounds. The field of subjective potency is also confused by the observation that different people prefer different kinds of effects from this plant. Varying proportions of *THC*, *CBD* and *CBN* give differing subjective experiences. Some people prefer the cerebral 'high' of material high in *THC* and low in other cannabinoids, whilst others prefer the heavy 'stone' resulting from material also high in *CBD* and *CBN*. Short-term side-effects include red eyes, dry mouth, raised pulse rate, raised body temperature and tachycardia. Short-term memory recall is also affected. Some people develop panic-attacks at higher doses; this is usually environment-related, or based on fears of insanity [from experiencing a stronger-than-expected altered state of consciousness] or arrest by police. Paranoia sometimes occurs during the intoxication, usually for similar reasons. Some people just seem to be very sensitive to the herb, and may 'freak out' at any dose. People with latent schizophrenic tendencies should not use Cannabis. Any negative psychological, cognitive or physical effects of Cannabis use are reversed with abstinence, even after heavy long-term use (Grunfeld & Edery 1969; Pope et al. 2001; Weil et al. 1968; pers. comms.; pers. obs.). One of the best-known effects of Cannabis is the stimulation of appetite, fondly referred to by users as 'the munchies'; if Cannabis is smoked regularly mixed with tobacco, this effect may be at least partially counteracted. Recent research has demonstrated that endogenous cannabinoids [eg. *anandamide*, 2-AG – see *Neurochemistry*] stimulate feeding in newborns, and are very important in survival and development in the early stages of life (Phillips 2000).

Although Cannabis can hinder 'normal' cognition, concentration, coordination and reaction speed during the normal course of effects, for most regular users it usually does not adversely affect driving ability except in high doses, or in combination with certain other drugs, particularly alcohol. Drivers affected by Cannabis alone tend to be more careful on the road to compensate for any impairment, as opposed to drivers under the influence of alcohol, who tend to over-estimate their abilities and under-estimate their degree of inebriation, often driving recklessly as a result. A person who is too stoned to drive is more likely to wait until the effects wear off before taking to the road (Cohen & Stillman ed. 1976; Coper 1982; DETR 2000; Dews et al. 1973; Goode 1970; Grinspoon & Bakalar 1995; Herer & Jiggens 1995; Mendelson et al. 1974; pers. comms.; pers. obs.; Robinson 1996; Weil et al. 1968). Nevertheless, this is not always the case, and it is never advisable to operate dangerous machinery [such as a vehicle] whilst intoxicated, as in the unpredictability of life a

minor degree of impairment can make the difference between having an accident or not.

Flowers of male plants contain some active resins, but are usually not very potent. Bracts of male flowers generally produce more *CBD* and cannabichromene than *THC*. Leaves can also bear resin glands, generally higher in *CBD* and *CBN* than *THC*, and are also not very potent, with some exceptions. Small upper leaves and new shoots can be sometimes quite potent, though leaves lose potency as they mature. Central leaflets may contain slightly higher cannabinoid levels than the adjacent leaflets, with concentration decreasing slightly in each subsequent adjacent leaflet. Leaves subtending flower bracts have similar cannabinoid profiles to the accompanying bracts, but in lower concentration. Potency of plant parts generally decreases going down the plant. Stems can bear some resin glands on the surface. Even cotyledons of seedlings have been shown to accumulate cannabinoids. Weaker plant parts may be used to make 'hash oil', or in cooking (Hemphill et al. 1980; pers. obs.).

Fresh or growing plants contain the *THC*s and other cannabinoids mostly in the inactive acid forms; heating [such as when smoking or cooking the herb] decarboxylates them to their neutral, active forms [eg. THCA decarboxylated to form *THC*]. Drying is thought to achieve some degree of decarboxylation. A small amount of decarboxylation occurs in the gut, but large amounts of unheated fresh Cannabis would have to be eaten to produce much effect. However, in the absence of air, cannabinoids are stable to heat (Clarke 1981, 1998; Mechoulam 1970; Turner et al. 1980).

C. indica contains similar constituents to C. sativa [and is reputedly often high in *CBD*] (Clarke 1998); verifiable analyses of this species are scarce, as many researchers do not distinguish it from C. sativa. Many studies that do purport to analyse C. indica are actually analysing hashish that was presumed to have come from C. indica.

C. ruderalis has yielded c.0.45% cannabinoids, less than 40% of which was *THC*. C. sativa x ruderalis yielded 0.36-1.3% cannabinoids, of which 30-60% was *THC* (Beutler & Der Marderosian 1979).

C. sativa has been found to be represented by 4 chemotypes – 'fibre' types, which are low in Δ-9-*THC* [<0.3%] and high in *CBD* [>0.5-2.4%]; 'intermediate' types which contain Δ-9-*THC* and *CBD* in amounts greater than 0.5%; 'drug' types, which are high in Δ-9-*THC* [>2%] and low or deficient in *CBD*; and uncommon 'cannabigerol-dominant' types, which contained low quantities of Δ-9-*THC* [0.001%], 0.04% *CBD* and 1.15% cannabigerol (Fournier et al. 1987). In general, C. sativa may yield mostly [0.3-20% or more] Δ-1-tetrahydrocannabinol [Δ-9-*THC*; *THC*], as well as Δ-6-*THC* [Δ-8-*THC*; similar activity to Δ-9-*THC*, but ¾ as potent], their 11-OH-derivatives [of similar activity, but with more intense onset of effects, and longer duration], 8-α-OH-*THC* [similar activity to Δ-9-*THC*, milder, c.¼ the potency], tetrahydrocannabinolic acid [THCA], Δ-9-tetrahydrocannabivarin [THCV; similar effect to Δ-9-*THC*, but ¼ as potent], *CBN*, *CBD*, cannabidiolic acid [CBDA], 10-ethoxy-9-OH-Δ-6a(10a)-*THC*, cannabitriol [9,10-dihydroxy-Δ6a(10a)-*THC*], cannabigerol, cannabicitran, cannabichromene, cannabichromanon, cannabielsoic acid A and other cannabinoid-acids, cannabicyclol, 4,4-dihydroxy-5-MeO-bibenzyl [shows some estrogenic activity], *eugenol*, guaiacol, humulene, *camphor*, camphene, *borneol*, 1,8-cineole, *pinene*, safranal, nerol, neral, ocimene, limonene, linalool, citronellol, α-*thujone*, pulegone, fenchone, myrcene, α-trans-bergamotene, piperitone, ledol [see **Ledum**], longifolene, 0.001% *hordenine*, *choline*, piperidine, muscarine [see **Amanita**], trigonelline, cannabamines A-D, anhydrocannabisativine [a spermidine alkaloid], cannabispiran, flavocannabiside, flavosativaside and orientin; many other trace compounds are present. Roots have been shown to contain the alkaloid cannabisativine (Clarke 1981, 1998; Dews et al. 1973; El-Feraly & Turner 1975a, 1975b; El-Feraly et al. 1976; Hollister 1974; Lotter et al. 1975; Mechoulam 1970, 1982; Rastogi & Mehrotra ed. 1990-1993; Segelman et al. 1976c; Turner & Elsohley 1976; Turner et al. 1976, 1980; Wirth et al. 1981), and surprisingly, roots also contain cannabinoids – one study found Δ-9-*THC*, Δ-9-THCA, Δ-8-*THC*, *CBD*, CBDA, *CBN*, cannabichroman, cannabicyclol, and cannabigerol in roots of a hemp strain of C. sativa (Hanus & Tesarik 1987).

Experiments with Italian cultivated C. sativa found that plants which were shaded and not irrigated were higher in *THC* [1.59%]; plants which were exposed to more light, but also not irrigated, contained the highest levels of *CBD* [0.67%]. Levels of *CBN* were low [0.03-0.07%] in all plants (Siniscalco 1985).

C. sativa seed contains a nutritious oil, with c.80% essential fatty acids; total oil may yield c.55% linoleic acid and 25% linolenic acid [supports immune function, maintains healthy skin, hair, eyes, nervous system and other tissue]. It is high in the edible proteins edestin and albumin, and also contains trigonelline, 2(d)-isoleucine, betaine, choline, vitamins B1 and B2, and traces of muscarine, *THC*, *CBD* and *CBN* (Herer & Jiggens 1995; Huang 1993); the traces of cannabinoids may possibly be due to contamination with flower-bracts. Others have noted the absence of cannabinoids in seeds from both 'drug' and 'fibre' strains (Hemphill et al. 1980), though the detection apparatus may not have been sensitive enough.

C. sativa pollen has been reported to be rich in Δ-9-*THC* [traces-0.26%] and THCA [levels were highest in plants grown under 16hr light at 24°C], also containing Δ-6-*THC* [0-0.02%], *CBD* [0-0.02%], *CBN* [0-0.05%] and cannabichromene [0-0.2%], as well as *apigenin* and luteolin. The analyses conducted by Hemphill et al., however, revealed [by electron microscope] the pollen samples of their study to be contaminated by resin glands. This common and unavoidable contamination is thought to be responsible for all reports of cannabinoids in the pollen (Hemphill et al. 1980; Paris et al. 1975).

It is of interest to note that Phelipaea ramosa [Orobanchaceae], a plant parasitic on C. sativa, has yielded 0.5-1% cannabinoids, of which c.95% was *CBD*, with traces of Δ-9-*THC* (Fournier & Paris 1983).

Cannabis sativa is an aromatic, resinous, scarcely branched erect annual herb to 2(-6)m high; usually dioecious, but sometimes hermaphroditic. Staminate plants tall, slender, dying after anthesis; pistillate stockier, more densely leaved in flowering, rarely perennial. Stems furrowed, often hollow, roundish, or angular in cross-section, scabrous, resin-dotted on younger growth. Leaves alternate, the lower leaves opposite, 5-15-partite, upper leaves often only 1-3-partite, palmatinerved, serrate, apex acuminate; leaflets sessile, +- slender-lanceolate, long-acuminate, very variable in size, 6-11(-20 or more)cm x 0.2-1.5(-3)cm, upper surface dark green with stiff, conic trichomes, underside pale green with distant brownish resin dots and strigose hairs; petioles 4-6cm long; stipules small, triangular, lateral, persistent. Flowers small, axillary, dioecious – males in short, pendulous cymose panicles; females crowded in leafy, convolute resinous bracts in dense axillary and terminal clusters. Males: pedicellate, pendent at maturity, falling after shedding pollen; tepals greenish, sometimes yellow or brownish purple, quincuncial in bud, spreading at anthesis, usually c.5mm long; perianth segments 5, imbricate; stamens 5, erect in bud; anthers pendent, dehiscing by apical pore, glandular hairs at junction of anther lobes. Females: usually in pairs, sessile, each enclosed in membranous green perigynous bracteole, subtended by bract; perianth hyaline, entire, embracing the base of the ovary, or 0; ovary sessile; style central, deeply bifid, c.5mm long, filiform, caducous, white at first, turning brown-reddish; ovule pendulous. Fertilised female bracts bear a single achene, c.3-5 x 2mm, ovoid, slightly compressed, with 2 faces, aril on flattened base, tip pointed, testa shiny, often reticulate, sometimes brownish, olivaceous-brown to ash-grey, sometimes mottled with black, covered by persistent calyx and enveloped by bract. Immature or infertile seeds are easily crushed with light pressure between the fingers. Fl. mid/late summer to late autumn; often forced to flower out of season with indoor cultivation, by manipulation of the light/dark cycle.

Native to temperate central Asia; widespread in cultivation and as a weed in temperate and dry-tropical parts of both hemispheres (Chopra et al. 1965; Schultes & Hofmann 1980; pers. obs.).

Cannabis indica is usually smaller and more compact, being much-branched. Its leaflets are shorter and wider, and flower clusters are often more compact and resinous.

Cannabis ruderalis is a wild Russian species that is even smaller [10-50cm high], and has a shorter life-cycle [8-10 weeks], though generally not of much use as a psychotrope (Clarke 1981).

Cannabis spp. are easy to cultivate, though to do so is illegal in most countries. There are many excellent and detailed books on its cultivation, some of the best written by Mel Frank and Ed Rosenthal. So, we will not go into detail about that here... There are two things which I believe should be stated, though. One is that a strong light source is essential for producing dense, resinous flowers. Another is that continuing regular application of fertiliser into the late flowering period can result in undesirable accumulation of nutrients in the flower heads, adversely affecting aroma, flavour and presumably, health [a hint to those inexperienced cultivators everywhere who are supplying such questionable produce].

Flower heads are considered mature for harvesting when maximum size development seems to have been reached, and many [but not all] of the styles have turned reddish-brown and begun to shrivel. The exact time of harvest is a matter of choice, with later harvests tending to be a little lower in *THC* and higher in *cannabinol*. Subjectively, however, some such late harvests can be exceedingly potent! Often, crops are tended so that no male flowers are allowed to pollinate the females [which is done easily by wind]. This requires constant observation for the first signs of developing sexual characteristics, so that male plants can be weeded out. Female plants also need to be watched after this period, as they may sometimes turn hermaphroditic and develop male flowers in amongst the female majority, which need to be picked carefully off before opening and releasing their pollen. When pollination is thus prevented, no seeds develop in female flowers, and greater energy is diverted to resin production. Such a seedless bud is called 'sinsemilla' [Spanish, roughly 'seedless-one']. However, it is difficult to follow this method to perfection, as all it takes is one male flower to produce some small amount of seed throughout a crop. This is generally regarded as acceptable, as long as the seed content is kept to a minimum. It can be very disappointing to find that much of the weight of a bud consist of seeds, especially if you have had to purchase it.

After harvest, some people simply hang the whole plant upside down to dry. It is preferable to cut individual branches for drying, to decrease

the drying time. When cut individually, branches or buds may also be dried carefully in cardboard boxes or paper bags. They must be checked regularly for mould or insect infestation, and turned for even drying. Turning should be done carefully as resin glands can easily dislodge or be crushed with careless handling. Drying should be done in a dark or dimly-lit cool area. The herb is considered ready when mostly dry and slightly flexible, not brittle. Although drying quickly in a conventional or microwave oven is feasible, Cannabis must be dried slowly and carefully [cured] without heat to maintain its aroma and develop its full potential of flavour and quality of effect (Clarke 1981; pers. obs.). In 19th century India, harvested bundles of the plant were trampled under mats for 4 days [rolling the plants was preferred in Bengal], believed to be necessary to properly develop the chemistry of the herb (Chopra et al. 1958; Mills 2003). Much commercially-available Cannabis in countries where it is illegal appears to have been treated in this way, but this is due to carelessness and compression for ease of smuggling, rather than out of an attempt to improve the product. It is doubtful that compression is necessary, as processing without such rough treatment often produces a superior drug, due to the resin glands remaining mostly intact until consumption (pers. obs.).

Hemp strains are usually grown close together, to encourage long, straight stems with few lateral branches. Stems can be harvested any time for fibre once sufficiently large, but before the fibres start to become too hard. Stems are 'retted' to free the fibres; this involves repeated soaking in water and laying out on the ground to be attacked by microorganisms. After this process is complete, the fibres are dried thoroughly and bundled for storage. Leaves and waste after retrieving fibre from the stems are used for pulping. Seeds are collected from fertilised female flower heads when ripe – that is, when the seeds easily fall from the flower calyces. They must be cleaned of plant matter and dried before storage (Clarke 1981).

The closely related **Humulus** lupulus ['hops'] has been experimentally grafted onto Cannabis sativa root-stock, but cannabinoids did not carry through to the hops grafts (Crombie & Crombie 1975). Cannabis growers had hoped that such a graft could be used to produce inconspicuous hops vines containing cannabinoids.

For excellent coverage of Cannabis in detail see the great works of Cherniak (1995), Clarke (1981, 1998), Herer & Jiggens (1995), Frank & Rosenthal (1978), Robinson (1996) and Solomon ed. (1970).

CAPSICUM

(Solanaceae)

Capsicum annuum *L.* **(C. conoide** *Mill.***; C. fasciculatum** *Sturtev.***; C. frutescens** *L.***; C. grossum** *L.***; C. longum** *DC.***; C. minimum** *Mill.***)** – sweet pepper, cayenne pepper, goat pepper, bird pepper, spur pepper, chilli, chili, hot chilli, capsicum
Capsicum chinense *Jacq.* – giimo
Capsicum spp. – khursani ['millipede']

It may come as a surprise to see these common fruits included here, yet several points of reference suggest that they may be considered to have psychoactive properties. Chillis are, of course, much used in cooking, and are known to stimulate circulation, preserve or disinfect foods, and ease sore throats; they are also high in vitamin C (Bremness 1994). However, the Culina of the Amazon sometimes eat a Capsicum sp. known as 'catsi' when they take ayahuasca [see **Banisteriopsis**] (Rivier & Lindgren 1972), and wives of Waorani shamans give their husbands C. chinense to bring them out of the effects of **Banisteriopsis** muricata (Davis et al. 1983). The Kakusi of British Guiana use a Capsicum sp. as a stimulant and excitant (Schultes 1966, 1967a). In Peru, the fruits have sometimes been used with tobacco [see **Nicotiana**] as a hunting aid. One person smokes the mixture, and blows the smoke up the nose of another, to improve their sense of smell (Bear & Vasquez 2000). In n. Ghana, red peppers are an ingredient of a composite intoxicating snuff, taken for shamanic initiation [see **Piper 1**]. In Angola, red pepper is sometimes added to tobacco snuff [see **Nicotiana**] if a 'stronger stimulation' is required (De Smet 1998).

In India, Capsicum spp. are considered powerful stimulants, and Ayurvedists use C. annuum fruit to treat delirium or loss of consciousness; the same fruit is also used to treat delirium tremens in Madagascar. Fruits of C. annuum and C. baccatum are also used in preparation of some arrow poisons (Kirtikar & Basu 1980). The Lisu of n. Thailand use the roots of C. annuum to treat numbness or paralysis (Anderson 1993). In Nepal, Capsicum spp. fruits [such as the very hot C. annuum variety, 'dhalo khursani'] are an ingredient of 'bokshi dhup', an incense used to protect against witches (Müller-Ebeling et al. 2002). The Cherokee also consider C. annuum to be a powerful stimulant (Hamel & Chiltoskey 1975).

Nowadays, hot chillis are extracted and concentrated into 'capsicum spray' or 'pepper spray', used by police forces in many countries. This is sprayed into the eyes and face to incapacitate felons [as well as passive protesters], a very dangerous useage which can lead to asphyxiation in some asthmatics if medical attention is not provided quickly. These substances are also highly irritating and painful when brought into contact with facial openings.

Smoking 'paprika' [which is prepared from a variety of C. annuum] has been rumoured to lead to a "powerful experience". A similar rumour has been circulating for decades about 'sweet green peppers' [also derived from C. annuum]. These are apparently left to rot until well-decomposed, and the rotted pulp is either smeared onto a cigarette and smoked, or a cigarette is inserted into the hollow of the pepper and the smoke drawn through the vapours of the decomposition by-products. This is claimed to produce hallucinations within 1 hour of smoking (Moore 1967; Weil 1969). Personal experiments have been inconclusive, and these claims may well be fallacious 'street myth'. There is the possibility that the initial experiments that led to these claims involved a specific mould-infection that could have contributed to, or created, the effects. Such a chance infection would be unlikely to be repeated reliably by chance, and would probably also be detrimental to health if inhaled [see also **Aspergillus**] (pers. obs.). As far as 'powerful experiences' go, one friend who smoked **Cannabis** which had inadvertently been chopped in a bowl previously used for chilli, did indeed report a powerful experience – powerfully hot and irritating (pers. comm.)! However, people who enjoy eating hot chillies undeniably do so because of the high that is experienced after pushing through the pain barrier; this is best achived by continuing to eat more chilli rather than taking breaks to recover. In the words of Andrew Weil, "One is then able to glide along on the strong stimulation, experiencing it as something between pleasure and pain that enforces concentration and brings about a high state of consciousness." As chilli eaters know, drinking water does not ease the heat and may even intensify it (Weil 1976a).

Capsicum spp. contain capsaicin, which is largely responsible for chilli's physiological effects, acting as a 'neurotoxin', stimulating gastric and nasal secretion, stimulating respiration, stimulating subtance P release [see *Neurochemistry*], and causing inflammation of mucous membranes, hypertension and later hypotension, brachycardia, broncho-constriction, hypothermia, long-term analgesia and peripheral vasodilation. The fruit also potentiates the activity of *theophylline*, increasing its absorption and bioavailability (Fugh-Berman 2000; Hall 1973; Nemeth et al. 1999; Suzuki & Iwai 1984), and is rich in vitamin C. Interestingly, even high doses of chilli do not harm the stomach or skin, and the fruit is used by herbalists to treat digestive complaints, ulcers and pain [it may be applied as a poultice, gargled for sore throat, and used (as the oil) to give long-term relief of toothache] (Weil 1976a).

C. annuum leaves have yielded the *phenethylamine* octopamine [0.0234% w/w] and an unidentified alkaloid (Wheaton & Stewart 1970), and roots have yielded *scopoletin* [0.0008% w/w] (Kala 1958). Rotten peppers [C. annuum] were reported to contain a *tryptamine*-like substance, which has not been formally identified (Weil 1969). The endosperm and embryo of the seed have yielded solanine and solanidine [see **Solanum**] (Wojciechowska & Dombrowicz 1966).

Leaf and root-bark of C. fastigiatum from Rockhampton, Queensland [Australia], harvested in December, tested strongly positive for alkaloids (Webb 1949).

Capsicum annuum is a shrubby perennial herb 75-180cm tall, glabrous or nearly so; branches angular. Leaves broadly ovate, acuminate, usually wrinkled, +- pubescent. Pedicels slender, usually 2 or more together, 2.5-5cm long; calyx embracing base of fruit, usually cup-shaped; corolla rotate, white or greenish white, often with ochreous markings in throat, 5-lobed, valvate in bud; stamens 5, attached near base of corolla; anthers not longer than filaments, dehiscing longitudinally. Ovary 2- or rarely 3-celled; style linear; stigma subcapitate. Fruit red, ovoid, obtuse or oblong, acuminate, many-seeded; seeds discoid, smooth or subscabrous.

Native to tropical America, widely cultivated (Kirtikar & Basu 1980).

Some consider C. frutescens and C. annuum to be separate species; even in this case, both are very variable and can be easily confused. Many hybrid strains and cultivars exist of these plants, giving rise to the wide variety of different chilli and capsicum fruits.

CARDAMINE

(Brassicaceae)

Cardamine concatenata *(Michx.) O. Schwarz* **(Dentaria concatenata** *Michx.***)** – toothwort
Cardamine hirsuta *L.* – common bitter cress
Cardamine spp. – pepper root

The little-known herb C. concatenata has been used by Iroquois shamans as a hallucinogen, and to 'mesmerise' (Ott 1993). C. hirsuta, growing as a weed in Victoria [Australia], has mild sedative and hypnotic effects when smoked. A large joint containing the dried and chopped whole plant [including roots and immature fruits] was sufficient to produce these effects, though the smoke was very hot and the taste chlorophyllous (pers. obs.). The related C. diphylla, 'crinkled toothwort', is used by the Cherokee as a poultice for headaches; the root may also be chewed for colds, or a root tea gargled to treat sore throats. The leafy parts of many

Cardamine spp. are eaten by indigenous peoples as a vegetable (Hamel & Chiltoskey 1975; Usher 1974). In Germany, the related C. pratensis has been known as 'hexenblume' ['witches flower'] (DeVries 1991).

As far as I am aware, nothing is known of the chemistry of C. concatenata. However, the roots and aerial parts of some Cardamine spp. [such as C. cordifolia] have been shown to contain isothiocyanate-yielding glucosinolates (Louda & Rodman 1983; Rodman & Louda 1984), well-known compounds in plants from the Brassicaceae, particularly **Brassica**.

Cardamine concatenata is a winter perennial herb with elongated, jointed white rhizomes, with segments 1-2cm long; stems glabrous, 20-40cm tall. 2-3 approximate, subopposite or subwhorled leaves 10-15cm above the base of stem, deeply palmately dissected, glabrous or pubescent; stem leaves subwhorled or proximate, with 3-5 divisions, each division 0.5-3cm wide, lobed or deeply toothed, teeth dentate or serrate, mucronate; basal leaves similar to stem leaves, often absent – when present, arising from the rhizome. Flowers white, pink or lavender; pedicels 1-2cm long in flower, to 3cm long in fruit; rachis of inflorescence pubescent; sepals 4; petals 4, 1-2cm long, entire; stamens 6. Ovary sessile. Fruit a 2-carpellate capsule called a silique, terete, 1-4cm x 2-3mm, beak 3-12mm long, round or elliptic in cross-section; valves of mature fruit coil elastically from base to apex and drop. Fl. Mar.-May.

Alluvial woods and adjacent slopes; N. & S. Carolina, Virginia, W. Virginia, Kentucky, Tennessee, Florida (Radford et al. 1964).

CAREX

(Cyperaceae)

Carex brevicollis *DC.* – rabid grass, parvsk sedge

'Rabid grass', one of the common names for this Russian sedge grass, suggests that it may be known for intoxicating stock animals, although it is reported that livestock choose not to eat it (Komarov & Shishkin ed. 1985a). It contains several interesting β-carboline alkaloids.

C. brevicollis leaves have yielded mostly [0.195-0.3%] brevicolline [4-(N-methylpyrrod-2-yl)-β-carboline; vasodilator, uterine contractant, inhibits peristalsis], as well as dehydrobrevicolline, brevicarine, *harmine*, *harmol* [0.041%], *harman* and *norharman*. Homobrevicolline [4-(1-methyl-2-piperidinyl)-β-carboline] is also known from the genus (Shcherbinina et al. 1969; Shulgin & Shulgin 1997; Terent'eva et al. 1969a, 1969b; Zsadon et al. 1978).

Alkaloids have also been detected in C. acuta, C. acutiformis, C. contigua and C. nigra (Hultin & Torssell 1965; Willaman & Li 1970).

Carex brevicollis is a perennial, light-green, densely caespitose plant with a long rhizome. Culms flattened-triangular, scabrous above, 30-45cm tall, covered at base with brown sheaths disintegrating into fibres; leaves rather soft, 3-5mm wide, rather abruptly pointed, equalling the culm, margin revolute. Spikelets 2-3, distant, the terminal spikelet staminate, clavate to obovoid, 1.5-2.5cm long, with oblong-ovate acute ferruginous scales; other spikelets pistillate, ovoid to oblong-ovoid, 1.5-2.5cm long, erect; lowest bract with spathiform sheath 1.5-2cm long, and a blade of equal length; pistillate scales abruptly attenuate into a subulate point, castaneous, 3-nerved, with green internerves, shorter than to nearly as long as perigynea; perigynea obovoid or broadly ellipsoid, terete, 5mm long, yellowish-green, scattered-setulose to glabrescent, obsoletely many-nerved, rather abruptly terminating in a broad, short, scabrous-margined, bidentate, subferruginous beak with spreading teeth. Fr. May.

Open forests, coppices and mountain slopes of e. Europe and Asia Minor (Komarov & Shishkin ed. 1985a).

CARNEGIEA

(Cactaceae)

Carnegiea gigantea *(Engelmann) Britton et Rose* **(Cereus giganteus** *Engel.*; **Pilocereus engelmannii** *Lemaire*; **P. giganteus** *Rümpler*) – saguaro, sahuaro, organ pipe cactus, giant cactus, hoshan, ha'rsany, harsee, moxéppe

The Pima and Papago of n. Mexico and Arizona [Sonoran Desert] make a fermented beverage from the fruits of this cactus. The beverage is called 'tiswin', 'sawado', 'haren', 'ha'san na'vai', 'nawai' or 'sitoli' and is used in their rain ceremonies, to receive rain and healing songs. They say that the preparation of the beverage, and its use to bring rain every year, was taught to them by the spirits of the crow, and of the 'elder brother' I'itoi. The annual rituals centred around saguaro are the highlight of Papago culture. The fruits of the cactus ripen at a time when food is scarce, and their ripening marks the end of the Papago calendar year, before the rains come. Thus, the preparation and group consumption of tiswin also marks a time in which to purify and renew for a new cycle of seasons. Unfortunately, as with 'peyote' [see **Lophophora**], the tiswin ceremony was subject to legal prohibitions early last century, on both sides of the border, due almost entirely to the wishes of Christian puritans. Although this prohibition is no longer in place [unlike peyote], the traditional ways of the Papago are dying out, partly as a result of this past oppression and the gap in tradition which it created. Both the fruit and the tiswin made from it are emetic in high doses (Bruhn 1971; Buhner 1998; Diaz 1979).

The stems have on occasion been tapped for 'cactus water' by besieged 'Indians' during battle with other tribes, though this liquid nourishment is bitter and nauseating to those unaccustomed to it (Bruhn 1971; Bruhn & Lundstrom 1976). The Seri of Sonora apply a heated slice of the stem externally, to ease rheumatic pains (Felger & Moser 1974). The fruits are much used as food, made into preserves and syrups, and the seeds eaten, either whole or as a ground meal. The ribs of the dried vascular bundle from dead plants have been used to make arrows, pole tools for harvesting the fruit from the top of the plant, and in construction, amongst other uses. However, the 'wood' of the plant contains mineral crystals that can dull the sharp edges of woodworking tools. The spines were once used as tattooing needles (Benson 1982; Bruhn 1971).

A tiswin beer or 'wine' may be prepared with c.8 litres of fruit pulp [free of seeds], 4 litres of water, and wine yeast. The measures can be adjusted to suit the desired size of the batch. The pulp and water are heated to a boil, and cooked for 1-2 hours, before cooling, straining, and slowly simmering to a syrup for another hour. The shaman of the tribe will usually purify the syrup by blowing tobacco smoke [see **Nicotiana**] over it. The syrup is generally diluted with water [syrup/water ratios varying from 1:1 to 1:16], mixed by hand. Before mixing, the syrup is spoken to – "I am now mixing you up. Do me the favour to bring good wind and clouds and rain, and to keep the people from bad behaviour after they have drunk the wine." Throughout the process, the cactus and its parts may be prayed to, spoken to, and generally treated with a great deal of respect and focus. When ready, the mixture [at c.21°C] is taken into a round hut [the 'yahki' or 'rain house'] and poured into 4 fermentation vessels, each settled into the ground at a point of one of the four cardinal directions; straw lines the depressions in the ground, and a fire is kept burning inside to keep a constant temperature. The fermenting mixture is watched over and sung to in shifts [never left unattended], for 4 days. When finished, the tiswin should contain c.5% alcohol. The beverage is consumed together by the whole group, with a sincere mood prevailing. Tiswin origin stories are told, portions of the beverage are given to the 4 directions, the earth mother, and the I'itoi, and everyone drinks until there is none left. To close, here is a translated excerpt from the Papago tiswin ritual – "Ready, friend! Are we not here drinking the shaman's drink, the magician's drink! We mix it with our drunken tears and drink." Also, this Papago song is sung after drinking tiswin – "Dizziness is following me! Close it is following me. Ah, but I like it. Yonder far, far on the flat land it is taking me. Dizziness I see. High up there I see it. Truly I like it. Yonder they lead me, and dizziness they give me to drink. 'Tis at the foot of little Gray Mountain I am sitting and getting drunk. Beautiful songs I shall unfold." (Buhner 1998).*

The yeasts for the fermentation can rely on a number of factors. Firstly, yeasts grow in association with the plant, aided by Drosophila sp. flies which have a specific relationship with C. gigantea. The main species associated with this plant is D. nigrospiracula (Kirscher & Heed 1970). The primary yeasts are Pichia spp., particularly P. heedii. Due to this relationship, stem injuries ferment readily in the plant (Holzschu & Phaff 1982). Just to be sure, sometimes there may be the addition of a yeast starter culture from the previous year's batch, and the residual yeast inside the used fermentation vessels would further ensure dominance of the desired yeasts. The reader would probably use store-bought wine yeast if requiring an extra yeast source (Buhner 1998); this may be necessary when using plants grown outside of their native range, as the Drosophila sp. relationship would probably be absent.

C. gigantea has yielded 0.6-1.7% alkaloids and 2.5% lipids. Those alkaloids found to date include [0.019% w/w] 0.575-0.7% carnegine [6,7-dimethoxy-1,2-dimethyl-THIQ; increases reflex-excitability in frog, MAOI], [0.0016% w/w] 0.18% *gigantine* [5-OH-carnegine; found in quantity only in old, wild plants; 25-30% of alkaloids in whole plant, but 50% in growing tip], [0.02% w/w] 0.096-0.47% salsolidine [N-norcarnegine; 6,7-dimethoxy-1-methyl-THIQ; see **Pachycereus**], 0.006% dehydrosalsolidine, 0.006% 1,2-dehydrosalsolidine, 0.007% heliamine [6,7-dimethoxy-THIQ], 0.0008% dehydroheliamine, 0.0036% [w/w] arizonine [1-methyl-7-MeO-8-OH-THIQ], 0.26% *dopamine* [from young, cultivated plants; 1% has been found in the cortex; higher content observed in callus-tissue and the areas near it, than healthy tissue], <0.00145% *DMPEA* and traces of 3-MeO-*tyramine*; other compounds found are glucaric acid, quinic acid, isocitric acid, ferulic acid, p-coumaric acid, 3,4-dihydroxybenzoic acid, p-OH-benzoic acid, vanillin, syringaldehyde, p-OH-benzaldehyde, campesterol, sitosterol, glucose, galactose, arabinose and xylose (Bembenek et al. 1990; Brown et al. 1968; Bruhn et al. 1970; Bruhn & Lundstrom 1976; Diaz 1979; Hodgkins et al. 1967; Pummangura et al. 1982a; Trout ed. 1999; Unger et al. 1980). As Cereus giganteus, this species has been claimed to contain *mescaline* (Štarha 2001), though this is not supported by any of the references given.

The psychoactivity of tiswin wine is thought to be entirely due to the

alcohol content, rather than any alkaloids that might be present in traces in the fruit (Bruhn 1971; Trout pers. comm.).

Carnegiea gigantea is a large, columnar cactus; stem simple and upright, stout, up to 12m tall, or with 1-2(-12) lateral branches, branches 30-65cm diam.; ribs 12-24, obtuse, 1-3cm high; areoles c.2.5cm apart or nearly contiguous on upper part of plant, densely brown-felted; spines of 2 kinds – those at top of flowering plants acicular, yellowish-brown, porrect, those of sterile plants and on lower parts of flowering plants +- subulate, central ones stouter than radials, often to 7cm long, usually 2.5-3.8cm long, to 1.3mm diam. at base; spines 15-30 per areole. Flowers borne singly at uppermost areoles, diurnal, funnelform-campanulate, 10-12cm long, sometimes nearly as wide when fully expanded; tube c.1.5cm long, stout, nearly cylindric, expanding into throat, green, scales broad and short, white-felted in axils; scales on tube few, broadly ovate to oblong, acute, bearing small tufts of hair in axils; throat c.3cm long, covered with numerous white stamens (c.¾ as long as inner perianth segments); inner perianth segments white, short, widely spreading or somewhat reflexed when fully expanded; stigma lobes 12-18, narrowly linear, reaching a little above the stamens; style stout, 5-6cm long, white or cream-coloured; ovary oblong, somewhat tuberculate, bearing scales with wooly axils; ovules numerous. Berry red or purple, obtuse, 6-9cm long, oblong, ellipsoid or somewhat obovoid, edible, splitting down from top into 2-3 sections, containing red pulp, scales few, distant, ovate, 2-4mm long, with or without 1-3 short acicular spines in axils; seeds very numerous, black and shiny, irregularly obovoid, 2 x 1.3 x 1mm, hilum oblique.

In coarse, rocky ground, adjacent to mountain ranges and hills, 180-1080[-1350]m; Arizona, s.e. California, Sonora [Mexico]. Shade is necessary for successfully establishing seedlings and young plants. Care should be taken in wet weather, as even in large plants, small wounds can quickly lead to rot of bacterial origin, which can kill the plant (Benson 1982; Britton & Rose 1963). This species is currently under threat in the wild due to disease, changes in local ecosystems due to grazing of stock animals, vandalism and illicit collecting of wild plants for horticultural purposes (Benson 1982; Bruhn 1971).

* I apologise to Stephen H. Buhner for borrowing so heavily from his work. However, his 1998 book contains much fascinating information on this topic which was hard to ignore, and the primary references were difficult for me to locate. I recommend anyone interested in 'indigenous beers' and brewing of a sacred nature to seek it out. The main references of interest used by Buhner were – Crosswhite, F. 1980. "The annual saguaro harvest and crop cycle of the Papago." Desert Plants 2(1):7. Univ. Arizona; Densmore, F. 1929. Papago Music. Smithsonian Institution Bureau of American Ethnology Bulletin 90; Lumholtz, C. 1912. New Trails in Mexico. Unwin, London; Underhill, R. 1936. Autobiography of a Papago Woman. Memoirs of the American Anthropological Assoc. 46; and Underhill, R. 1938. Singing For Power. Univ. California Press.

CASIMIROA

(Rutaceae)

Casimiroa edulis *Llave et Lex.* **(Fagara bombacifolia** *(A. Rich.) Krug et Urb.***; Zanthoxylum araliaceum** *Turcz.***; Z. bombacifolium** *A. Rich.***)** – cochiztzapotl, zapote blanco, white sapote, Mexican apple

This Central American tree is cultivated for its tart, aromatic fruit. However, in the translation of the Badianus Codex, the seeds of C. edulis were referred to as being powdered and burned by the Aztecs for their action as a sedative hypnotic. They are still used as a tranquilliser today in rural Mexico. In Monterrey, the leaves are infused as a sedative antispasmodic which calms the nerves and heart, treats insomnia, and lowers high blood pressure. A seed extract is also given to produce sleep for 5-6hrs, without negative side-effects. From 1-2tsp of the extract is said to be sufficient (Emboden 1979a; Heffern 1974; Nicholson & Arzeni 1993; Ruiz et al. 1995; Usher 1974). The Tarahumara of n. Mexico have been reported to use the bark from C. edulis and C. sapota, crushed and thrown into water to stupefy fish and make them easy to catch (Pennington 1958).

Seeds, root, and bark of C. edulis have been shown to contain *histamine* derivatives with hypotensive activities, including N,N-dimethyl-*histamine* [0.05% in seed], casimidine [1-β-D-glucosyl-D-N-methyl-*histamine*] and casimiroedine [major seed constituent; N-cinnamoyl-N-methyl-*histamine* N-glucoside]. Seeds have also yielded N-methyl-*histamine*, N-benzoyl-*tyramine* [possibly an artefact of extraction], 4'-dehydrogeranyl-N-benzoyl-*tyramine* [tentatively identified, possibly an artefact] and zapotidin [6-methylimidozo(1,5-C)-tetrahydropyrimidine-5-thione; hypotensive]; the quinolines casimiroine, eduline, edulein, β-fagarine [analgesic, anticonvulsant, antipyretic, CNS-depressant], phellopterin, 5-MeO-8-geranyloxypsoralen and 1-methyl-2-phenyl-4-quinolone; the limonoid nortriterpenoids zapoterin [12α-OH-obacunone], 7α-obacunol and deacetylnomilin; and the flavonoids zapotin [2',5,6,6'-tetramethoxyflavone], 2',5,6-trimethoxyflavone, 3',5,6-trimethoxyflavone and 3',5,5',6-tetramethoxyflavone. Leaves and twigs also yielded quinolines [0.00016% casimiroine, 0.0003% edulein, 0.00055% 1-methyl-2-phenyl-4-quinolone, 0.00063% *skimmianine*], coumarins [0.0003% isopimpinellin, 0.00016% *scopoletin* methyl ether], 0.0083% n-hentriacontane [antiinflammatory] and 0.00166% carnoubyl cerotate. Bark also yielded [as % from trunk bark/root bark] the quinolines casimiroine [0.0052/0.225], edulein [0.0021/0.043], edulinine [0.003/0.0026], edulitine [0.0006/-], dictamnine [0.0008/0.0038], *skimmianine* [0.002/-] and γ-fagarine [0.0024/0.01]; the coumarins *scopoletin* [0.0015/-], bergapten [-/0.0035] and isopimpinellin [-/0.0122]; and the flavonoids zapotin [0.122/0.425] and 5,6-dimethoxyflavone [0.0122/0.645] (Djerassi et al. 1956; Dreyer 1968; Harborne & Baxter ed. 1993; Iriarte et al. 1956; Major & Dürsch 1958; Rizvi et al. 1985). The plant has also yielded stemmadenine, obacunone [casimirolide], condylocarpine [methyl-2,14,16,19-tetradehydrocondyfolan-16-carboxylate], hexadecanamide [palmitamide] and 9-OH-4-MeO-psoralen (Buckingham et al. ed. 1994; Rastogi & Mehrotra ed. 1990-1993).

Casimiroa edulis is a large or medium sized tree. Leaves digitately 3-7-foliate, leaflets ovate to ovate-oblong, lanceolate, or sometimes obovate, 4.5-12 x 1.7-5.5cm, obtuse or retuse at apex, base cuneate, glabrous or sometimes minutely puberulous above, densely papillose and +- puberulent, especially on midrib and veins, coriaceous beneath, margin entire or obscurely crenate, petioluled; petioles 2.5-9cm long, puberulent. Inflorescence terminal or axillary; sepals usually 5, triangular, ciliate; petals usually 5, greenish, lanceolate to oblong-ovate, ovate or oval, 4-5mm long, 2-2.5mm broad; stamens as many as petals, inserted at base of disc; filaments subulate or linear-lanceolate; anthers elliptic, ovate or oval. Ovary subglobose or obovoid, (2-)4-5(-8)-celled, usually 5-lobed; stigma 5-lobed or entire; ovules solitary in each cell. Drupe greenish-yellow, subglobose, 8-10cm diam., pubescent, 2-5-celled; pulp soft, cream-coloured, very sweet; seeds 2-5, 1.8-2.3cm long, 1-1.5cm broad.

Mexico, Guatemala, Nicaragua; cultivated in Cuba (Wilson et al. 1911), Florida and s. California; naturalised in India; usually above 910m (Bailey & Bailey 1976).

Propagate from seed; best planted immediately after removal from the fruit, or else store the seed in sterilised slightly damp peat-moss in refrigeration; seedlings may grow quickly. If purchasing a plant, check that you have a self-fertile variety, or if not, one which has a pollinating branch grafted to it. Plant out in spring [in cold climates] or autumn [everywhere else] when 1m tall. Plant away from water pipes and paths; the strong roots can cause problems with these later. Water liberally when young and remove tip to promote branching; cut back the new main shoot when 30cm long; trim side branches and long, thin, whippy shoots regularly, though do not prune excessively. Established trees are partially drought-tolerant, and cold tolerant to c.-5°C [even though trees may defoliate at such low temperatures, they can recover well]. In warm areas, water mature trees less during late autumn and winter to encourage flowering; water well during flowering and fruiting. Prefers well-drained soil or sandy loam, in a sunny position. Does not like true tropical humid conditions [it will still grow but not necessarily produce fruit]. May need to be staked when young to protect against wind damage. Trees grow well with less fertilisation than **Citrus**, and may be able to subsist on the nutrients gained from their own leaf litter. Some say annual dolomite supplementation is beneficial after harvesting fruit; 250g per year of age [to a max. of 2kg] is suggested for each tree. Trees may yield fruit very heavily. Harvest fruit when mature [ie. when it easily detaches from the tree] and ripen off the tree [may take 1-2 weeks]; such fruits store for longer than those picked at full ripeness, though once ripe, they will keep for only a couple of days. Also, fruits which are allowed to drop to the ground can rot and ferment within hours. Fruits of some varieties do not considerably change colour when ripening, though others do. The fruit bruises easily due to its thin skin, and is generally considered delicious, with a taste and texture compared by some to banana custard. Some strains, however, as well as fruit-bearing 'seedlings', may bear fruit with a bitter after-taste (Bailey & Bailey 1976; Glowinski 1997).

CASTANOPSIS

(Fagaceae/Cupuliferae)

Castanopsis acuminatissima *(Bl.) A. DC.* **(C. carlesii** *(Hemsl.) Hayata***; C. hamata** *M.S. Duan***; C. longispicata** *Hu***; Quercus carlesii** *Hemsl.***; Q. lanceaefolia** *Roxb.***)** – kawang, tuktukiin

Native peoples of Banz, in the Western Highlands of Papua New Guinea, steam the seeds ['kawang'] of this tree and eat them in large quantities as an intoxicant. They are said to produce the same effects as the 'nonda' mushrooms [see **Boletus, Heimiella, Russula**], many of which actually grow beneath this tree. The Bimin-Kuskusmin of West Sepik call the seeds 'tuktukiin', and use them in the highest two levels of shamanic initiation. At these proceedings [see also *Endnotes*], they are consumed with other plants. In the 11th stage, they are taken with a **Heimiella** sp., a **Russula** sp. [see **Boletus**], **Pandanus** julianettii, 'agara' bark [see **Galbulimima**], 'ereriba' leaves [see **Homalomena**], **Kaempferia** galanga rhizome, **Musa** sp. flowers, Baccaurea sp. fruits, and

the skin of the frog Litoria angiana [see *Endnotes*]. In the 12th stage, they are taken with **Psilocybe** mushrooms, **Pandanus** brosimos, P. julianettii, Lithocarpus sp. nuts [see *Endnotes*], agara leaves and bark, **Kaempferia** galanga, Colocasia esculenta and skin of the frog Phyrnomantis lateralis [see *Endnotes*] (Bock unpubl.; Heim & Wasson 1965; Poole 1987).

C. indica ['phang-rang-araung'] is used by the Mikir of India "in their various ceremonies of worship" (Jain & Borthakur 1980); no further details were given. In Nepal, Castanopsis spp. ['katus'] and the interior of their fruits are considered to be a form of 'amrita' (Müller-Ebeling et al. 2002). Castanopsis spp. are related to 'oaks', Quercus spp., which were very sacred trees to the Celtic Druids. Oak has numerous medicinal uses, and was believed to offer protection against evil (Bremness 1994; Cunningham 1994). In Mexico, inflorescences of a Quercus sp. are decocted to counter nervous excitation (Heffern 1974).

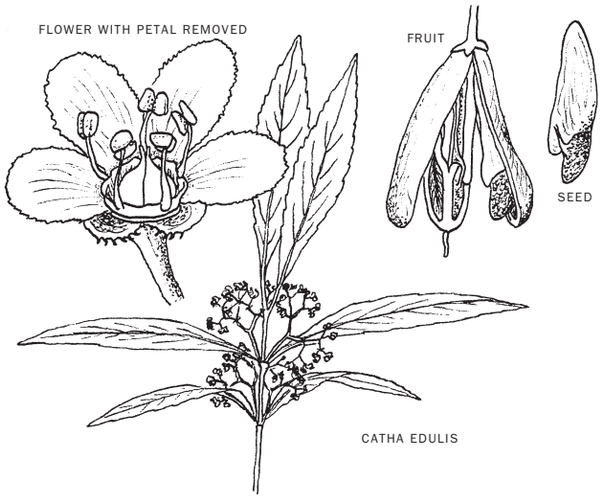
Apparently nothing is known of the chemistry of C. acuminatissima. The raw seeds can cause emaciation, anaemia and mouth ulcerations when eaten (Thomas 2001a).

Castanopsis acuminatissima is a small to large tree, glabrous. Leaves alternate, entire, very variable in size, c.10.1-25.4cm long, thin, lanceolate, membranous, subcaudate, base acute or rarely rounded, grey-green above, pale reddish-grey to subsilvery below; nerves reticulate, 8-15 pairs, slender, arched and raised on both surfaces; petiole to 2.54cm long. Flowers monoecious, small, spicate; male in pendulous or erect spikes; female erect; bracts small; involucre 2.5-3.8cm long, very stoutly pedicelled, in long spikes obliquely ascending, ovoid, hoary, with 3-4 broad, wavy, often interrupted concentric ridges enclosing the nut, bursting irregularly. Male – perianth campanulate, 4-7-lobed; stamens indefinite, filaments slender; anther cells contiguous. Female – enclosed in imbricate bracts; perianth tube adnate to ovary, limb very minutely lobed or toothed; staminodes minute or none; ovary after fecundation +- perfectly 3(-5)-celled; styles 3-5, short; ovules 2 in each cell. Nut ovoid, thin, puberulous, 1-celled, attached to involucre of imbricate hardened bracts; seeds 1-2, testa membranous.

India, Upper Burma (Hooker 1954-1961), Papua New Guinea (Paijmans ed. 1976).

CATHA

(Celastraceae)



Catha edulis *Forssk.* **(Celastrus edulis** *(Forssk.) Vahl.***; Methyscophyllum glaucum** *Eckl. et Zeyh.***)** – khat, qat, chat, gaat, miraa, marongi, kafta, Abyssinian tea

Khat is a tall tree [often kept bushy by pruning] which grows both wild and cultivated in the fertile plains and mountains of northern, eastern and southern Africa, as well as Saudi Arabia and Yemen. Yemen is considered the centre of khat use, though it is also widely used in Somalia, Kenya and Ethiopia. It was known by the 13th century that the plant was being taken as a tea by Sufis and other spiritually-inclined persons to 'intensify their mystical experiences'. Its use is now common where available, and it is often consumed daily as a euphoric stimulant. Khat is said to stimulate mental faculties ['widens the mind'], relax the body, give good spirit, endurance, concentration, alertness and confidence, as well as relieving colds, fevers and headaches.

The herb is purchased fresh daily from stores or street vendors, in bundles of varying quality and composition. The most expensive types come in slender, leafy bunches 60-76cm long; the cheapest usually come in 12-15cm packets of pre-picked leaves, which have been brought over a greater distance wrapped in banana-leaf containers [see **Musa**]. Users recognise many varieties, mostly 'red' and 'white', but also 'blue' and 'yellow'. 'Red' is considered to possess negative qualities, often due to the maturity of the herb [see below]. Cheaper types, such as the red, are said to be 'strong', and cause more negative side-effects, ie. insomnia, anaphrodisia, confusion, and irritability. Overly-astringent khat is called 'weak'. Good quality khat is young, tender growth, not too bitter, and produces euphoria and mental stimulation with few side-effects, followed by a 'coming down' period of detached contemplation and somnolence. Chewing too much can produce confusion, delirium, dizziness, and the sensation of insects crawling on or under the skin. Khat is usually consumed by picking the choicest leaves from their branches and chewing them in large amounts [100g or more per session, sometimes up to 500g or more per day], swallowing the juice; only rarely is the plant matter also swallowed. Sometimes a chunk of sugar or a clove [see **Syzygium**] is taken with the leaf. Khat has also been brewed into coffee [see **Coffea**], or the fresh flowers brewed as a tea [see **Camellia**]. It is usually consumed only from the early afternoon onwards. On a Friday, more than 80% of adult Yemenis will be chewing khat, whilst on other days, this is only 50-60%. At such times, most businesses close and the streets are empty, while people chew khat and smoke tobacco [see **Nicotiana**] in water pipes inside in social groups [sometimes khat is also smoked]. Khat sessions are predominantly a male affair, though a smaller proportion of women also chew and have khat gatherings of their own. Such sessions are important for social bonding and diplomatic affairs, and its use during the working day is valuable for its stimulant effects. Today, khat is illegal in some countries [such as Australia and the US, where there are strong Somali communities], and its negative impact in its area of use has been somewhat exaggerated. Khat use on the whole has had little negative social influence, with difficulties arising only from excessive and compulsive use, which is often seen more with the poor and unemployed (Gess 1998; Getahun & Krikorian 1973; Kalix 1991; Kennedy 1987; Tyler 1966; Von Bibra 1855; Watt & Breyer-Brandwijk 1962). It should be noted, however, that the poor and unemployed are a group becoming more and more common throughout the world.

C. edulis leaves and twigs have yielded 0.02-5% phenylpropylamine or phenylalkylamine alkaloids [*phenethylamine* derivatives; those found in khat are referred to as khatamines], consisting of *cathinone* [up to 70% of total bases in fresh material], d-*norpseudoephedrine* [cathine], l-*ephedrine* [needs verification], (-)-norephedrine, merucathine, merucathinone, pseudomerucathine; as well as sesquiterpene-derived alkaloids called cathedulins or cathedulines, including cathidines A-D; flavonoids such as kaempferol [MAOI (Sloley et al. 2000)], quercetin and myricetin; the sugar alcohol mannitol; glucose, fructose, rhamnose, galactose, xylose, dulcitol, 0.136-0.324% ascorbic acid [vitamin C], 0.0148% niacin [vitamin B3], 0.0185% iron, 0.29% calcium, and traces of β-carotene [vitamin A], thiamin [vitamin B1] and riboflavin [vitamin B2]; 0.04-0.08% essential oil, containing α- and β-*thujone*, fenchone, linalool, α-terpineol, nerol, *pinene*, terpinolene, ocimene and β-phellandrene; 5.5-14% condensed tannins, 2.7% fibre, 5.2% protein and 17 amino acids [including *aspartic acid*, *glutamic acid*, *glycine*, *phenylalanine*, α-aminobutyric acid, lysine, threonine, serine, phenylserine, proline, alanine, valine and 0.05% *choline*] (Al-Meshal et al. 1986; Brenneisen & Geisshusler 1987; Brenneisen et al. 1984; Bruneton 1995; Crombie et al. 1990; El Sissi & Abd Alla 1966; Kalix 1991; Krikorian & Getahun 1973; Qédan 1972; Rastogi & Mehrotra ed. 1990-1993; Szendrei 1980).

Cathinone [the keto-analogue of *norpseudoephedrine*, existing in dynamic equilibrium with the enol-analogue] is considered the most important active chemical in C. edulis, and is mainly present in young, fresh leafy tips – it is 7-10 times as potent as cathine, and has more desirable effects [see *Chemical Index*]. In older, wilted or dry leaves, the unstable *cathinone* is believed to have converted to an 80/20% mix of *norpseudoephedrine* and norephedrine. This has been presumed to be due to enzymatic activity (Bruneton 1995; Kalix 1991; Kennedy 1987), though the precise process occurring here is still not fully understood. 3,6-Dimethyl-2,5-diphenylpyrazine has been isolated as a probable product of the oxidative dimerisation of *cathinone*; 1-phenyl-1,2-propanedione has also been isolated as a degradation product (Szendrei 1980). It has been suggested that the pyrazine derivative, or possibly the propanedione, might be responsible for some side-effects of stale or old khat (theobromus pers. comm. 2001), such as a strong and unpleasant 'drying' action on mucous membranes; the enol-analogue may also contribute to this (Torsten pers. comm. 2001). Tannins are thought to be responsible for gastrointestinal side-effects (Kennedy 1987).

C. edulis, as well as *cathinone* and *norpseudoephedrine*, produced an increase in adrenal phosphorylase and *adrenocorticotropin* activity, and a decrease in cholesterol, glycogen and ascorbic acid levels in rabbits (Ahmed & El-Qirbi 1993).

C. transvaalensis leaves have yielded at least four sesquiterpenes [vaalens 1, vaalens 3, vaalens 5, vaalens 7] (Crombie et al. 1990).

Catha edulis is an evergreen shrub or tree 2-15(-25)m tall; stems pale green-grey and flattened when young, becoming wine-red and rounded with age. Leaves dark green or grey-green, glossy above, paler beneath, (3.7-)5.5-11 x (0.8-)1.5-6cm, oblong to elliptic or obovate, apex acute

to acuminate, rarely obtuse, margin glandular, crenulate to dentate, base narrow-cuneate, texture tough, venation finely networked, more prominent below than above; petiole 3-10mm long; stipules c.2mm long, triangular-needle-like. Flowers many; peduncle 6-12mm long; bracts 0.5-1mm long, triangular-needle-like; sepals 0.5-0.7mm long, broadly ovate to semicircular, rounded, with margin fringed with fine, soft hairs; petals 1-1.5mm long, elliptic-oblong, margin minutely haired and paler when dry. Ovary broadly ovoid; styles short. Capsule red, 6-10mm long, narrowly oblong with 3 segments, pendulous; seeds wrinkled, with a basal wing.

Usually near margins of forest or woodland, often on rocky hills, 1100-1435m; from Cape Province [S. Africa] to eastern Africa from Ethiopia to s.w. Arabia (Exell et al. ed. 1960-1993).

Ideal growth requires a min. temp. of 19°C., and rainfall of 600mm per year; too much humidity can result in fungal damage. When grown below its preferred altitude, alkaloid levels are said to be greatly diminished. The best khat is grown from suckers or cuttings, not from seed. Cuttings are sometimes stripped of leaves, and planted in the ground [1-4 together] at a 45° angle, 20-25cm deep, and watered regularly while the roots form; water less regularly later in life. The soil should be well-drained, and khat tolerates a variety of soil types. Each year the ground at the base of the plant must be hoed to aerate the soil. Harvesting can begin after 4-5 years, and healthy plants may yield for up to 50 years. Harvest may occur in all times of year, but mostly in the latter part of rainy seasons (Getahun & Krikorian 1973; Kennedy 1987).

There appear to be two noticeably different plants circulating as C. edulis. The more typical form has broader leaves with a more obtuse apex, and often with a reddish tint on petioles, midribs and leaf margins; the other has slightly tougher leaves which are narrower, and more of a grey-green in colour. Both are psychoactive, though people have their preferences (pers. comms.; pers. obs.). The description of C. edulis given above does not refer to the reddish tint often observed, though the leaf dimensions do encompass those of both varieties; the accompanying picture depicts a plant more typical of the narrow-leaf form.

In Australian-grown plants [n.e. New South Wales], winter harvests may be noticeably weaker in potency, compared to harvests in warmer times of year with plentiful new growth. Khat also seems to be less psychoactive when harvested in the middle of a hot day (Torsten pers. comm.), which may be due to an increase in the degradation of *cathinone*, perhaps stimulated by a combination of heat, oxygen, and dehydration (theobromus pers. comm.).

Cultivation from seed should preferably be done using fresh seed; germination is easy (pers. comms.; pers. obs.).

The only other members of this genus are C. abbottii, known only from a small area in s. Natal and Pondoland, and C. transvaalensis [Lydenburgia cassinoides], known only from a small area in n.e. Transvaal. Neither have been analysed for alkaloids (Wyk & Prins 1987).

CECROPIA

(Cecropiaceae/Moraceae)

Cecropia glaziovi *Snethlage* – embaúba

Cecropia mexicana *Hemsl.* **(C. burriada** *Cuatrec.***; C. mexicana var. macrostachya** *Donn.-Sm.***; C. obtusifolia** *Bertol.***; C. obtusifolia ssp. burriada** *(Cuatrec.) Berg et Franco***; C. panamensis** *Hemsl.***)** – guaruma, guarumo, trumpet tree

In Veracruz, Mexico, dried leaves of C. mexicana are known as 'guaruma', and are smoked as a **Cannabis** substitute (Ott 1993), as well as being used to treat diabetes (Jiu 1966). I recently verified that C. mexicana [harv. Feb., Chiapas] is psychoactive when smoked, and that the fallen, dead leaves retain their activity. Effects of the inebriation are felt rather rapidly after smoking, building gently to a peak over c.30 minutes, and lasting several hours, perceived as a pronounced sedation and inebriation, accompanied by confusion of thought and mild perceptual alterations. The effect was not overly pleasant, but definitely intoxicating. The leaves are seemingly high in tars, and smoking them is rough on the lungs as an after-effect (pers. obs. 1999).

The Candomblé of Brazil use leaves of C. pachystachys [the 'hands of Omulu'] as trays for offerings to Omulu, god of skin diseases. A leaf decoction is also used to treat urinary disorders (Voeks 1997). Leaves of several species, such as C. ficifolia and C. sciadophylla, are burnt to provide alkaline ashes for use in coca chewing in parts of n.w. Amazonia [see **Erythroxylum**] (Schultes & Raffauf 1990; Uscategui 1959). In Central and South America, C. glaziovi has been used as an antiasthmatic, antihypertensive and cardiotonic (Rocha et al. 2002).

Chemical and pharmacological studies of this genus are few.

C. adenopus has yielded triterpenes and sterols (Schultes & Raffauf 1990).

C. carbonaria extracts had antispasmodic activity in animals (Schultes & Raffauf 1990).

C. glaziovi aqueous extracts had anxiolytic activity in mice [given p.o.]; such extracts contained mostly flavonoids and terpenes (Rocha et al. 2002).

C. mexicana leaf aqueous extract [as C. obtusifolia] had CNS-depressant, muscle relaxant, peripheral analgesic and antiinflammatory effects in animals, as well as impairing motor coordination and showing low toxicity (Perez-Guerrero et al. 2001); a lyophilised aqueous leaf extract also had antihypertensive effects in rats [given i.v.] (Salas et al. 1987).

Cecropia mexicana is a dioecious tree with milky sap; trunk and branches stout, hollow, divided by partitions, to 5-10m tall. Leaf blades usually 20-30cm long or more, divided more than ½ to the centre, palmately 9-15-lobed, lobes occasionally with 1-several lateral lobes, upper surface scabridulous and sparsely web-like pubescent, lower surface very pale to nearly white, minutely and usually densely puberulent; petioles usually 22-30cm long; stipules 7-11cm long, amplexicaul, leaving a scar completely surrounding the stem. Flowers in palmately arranged spikes; staminate flowers in spikes (10-)12-18cm long, in clusters of 3-9, spathes (11-)12-20 x 0.3-0.4cm; calyx tubular, entire or 2-lobed; stamens 2; ovary absent. Pistillate flowers in spikes 17-30cm long, c.0.5cm diam. at flowering, enlarging to 0.6-0.9cm diam. in fruit, spikes in clusters of 2-4, spathes 16-20cm long, outer face usually web-like pubescent, inner face shaggy; calyx tubular, apex porelike. Ovary included; style short; stigma exserted. Fruit ovoid to oblong-ovoid, somewhat flattened, 3.3-3.7mm long, enclosed by thin calyx.

Native from s. Mexico to Ecuador and Colombia; naturalised in pastures and low, wet forests in Hawaii (Wagner et al. 1990).

CENTELLA [including Hydrocotyle]

(Umbelliferae/Apiaceae)

Centella asiatica *L.* **(C. biflora** *(P. Vell.) Nannf.***; C. coriacea** *Nannf.***; C. dusenii** *Nannf.***; C. erecta** *(L. f.) Fernald***; C. floridana** *(Coult. et Rose) Nannf.***; C. hirtella** *Nannf.***; C. repanda** *(Pers.) Small***; C. triflora** *(Ruiz et Pav.) Nannf.***; Hydrocotyle asiatica** *L.***)** – gotu-kola, marsh pennywort, Asiatic pennywort, Indian pennywort, waternavel, centella, di chien tsao, di qien cao, brahmi, manduka-parni, cheka-parni, khulakudi, brahma-manduki, karinga, tholkuri, kutakam

Hydrocotyle javanica *Thunb.* **(H. nepalensis** *Hook.***; H. polycephala** *Wight et Arn.***)** – rau mo Java

C. asiatica, a small Asian herb with tonic properties, is well-known today as the subject of a widespread scam perpetrated by hack journalists and the health supplements industry. Some time in the early 1970's or earlier, stories began to circulate about 'fo-ti-tieng', an 'elixir of long life' reputed to have been responsible for the longevity of several famed Chinese hermits. Herbal preparations consisting of C. asiatica, **Cola** nuts, and 'meadowsweet' [Filipendula ulmaria] were subsequently sold as fo-ti-tieng® to an unsuspecting public. Further deception was found in the marketing of Polygonum multiflorum ['he-shou-wou' – see *Endnotes*] as 'fo ti', to take advantage of customers looking for the famed fo-ti-tieng. The toxic aconite [see **Aconitum** in *Methods of Ingestion*] was also sold as fo-ti by unscrupulous 'herbalists', due to the similarity of the English bastardisation ['fo-tse'] of the Pinyin word for aconite ['fuzi']. In fact, both 'fo-ti' and 'fo-ti-tieng' are invented names and can not be found in any Chinese Materia Medica. Furthermore, the original cases of longevity that inspired these marketing scams are most likely attributable to Polygonum multiflorum, and a combination of Lycium sp. fruits [see *Endnotes*] and Tai-Ch'i exercises, in separate cases (Dharmananda undated). The 'fo-ti-tieng' deception continues to this day, with such preparations often consisting of C. asiatica alone. The fraud is exacerbated by claims that 'true' fo-ti-tieng is made using Hydrocotyle asiatica minor, a non-existant variety of an old synonym for C. asiatica. Some companies even offer separate products consisting of what is labelled as both C. asiatica and H. asiatica minor, giving them different names [including 'fo-ti-tieng', 'fo-ti', 'gotu-kola' and 'brahmi' (see also **Bacopa**)] to maintain the impression that they are different herbs (Dharmananda undated; pers. obs.).

C. asiatica is reputed to have been used as a longevity tonic by Taoist hermits and Himalayan yogis (Rätsch 1992), though this might be a confusion of facts relating to the 'fo-ti-tieng myth' discussed above, and thus may refer to Polygonum multiflorum [see *Endnotes*]. The Lahu of n. Thailand say that if you eat C. asiatica at every meal of every day for 3 years, one becomes invulnerable, and cannot be harmed in any way. The Chinese name for the herb, 'di chien tsao', means 'ground coin grass', referring to the resemblance of the leaves to Chinese copper coins. In TCM, it is used as a rejuvenative, nerve tonic, immune stimulant, diuretic and antipyretic. In Ayurvedic medicine, is it used as a blood-purifier and nerve tonic, and to treat skin diseases and insanity – it is said to "improve the colour of the body, youth, memory and give long life". An infusion with honey is recommended as a supplement to meditation. Incidentally, the herb is the favourite food of the Indian elephant (Anderson 1993; Kirtikar & Basu 1980; Nadkarni 1976; Reid 1995; Watt & Breyer-Brandwijk 1962). Perhaps this is why it is said that elephants never forget? As C. coriacea, it is said to be narcotic in Africa (Watt 1967).

Infusion of the related Hydrocotyle javanica is said to act as a hypnotic (Perry & Metzger 1980).

Last century, modern methods confirmed many of the virtues of C. asiatica. It balances brain function across the hemispheres, improves learning and memory processes, restores nerves, accelerates cellular repair [especially skin and connective tissue], improves peripheral circulation, tones and stimulates the immune system and stimulates digestion; it also shows antiinflammatory, antioxidant, antitumour and diuretic effects, and has been used to treat asthma and bronchitis. It may cause itching of the skin and genito-urinary tract; if so, use should be discontinued. It is a mild sedative, and large doses may cause narcosis, headache and vertigo (Babu et al. 1995; Bremness 1994; Huang 1993; Kirtikar & Basu 1980; Miller 1985; Nadkarni 1976; Reid 1995). Some Thai kick-boxers have been reported to use C. asiatica to aid in recovery from injury; the herb is known to have a powerful healing action on both internal and external bruises (theobromus pers. comm.).

It is best to use the fresh herb, in which case 2 or more leaves and stems should be chewed daily. Best results are obtained if used daily in moderate amounts, as the effects are often cumulative. If it is to be dried, this should be done in a cool, shady place to preserve the volatile constituents. In dried form, ½ tsp is taken as a hot water infusion. A dose of 1-2 tab. may act as an aphrodisiac. In TCM, 3-5g is decocted and taken in 2 doses on an empty stomach, for short-term use (Chopra et al. 1965; Huang 1993; Miller 1985; Rätsch 1990). It is recommended that you grow your own, as much of the dried herb of commerce is collected from irrigation ditches in Asia (pers. comm.). Although aerial parts are usually used, the roots are said to be the most potent part (Nadkarni 1976).

C. asiatica contains an alkaloid, hydrocotyline, but its main medicinal efficacy comes from its saponin ester content – including asiaticoside, brahmoside, brahmissoside, brahminoside, madecassoside, thankuniside, and isothankuniside; as well as its triterpene acid content – brahmic acid, isobrahmic acid, thankunic acid, isothankunic acid, asiatic acid, betulic acid and madecassic acid are produced on hydrolysis. Flavonoids are found, such as 3-glucosylquercetin, 3-glucosylkaempferol and 7-glucosylkaempferol; as well as tannins, sterols, volatile oil and vitamin C (Bruneton 1995; Chopra et al. 1965; Huang 1993; Rastogi & Mehrotra ed. 1990-1993; Singh & Rastogi 1968). Leaf gave positive tests for HCN (Watt & Breyer-Brandwijk 1962).

Centella asiatica is a slender annual-perennial creeping herb; stems long, prostrate, spreading from leaf axils of a vertical rootstock, filiform, often reddish and with long internodes, rooting at the nodes. Leaves 1.3-6.3cm diam., several from stems, orbicular-reniform, rather broader than long, +- cupped, entire or shallowly crenate, glabrous on both sides, with numerous slender nerves from a deeply cordate base; petioles very variable in length, 1.5-15cm long or more, channeled, glabrous or nearly so; stipule short, adnate to the petioles forming a sheathing base. Flowers in fascicled umbels, each umbel consisting of 3-4 pink, sessile (rarely pedicelled) flowers; peduncles pubescent or glabrous, short, pink; bracts ovate, acute, concave, 2 beneath each umbel; calyx truncate, toothless; petals minute, pink, ovate, acute. Fruit 4mm long, longer than broad, ovoid, hard, with thickened pericarp, reticulate-rugose, often crowned by persistent petals, primary and secondary ridges distinct.

In marshy or damp places throughout Asia, up to 1800m; also in parts of Africa and Australia (Chopra et al. 1965; Kirtikar & Basu 1980).

Easy to grow, given space to spread, constant moisture and indirect sunlight. This species can sometimes be purchased from nurseries, though the uninvestigated C. cordifolia is often sold as C. asiatica, at least in Australia (pers. obs.).

CESTRUM

(Solanaceae)

Cestrum aurantiacum *Lindl.* **(C. chaculanum** *Loes.***; C. paucinervium** *Francey***)** – orange flowered cestrum

Cestrum diurnum *L.* **(C. album** *Ferrero ex Dunal***; C. elongatum** *Steud.***; C. fastigiatum** *Jacq.***; C. fastigiatum** *Jan***; C. tinctorium** *Griseb.***)** – day blooming jessamine

Cestrum laevigatum *Schltdl.* **(C. axillare** *Vell.***; C. foetidissimum** *Dunal***; C. multiflorum** *Schott ex Sendtn.***; C. pendulinum** *Hort. Monsp. ex Dunal***; C. undulatum var. orites** *Dunal***)** – dama de noite ['lady of the night'], coerana

Cestrum nocturnum *L.* **(C. hirtellum** *Schltdl.***; C. leucocarpum** *Dunal***; C. scandens** *Thib. ex Dunal***; C. suberosum** *Jacq.***)** – night blooming jessamine, hierba hedionda, pipiloxihuitl, galan de noche, hasana, bounwat, michili boung, ati bas aune, jahiko phul, pahelo jayi phul

Cestrum ochraceum *Francey*

Cestrum parqui *L'Hér.* **(C. campestre** *Griseb.***; C. foetidissimum var. pallidisimum** *Dunal***; C. jamaicense var. parqui** *Lam.***; C. mandoni** *Rusby***; C. pseudo-quina** *Mart.***; C. salicifolium** *Hort. Monsp. ex Dunal***; C. salicifolium** *Kunth ex Spreng.***; C. virgatum** *Ruiz et Pav.***)** – green cestrum, Chilean cestrum, green jessamine, willow leaved jessamine, green poison berry

Cestrum spp.

Attention was brought to these plants by the announcement that a Cestrum sp., probably C. laevigatum, is smoked by seafarers around the southern coast of Brazil, as a **Cannabis** substitute (Schultes & Hofmann 1980). C. laevigatum is used as a fish poison, and a sedative dressing for wounds and ulcers. In Brazil the leaf has been used as a soap substitute, and is also considered antispasmodic and diuretic. C. aurantiacum is reported as narcotic in Guatemala, and has poisoned cattle in Africa [resulting in irritability, hypersensitivity to stimuli, and paralysis]. In the Sibundoy Valley of the Amazon, shamans use a tea of C. ochraceum fruits to induce sweating in rheumatic patients. It is said that the patient experiences slight delirium if too much is taken. A leaf infusion is also applied to swollen joints. Kamsa shamans consume a cold water leaf infusion from a Cestrum sp. known as 'borrachera andoke', in order to "see all things like yajé" [see **Banisteriopsis**]. C. nocturnum is used in Martinique and Mexico to treat epilepsy, and in the West Indies as a stupefying charm medicine (Schultes & Raffauf 1990; Watt 1967; Watt & Breyer-Brandwijk 1962). In the Kathmandu Valley, the flowers are used as offerings to Shiva and Ganesha. Nepalese shamans use the aerial parts as ritual incense, as well as sometimes consuming the flowers [eaten fresh, or smoked when dry] to increase their spiritual healing energy. In the Kalinchok region, the plant is sometimes added to liquor (Müller-Ebeling et al. 2002).

It seems that many members of the genus share similar properties, and have been reported on occasion to cause stock poisonings (McBarron 1983). C. parqui has poisoned animals in Australia, with symptoms including "fever, gastroenteritis [including bloody faeces], and occasionally excitement. Death usually follows within a few hours after onset of symptoms." C. diurnum and C. nocturnum have caused poisonings in humans as well as other animals. "Symptoms are largely nervous in character and resemble those produced by *atropine* [...] Included were hallucinations, muscular and nervous irritability, tachycardia, elevated temperature, salivation, dyspnoea, and paralysis" (Kingsbury 1964; Tamplon 1977). However, in some feeding tests, C. nocturnum displayed no apparent toxicity (Watt & Breyer-Brandwijk 1932). Many are naturalised weeds or garden plants in some parts of the world, the most common in cultivation probably being C. parqui.

C. parqui leaves, when smoked as a large cigarette, can produce a mild narcotic effect, yet the smoke is very harsh (pers. obs.). Overdose symptoms include gastric pain and slight convulsions; children have died from eating the fruits. The fruit is considered to be more toxic than the leaf; however, leafy tips can still be quite potent (Watt & Breyer-Brandwijk 1962).

C. diurnum leaves have yielded saponins with cardioactive properties, as well as traces of *nicotine*, *nornicotine* and *anabasine* from plants harvested in mid-summer (Halim et al. 1971). As with **Bufo** venom, the cardioactive saponins should presumably be largely destroyed on smoking.

C. laevigatum unripe fruit contains saponins [which yield gitogenin and digitogenin on hydrolysis]; these saponins are also found in other parts of the plant (Schultes 1979; Schultes & Hofmann 1980).

C. nocturnum has yielded 0.5% yuccagenin, 0.04% gitogenin (Rastogi & Mehrotra ed. 1990-1993), parquine, and volatile oil (Schermerhorn et al. ed. 1957-1974); leaves also yielded traces of *nicotine*, *nornicotine* and *anabasine* (Halim et al. 1971).

C. parqui contains saponins, and has yielded gitogenin, digitogenin, parquinoside, and the alkaloids parquine, carboxyparquine, solasonine (Buckingham et al. ed. 1994; Schermerhorn et al. ed. 1957-1974; Schultes 1979), and solasodine (Willaman & Li 1970). Leaf and stem from Brisbane, Australia [harv. Apr.] gave weak to strong positive tests for alkaloids (Webb 1949).

C. purpureum has yielded solasodine and solanidine [see **Solanum**] (Schultes & Raffauf 1990).

C. lanatum and C. strigillatum have tested alkaloid-positive (Fong et al. 1972).

Cestrum parqui is an erect glabrous shrub to 3m tall, spreading by creeping roots; young branches whitish, older stems darker, woody, striate at base, mottled above, one or more stems emerging from each crown; roots yellow, shallow, extensive, producing new plants from suckers. Leaves alternate, lanceolate, entire, glabrous, 5-14 x 1-2.5cm, margin undulate, base cuneate, apex acuminate, older leaves dark green, younger leaves lighter, slightly paler beneath; unpleasant odour when crushed; petioles 5-10mm long. Flowers greenish-yellow, sessile, borne in axillary and terminal panicular cymes; calyx 5-toothed, short; corolla yellowish-green, tubular, salverform or funnelform, with slender tube to 2.5cm long, with 5 small terminal spreading acute lobes, dilated at mouth; unpleasant odour by day, powerfully fragrant by night; stamens inserted around middle of corolla tube, included; filaments filiform, often pilose below, sometimes with a tooth-like appendage; anthers small, with parallel sacs. Ovary 2-celled, usually short-stipitate; ovules few; style filiform; stigma dilated, entire or 2-lobed. Fruit a purplish to black shiny ovoid berry, c.1cm long,

1-4-seeded, in dark purple pulp; seeds dark green to brown, 3-4mm long, irregularly shaped with sharp angles, surface roughened.

Native to Chile and Peru; naturalised in parts of eastern Australia, mainly on alluvial soils along streams; widely cultivated as an ornamental, sometimes escaping [eg. in Texas].

Sow seed in autumn; plants flower after 2 years (Correll & Johnston 1970; Parsons & Cuthbertson 1992).

CINNAMOMUM

(Lauraceae)

Cinnamomum camphora *(L.) J. Presl.* **(C. camphora** *(L.) Nees et Eber.***; C. camphora** *(L.) Sieb.***; C. camphoroides** *Hayata***; C. nominale** *(Hayata) Hayata***; C. simondii** *Lecomte***; Camphora camphora** *(L.) Karst.***; Ca. japonica** *Garsault***; Ca. officinarum** *Bauh.***; Ca. officinarum** *Nees***; Laurus camphora** *L.***; Ocotea japonica** *(Gars.) Thell.***; Persea camphora** *(L.) Spreng.***)** – camphor laurel, Chinese sassafras, Japanese camphor tree, kapuru-gaha, chang nao, karpoor, kapur, himavulaka, obchoei-yuan

Cinnamomum sp. 'Carpano' – carpano

Cinnamomum cassia *L. Presl.* **(C. aromaticum** *Nees.***; Laurus cassia** *L.***; L. cassia** *Nees et Nees***; L. cinnamomum** *Andrews***)** – cassia, Chinese cinnamon, wood cinnamon, mu gui, rou qui, gudatvak, dalchini, daruchini, darasini

Cinnamomum iners *Reinw. ex Blume* – chiad

Cinnamomum laubatii *F. Muell.* **(C. tamala** *(Buch.-Ham.) T. Nees et Eberm.***; Laurus tamala** *Buch.-Ham.***)** – Indian cassia, camphorwood, pepperwood, pepperberry, brown beech, tamal, tejpat, dalchini

Cinnamomum mercadoi *Vidal* – kalingag, canela, kanila, kandoroma, kasiu, samiling

Cinnamomum micranthum *(Hayata) Hayata* **(C. kanehirai** *Hayata***; C. xanthophyllum** *H.W. Li***; Machilus micranthum** *Hayata***)** – camphor tree, micranthum

Cinnamomum mindanaense *Elmer* – Mindanao cinnamon, canela, kalingag

Cinnamomum mollissimum *Hook. f.* – obchoei

Cinnamomum oliveri *Bailey* – camphorwood, sassafras, Oliver's sassafras

Cinnamomum porrectum *(Roxb.) Kosterman* **(C. barbato-axillatum** *N. Chao***; Camphora porrecta** *(Roxb.) Voigt***; Laurus porrecta** *Roxb.***; Phoebe latifolia** *Champ. ex Benth.***)** – theptaro

Cinnamomum siamense *Craib* – trakraiton

Cinnamomum zeylanicum *Blume* **(C. verum** *J. Presl.***; C. zeylanicum** *Breyn.***; Laurus cinnamomum** *L.***; L. cinnamomum** *Roxb.***)** – cinnamon, true cinnamon, Ceylon cinnamon, kurundu, kuruva, dalchini, bahugandha, shakala, karaboon

Cinnamomum spp.

Cinnamon trees have enjoyed a lofty medicinal reputation since antiquity. Cinnamon spice [usually C. zeylanicum bark] was used by the ancient Egyptians as a medicine, incense and perfume, and it was one of the important ingredients in the mummification process. Moses used it, with 'myrrh', to make a holy ointment, and the Arabs valued it as a symbol of wealth, using it to anoint sacred vessels used in important ceremonies. When it was introduced into Europe at the time of the Crusades, it acquired a reputation as an aphrodisiac; the oil may be rubbed on the genitals for this purpose, or the bark may be taken internally. The bark of the very similar C. cassia used in TCM has pungent, sweet and hot characteristics, and bears an affinity for the liver, spleen and kidneys. Decocted in doses of 2-5g, it is considered stomachic, analgesic, stimulant, astringent, diaphoretic, and improves vision and circulation. In India, C. cassia is considered an antispasmodic, aphrodisiac and nervine stimulant, which acts as an irritant narcotic poison in large doses. C. zeylanicum ['true' cinnamon] has similar properties, though its aroma is generally considered superior to that of C. cassia. Leaves, twigs and bark fragments are used to produce 'cassia oil'. C. zeylanicum is also considered aphrodisiac, antispasmodic, anthelmintic, antiputrescent, carminative, antimicrobial, antiseptic, digestive, emmenagogic, haemostatic, parasiticidal and stimulant to respiratory and circulatory functions. Both herbs are still widely used as a cooking spice and flavouring (Bremness 1994; FAO 1995; Lawless 1994, 1995; Nadkarni 1976; Rätsch 1990; Reid 1995; Watt & Breyer-Brandwijk 1962). Barks from other species have been used to adulterate or replace C. zeylanicum as cinnamon, such as C. iners, C. mercadoi and C. mindanaense (Lawrence & Hogg 1974; West & Brown 1920).

The ingestion of powdered cinnamon is said by some nutmeg users [see **Myristica**] to produce a dreamy sedation. It has been claimed that cinnamon sticks are smoked ritually in rural Mexico (Weil 1969), and may be smoked with **Cannabis** as a mild stimulant (Siegel 1976). More recently, in some areas of the US, cinnamon oil has become popular with teenagers as a mild psychoactive drug. It is generally used for this purpose by sucking on a finger or toothpick which has been dipped in cinnamon oil. Effects reported include "a rush or sensation of warmth, facial flushing, and oral burning", sometimes also with nausea or abdominal pain (Perry et al. 1990).

In some areas of Papua New Guinea, a Cinnamomum sp. is used "to make young warriors fierce" (Paijmans ed. 1976). On Mailu Island, near PNG, sorcerers chew the bark of a Cinnamomum sp. to make themselves magically powerful (Thomas 2001a).

Camphor from C. camphora is sometimes consumed by shamans in Peru to prevent sexual thoughts and nocturnal emissions during plant diets (Bear & Vasquez 2000). Some take it by itself as a teacher (Luna 1984). In Nepal it is used as a shamanic and medicinal incense, and is invoked with a mantra for shamanic travel. C. laubatii and C. glanduliferum are also used as incense (Müller-Ebeling et al. 2002). *Camphor* has been used by the Arabs as an anaphrodisiac, and was sometimes worn in a pouch around the neck to ward off colds and flu. It has been burned as an incense in s.e. Asia to ward off demons. It was used to make the original moth balls, and has been used medicinally to treat various nervous system conditions. Swahili natives wash their dead with *camphor* water, and insert pieces of it into the orifices. In India, c.1.2g is given with plantain [see **Musa**] to procure abortion. It is also given there to treat many other disorders, including nymphomania, and is said to act as a sedative in treatment of delirium tremens. The plant is sometimes used in TCM as an antibacterial, to relieve skin itches, relax gastrointestinal muscles, and to stop vomiting and pain. C. camphora otherwise has similar uses to cinnamon spice, but is more toxic, largely due to the high *camphor* content. In excess, *camphor* is a powerful irritant narcotic poison, causing 'maniacal delirium', convulsions, nausea, vomiting and epigastric pain. *Camphor* is distilled from the plant for commercial and industrial uses (Chopra et al. 1965; Huang 1993; Lawless 1994; Morton 1977; Nadkarni 1976; Rätsch 1992; Watt & Breyer-Brandwijk 1962). Essential oil extracted from the leaves is called 'Ho leaf oil'. C. camphora wood has also been used in China and Vietnam to produce 'Chinese sassafras oil' [see **Sassafras**], though wild stands are becoming depleted from overharvesting (FAO 1995).

C. camphora is very chemically variable, and appears to exist in numerous chemical races (FAO 1995). From C. camphora, both crude *camphor* and oil of *camphor* may be obtained. In some old trees, the *camphor* may actually be found concentrated in solid lumps, whereas some varieties have no *camphor* at all. It is found mainly in the yellow oil fractions; white *camphor* is the more or less pure form that is generally used, as it is safer than brown or yellow *camphor*. *Camphor* is most concentrated in the roots and base of the trunk [said to bear the most *safrole*], and some is found in leaves, with younger leaves bearing higher concentrations. Leaves from shaded trees, or harvested in overcast or rainy conditions, yield less *camphor*, though shade is known to increase the *safrole* content. Leaf may yield 0.1-4.4% *camphor*, and 0.3-4.2% oil of *camphor*; wood may yield 0.6% *camphor*, and 0.15% oil of *camphor*. Seeds are reported to produce hydrocyanic acid [HCN], which is also found in traces in the leaves, bark and flowers (Lawless 1994; Morton 1977; Nadkarni 1976; Watt & Breyer-Brandwijk 1962); seed essential oil also contains *safrole* (Lakanavichian 2007). The roots have also yielded the alkaloids norboldine [laurolitsine] and reticuline [see **Magnolia**] (Rastogi & Mehrotra ed. 1990-1993). White oil of *camphor* contains mainly cineol, and no *safrole*; the yellow oil contains 10-20% *safrole*, as well as sesquiterpenes; and the brown oil contains up to 80% *safrole*. *Camphor* is still often a component of oil of *camphor*, sometimes accounting for more than 50%. *Eugenol* may be present at up to 0.12% of the oil; *elemicin* is found in some oils of *camphor*, as is *anethole* (Battaglia 1995; Lawless 1995); other essential oil constituents include humulene, selinene, d-nerolidol, calamenene, calacorene, camphorenone, camphorenol and α-ylangene (Rastogi & Mehrotra ed. 1990-1993). Although the wood from which 'Chinese sassafras oil' is obtained is richest in *camphor*, fractional distillation is used to yield an essential oil richest in *safrole* (FAO 1995).

C. sp. 'carpano' from Bouganville yielded 0.085% *carpacin* from heat-dried bark (Mohandas et al. 1969).

C. cassia essential oil ['oil of cassia', 'oil of cinnamon' (not to be confused with 'cinnamon oil' from C. zeylanicum)] is obtained from the bark in a yield of c.0.9%, and may contain 50-90% cinnamaldehyde [sedative, analgesic] and up to 10% *eugenol* (Chevallier 1996; Watt & Breyer-Brandwijk 1962).

C. iners from Thailand contains over 50% *safrole* in essential oils from bark, root, leaf and seed (Lakanavichian 2007).

C. laubatii from Queensland [Australia] contains the alkaloid reticuline in the bark; bark [harv. Jul.] tested weakly positive for alkaloids in an alkaloid screening. Bark essential oil contains *safrole* (Lawrence & Hogg 1974; Webb 1949; West & Brown 1920). As C. tamala, the leaves have yielded an essential oil containing mostly [c.78%] *eugenol* and d-α-phellandrene. The leaves ['tejpat'] are used in India as a cooking spice (Anon. 1911b; Ilyas 1978).

C. mercadoi bark yielded 1.2% essential oil, consisting of c.30% *safrole*, 29% 1,8-cineole, and 15% *eugenol*; early studies suggested that the oil was composed almost entirely of *safrole* (Lawrence & Hogg 1974; West & Brown 1920).

C. micranthum essential oil ['micranthum oil'] may contain c.95%

safrole (Hall 1973).

C. mindanaense bark yielded 0.9% essential oil, consisting of c.39% *eugenol*, 19% linalool, 15% *safrole*, 0.5% geraniol, <0.1% *methyleugenol* and <0.1% *camphor* (Lawrence & Hogg 1974).

C. mollissimum from Thailand contains over 50% *safrole* in its bark essential oil (Lakanavichian 2007).

C. oliveri from NSW and Queensland [Australia] is known to exist in several chemical varieties – one contains a bark oil rich in *camphor*, *safrole* and *methyleugenol*, and another is richest in *eugenol* and cinnamaldehyde (Lassak & McCarthy 1990). Leaves [harv. Jan.] tested weakly positive for alkaloids (Webb 1949).

C. porrectum from Thailand contains over 50% *safrole* in essential oils from bark, wood and seed; leaf essential oil has yielded 99.8% *safrole*, and that from root yielded 95.5-97.8% *safrole* (Lakanavichian 2007).

C. siamense from Thailand contains over 50% *safrole* in essential oils from leaf and bark (Lakanavichian 2007).

C. zeylanicum bark may yield 0.5-2% essential oil, of which 40-75% may be cinnamaldehyde, 4-10% *eugenol*, and lesser amounts of 1,8-cineole, *pinene*, benzyl benzoate, linalool, caryophyllene and other compounds; the essential oil is yellow at first, but turns red on storage. *Safrole* was found as a major component in Thai bark and leaf oils. Leaves may yield c.0.1-0.15% greenish essential oil, consisting of 80-96% *eugenol*, 1% *eugenol* acetate, 3% cinnamaldehyde, 3% benzyl benzoate, and lesser amounts of *safrole* and other compounds. The leaf oil is less irritating to the skin than the bark oil. Trees that are highly fertilised give poor-quality essential oil (Battaglia 1995; Bruneton 1995; Ilyas 1978; Lakanavichian 2007; Lawless 1994, 1995).

As a note of interest, C. triplinervis has yielded 3-[2-(trans)-cinnamoylamino-ethyl]-3-OH-indolin-2-one-oxo-2-*tryptamine* (Husson 1985).

Cinnamomum zeylanicum is a moderate-sized evergreen tree; bark rather thick, smooth, pale; twigs often compressed; young parts glabrous except the buds, which are finely silky. Leaves opposite or subopposite (rarely alternate), hard and coriaceous, 7.5-20 x 3.8-7.5cm, ovate or ovate-lanceolate, subacute or shortly acuminate, glabrous and shining above, slightly paler beneath, base acute or rounded, main nerves 3-5 from the base or nearly so, strong, with fine reticulate venation between; petioles 1.3-2.5cm long, flattened above. Flowers hermaphrodite, numerous, in silky-pubescent lax panicles usually longer than the leaves; peduncles long, often clustered, glabrous or pubescent; pedicels long; perianth 5-6mm long, tube 2-5mm long, lobes of limb subequal, segments pubescent on both sides, oblong or somewhat obovate, usually obtuse; stamens 9, perfect, or by abortion fewer, those of the 2 outer rows with eglandular filaments and introrse 4-celled anthers, those of the third row with glandular filaments, the glands subsessile or stipitate, and extrorse (2-)4-celled anthers, those of the fourth row replaced by shortly stipitate cordate or sagittate staminodes. Ovary sessile, free from the perianth, narrowed into the style; stigma discoid or obscurely 3-lobed. Fruit a berry, 1.3-1.7cm long, oblong or ovoid-oblong, minutely apiculate, dry or slightly fleshy, dark purple, surrounded by the enlarged campanulate perianth which is 8mm in diameter.

Burma, w. Peninsula [India], Ceylon, Malay Peninsula; indigenous or cultivated (Kirtikar & Basu 1980).

Cultivate from seed or cuttings [though cuttings from *camphor*-rich trees are difficult to root]. Seed should be taken from 20-30 year old trees and planted [cleaned free of pulp] as soon as possible when dry, as the period of viability is short, and germination rate is low. May also be cultivated by layering and grafting young shoots on old stumps [see below]. Plant seeds in shaded raised beds of light sandy loam enriched with manure, water regularly; should germinate in 20-90 days. Shade is removed when 12-15cm high. When 6 months old, transfer the seedlings to pots, grass baskets or polythene bags filled with fertilised soil for another 6 months, before transferring to the final bed during the rainy seasons. Should be mulched and watered immediately after planting out. Prefers humus-rich sandy loam, some shading, 20-35°C temps., and average annual rainfall of 150-300cm. These trees are prone to manganese deficiency. Every year in the rainy season, young trees two years and older are cut back to c.10-15cm above the ground, the stump covered with earth, and shoots allowed to re-grow from the stump. After 3-5 years of growth, the bark from these new branches may be harvested to prepare cinnamon. Bark from shoots that are too young is too thin and scentless to be desired. The first bark peelings of a plant are also not of good quality. The main shoot gives the best quality essential oil. Longitudinal slits are made with a knife, and a rounded blade inserted to test for peelability; if the bark peels away easily, the branch shoots are cut off for processing. The peelings of bark are stacked and sweated, wrapped in coir, for 24hrs; this softens the bark to make it easy to scrape off the outer bark, which is not used. The inner bark peelings [the 'cinnamon quills'] are sun-dried for 3-5 days, then lightly rolled and pressed by hand, to prevent the bark swelling or cracking. Bark portions that do not roll easily to form quills [called 'quillings'], and rough bark chips, are used locally in cooking, as well as the buds and flowers of the tree; the neat quills themselves are usually reserved for export. Quillings and bark powder are also used in the manufacture of essential oil (Chevallier 1996; Ilyas 1978; Morton 1977).

CITRUS

(Rutaceae)

Citrus aurantiifolia *(Christm.) Swingle* **(Limonia aurantifolia** *Christm.***)** – lime tree, limón agrio

Citrus aurantium *L.* **(C. bigaradia** *Loisel.***; C. hystrix** *H. Perrier***; C. vulgaris** *Risso***; Aurantium acre** *Mill.***)** – bitter orange, zorange si ['sour orange'], zhi shi

Citrus aurantium var. amara *L.* – neroli, neroli bigaradia, petit-grain

Citrus limon *(L.) Burm. f.* **(C. limonelloides** *Hayata***; C. x limonum** *Risso***; C. medica var. limon** *L.***)** – lemon tree

Citrus maxima *(Rumph. ex Burm.) Merr.* **(C. aurantium var. decumana** *L.***; C. aurantium var. grandis** *L.***; C. grandis** *(L.) Osbeck***; C. kwangsiensis** *Hu***; C. x aurantiifolia** *(Christm.) Swindl.***; C. x aurantium** *L.***; C. x limetta** *Risso***; C. x nobilis** *Lour.***; C. x paradisi** *MacFad.***; C. x sinensis** *(L.) Osbeck***; Aurantium maximum** *Rumph. ex Burm.***; Limonia x aurantiifolia** *Christm.***)**

Citrus medica *L.* **(C. x limon** *(L.) Burm. f.***; C. x limon** *(L.) Osbeck***; C. limonia** *(L.) Osbeck***; C. limonum** *Risso***; Aurantium medicum** *(L.) M. Gómez***)** – citron, Rangpur lime

Citrus paradisi *MacFad.* **(C. decumana** *L.* **var. paradisi** *Nich.***)** – grapefruit, pomelo

Citrus reticulata *Blanco* **(C. deliciosa** *Ten.***; C. depressa** *Hayata***; C. nobilis** *Lour.***; C. reticulata** *Blanco***; C. reticulata var. austera** *Swingle***)** – mandarin, tangerine, satsuma

Citrus sinensis *Osbeck* **(C. aurantium var. sinensis** *L.***; Aurantium sinensis** *Mill.***)** – sweet orange, hojas de naranja

Citrus trifoliata *L.* **(Poncirus trifoliata** *(L.) Raf.***)**

Citrus unshiu *(Makino) Marcovitch* **(C. nobilis** *Lour.* **var. unshiu** *Swingle***; C. reticulata** *Blanco* **var. unshiu** *(Marco.) H.H. Hu***)** – unshiu orange, mandarin orange, satsuma orange, satsuma mandarin, cheju mandarin, Japanese mandarin, unshuu mikan, wen zhou mi gan

Citrus spp.

Citrus trees are well known for their delicious, edible fruits and associated perfumes – however, they are less known for their mood-altering properties and their chemical content. Modern 'orange' varieties derive from C. aurantium, whose properties were recognised by the Arabs and the Chinese. The Arabs brought it to the Mediterranean in 0AD, and by 9AD it was being used in Europe for epilepsy and heart problems, as well as to strengthen the brain and lift the spirits. The essential oil of the fruit peel acts as a soothing sedative and uplifting nervous tonic, and is considered warming and comforting by aromatherapists. 'Neroli oil' was distilled [now extracted with spirits] from the flowers of C. aurantium var. amara, and was used by inhabitants of Venice to cure bad nerves, plague and fever. Once it was so widely used by the prostitutes of Madrid, that the smell of it came to represent prostitution in that city. In Europe today, the flowers are infused and drunk as a tasty nerve tonic, tranquilliser, and blood cleanser. 'Petit-grain oil' is distilled from the young shoots and leaves, but is weaker and has slightly different properties to neroli. Neroli oil is soothing, tranquillising, hypnotic, antidepressant, aphrodisiac, restorative and uplifting; petit-grain oil is more a relaxing sedative and cardiac tonic (Chiej 1984; Lawless 1994; theobromus pers. comm.).

C. aurantium is used almost world-wide as a nervous tonic, digestive and purgative. It has many uses on Haiti, in medicine and magic. Medicinally, the leaves treat fever and flu, or they may be heated and tied to the forehead for headaches. A leaf tea with equal amounts of coffee leaves [see **Coffea**] treats emotional shock. The juice is used to treat anaemia, digestive disorders and skin problems. It is also very important as a 'cleanser' in wanga potions used in some Voodoo ceremonies. The fruit itself is used as a power-object in various magic spells – eg. to strengthen or call up one's own spirit, the orange is peeled, and the ½ attached to the branch is cut into 7 pieces. 'Castor oil' [from Ricinus communis] is poured over the skins, and a piece of cotton is set on fire in the middle. The skins of the fruit of this species and of C. sinensis are exported from Haiti to be used in the manufacture of 'Grand Marnier' liqueur; they are also used domestically to flavour rum (Paul & Cox 1995).

In Nuevo Leon, Mexico, C. sinensis is used as a flower and leaf infusion to calm the nerves (Nicholson & Arzeni 1993), and C. aurantium leaves ['hojas de naranjo agrio'] are used as a relaxing nerve tonic (Heffern 1974). In Peru, C. aurantiifolia juice is mixed with water, sugar, corn [Zea mays - see *Endnotes*] and white rose petals to make 'arranque' or 'corte', a substance used to terminate the effects of various psychoactive or potentially toxic plants [eg. see **Brugmansia**, **Trichocereus**] (De Feo 2003). In Irian Jaya, the Marind-Anim use leaves of an unidentified Citrus sp. "to induce ecstasy". In intitiation ceremonies for becoming sorcerers, they also consume leaves of C. aurantium [as C. hystrix; 'tadi'] mixed with Codiaeum variegatum ['kundama'], Cordyline fruticosa ['ngasi'], Crinum asiaticum ['jarangar'], and other unidentified plants

(Thomas 2001a).

In TCM, the dried peel of the unripe fruit of Citrus spp. ['jih shih', 'zhi shi'] is used – C. reticulata is used to treat chest pain, congestion and malaria (Bremness 1994); C. trifoliata is used to treat sluggish digestion and low vitality, as well as being an expectorant (Reid 1995); and the dried fruit of C. aurantium is used to treat shock (Huang 1993). The essential oil of C. reticulata is sedative, tonic, stimulant to digestion and lymph glands, antiseptic, antispasmodic, carminative, mildly laxative, and diuretic (Lawless 1995). Butanol and water extracts of the unripe fruit peel appear to have antidepressant activity in mice, given orally (Song et al. 1996).

Many Citrus spp. contain a variety of simple *phenethylamine* alkaloids, some in high enough amounts to be pharmacologically significant [such as p-synephrine – see *Neurochemistry*], as well as indole and purine alkaloids. Following the banning in some countries of *ephedrine* and Ephedra spp. extracts due to adverse cardiovascular reactions in some consumers, synephrine and extracts from Citrus spp. containing it have recently become popular for weight loss and bodybuilding [with weight loss doses being c.32mg a day of synephrine], as they are not yet regulated and are believed [possibly incorrectly] to be safer; their efficacy for these purposes has also not been well demonstrated (Arbo et al. 2008; Dragull et al. 2008). They are also seeing use as main ingredients of some 'herbal ecstasy party pills' currently being sold (pers. obs.). Also of importance are terpenoids in their essential oils [usually from the fruit peel], some of which are useful in the synthesis of other compounds [see below].

C. aurantiifolia essential oil contains limonene and *citral* (Erickson 1976); the peel has also yielded 6,7-dimethoxycoumarin (Tatum & Berry 1977) – coumarin itself is a sedative hypnotic in high [near toxic] doses (Macrae & Towers 1984b); flowers yielded c.0.0028% *caffeine* (Stewart 1985).

C. aurantium leaves have yielded 0.006-0.007% [w/w] synephrine; fruit has yielded *tryptamine*, synephrine [0.041-0.048% from unripe Brazilian fruits] and N-methyltyramine, as well as the flavones nobiletin and tangeratin; unripe fruit peel has yielded 0.056% synephrine, albedo 0.028%, and pulp 0.019%; peel has also yielded 6,7-dimethoxycoumarin (Arbo et al. 2008; Huang 1993; Schneider et al. 1972; Tatum & Berry 1977); flowers yielded c.0.0031% *caffeine* (Stewart 1985), synephrine, neohesperidin, *adenosine*, asparagine, alanine, isoleucine, tyrosine, valine, β-sitosterol, β-daucosterol and 5,8-epidioxyergosta-6,22-dien-3β-ol (Huang et al. 2001). Bitter orange jam was found to contain c.0.0000019% trans-1,2,3,4,5-pentahydroxypentyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid, and c.0.0000115% of the cis-isomer (Herraiz & Galisteo 2002). Extracts of the fruit [containing 2.5% synephrine] were non-toxic in mice, and 1-5g/kg [oral] reduced locomotor activity; synephrine alone caused gasping and salivation at 150mg/kg, and reduced locomotor activity at 300-2,000mg/kg. It is thought the cardiovascular activity of both may be enhanced by the stimulants with which they are sometimes combined in weight-loss or other products (Arbo et al. 2008).

C. aurantium var. amara leaf essential oil contains limonene, aurantiamarin, hesperidin, neohesperidin and stachydrine; flower oil contains limonene, *pinene*, linalool, citronellol, nerol, camphene and geraniol; peel oil contains d-limonene, *citral*, *citronellal*, hesperidin and methyl anthranilate (Chiej 1984; Erickson 1976); fruit has yielded 0.1-0.35% synephrine, and the flavonoids naringin, naringenin, neohesperidin, hesperidin, hesperetin, neoeriocitrin and narirutin (Pellati et al. 2004).

C. australis bark and wood [from Queensland, Australia] tested weakly positive for alkaloids (Webb 1949).

C. limon has yielded *tyramine*, N-methyltyramine, synephrine and octopamine from unspecified parts (Smith 1977a); unripe fruits yielded 0.037-0.045% synephrine, and leaves 0.01% [w/w] (Arbo et al. 2008); fruits have also yielded up to 0.000205% 1-methyl-1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [MTCA], as well as 1,2,3,4-tetrahydro-β-carboline-3-carboxylic acid [THCA] (Herraiz 1999); flowers yielded *caffeine* [major alkaloid; c.0.005% in the 'Lisbon' variety], *theobromine*, *theophylline* and paraxanthine, almost entirely concentrated in the stamens, especially the anthers. The small, round flower buds were almost alkaloid-free, but the elongated buds just before anthesis show the first signs of alkaloidal concentration, which increases during anthesis. Anthers yielded c.0.9% total alkaloids, with 0.7-0.8% *caffeine* (Kretschmar & Baumann 1999; Stewart 1985).

C. macroptera [from Papua New Guinea] yielded 0.02% alkaloids from bark, consisting mostly of edulinine [see **Casimiroa**]; in very large doses [500-2,000mg/kg (oral) in mice], the total alkaloids acted as a respiratory toxin (CSIRO 1990).

C. maxima flowers yielded purine alkaloids of similar proportions to C. limon.

C. medica unripe fruits yielded 0.012-0.051% synephrine, and leaves 0.016-0.025% [w/w] (`Arbo et al. 2008); pollen contained similar levels of purine alkaloids to anthers of C. limon (Kretschmar & Baumann 1999).

C. medica x sinensis has yielded *tyramine*, octopamine and synephrine from unspecified parts (Lundstrom 1989).

C. paradisi flowers of the 'Ruby Red' variety yielded c.0.0029% *caffeine* (Stewart 1985), as well as *theobromine*, *theophylline* and paraxanthine (Kretschmar & Baumann 1999). Leaves and fruit contained no *tyramine*, N-methyltyramine, *hordenine*, synephrine or octopamine (Wheaton & Stewart 1970). Fruits have yielded up to 0.000837% MTCA, as well as THCA (Herraiz 1999); fruit rind essential oil may contain c.26% *citral* (Watt & Breyer-Brandwijk 1932). Fruit juice contains, besides vitamin C [ascorbic acid], flavonoids including c.2% naringin [which is metabolised to its aglycone form, naringenin, after consumption], and the furanocoumarin 6',7'-dihydroxybergamottin; this latter compound, as well as naringenin [but not naringin], inhibits cytochrome P450 isoenzymes 1A2, 2A6, 3A4 and 3A5, leading to potentiation of *caffeine*, *theophylline*, *diazepam*, coumarin, and many other drugs [see *Neurochemistry*] (Chan et al. 1998; Edwards et al. 1996; Fuhr & Kummert 1995; Fuhr et al. 1993; Runkel et al. 1997; Watt & Breyer-Brandwijk 1932). Anecdotal reports suggest the juice is also useful in potentiating the effects of *THC*, opiates and MDMA (pers. comm.).

C. reshni has yielded *tyramine*, N-methyltyramine, octopamine and synephrine from unspecified parts (Lundstrom 1989).

C. reticulata leaves have yielded [as % (w/w) from 'tangerine' and 'Cleopatra mandarin', respectively] *tyramine* [0.0011, 0.0028], N-methyltyramine [0.0019, 0.0031], *hordenine* [0, 0.0008], synephrine [0.2031, 0.2215] and octopamine [0.0024, 0.0012]. Fruits yielded [% as above] *tyramine* [0.0001, <0.0001], N-methyltyramine [0.0015, 0.0058], *hordenine* [0, 0.0007], synephrine [0.0125, 0.028] and octopamine [0.0001, 0.0002] (Wheaton & Stewart 1969, 1970); juice of 'Dancy' tangerines has yielded 125mg/L synephrine, and that of 'Cleopatra' mandarins yielded 280mg/L (Dragull et al. 2008); tangerine fruit juice concentrate yielded 24.5-34.6mg/6oz synephrine (Stewart 1963); fruits have also yielded up to 0.00025% MTCA, as well as THCA (Herraiz 1999). As C. deliciosa, Brazilian trees yielded 0.077-0.197% [w/w] synephrine from unripe fruits, and 0.028-0.087% from leaves (Arbo et al. 2008). Flowers of the 'Dancy' tangerine variety yielded c.0.0019% *caffeine*; flowers of the 'Willow leaf' variety of mandarin yielded c.0.0032% *caffeine*; and flowers of the 'Cleopatra' variety of mandarin yielded c.0.0021% *caffeine* (Stewart 1985). Essential oil contains limonene, geraniol, *citral*, *citronellal* and methyl anthranilate (Lawless 1995); the plant has also yielded nobiletin, 5-demethylnobiletin, ponkanetin, 4,5,7,8-tetramethoxyflavone, 6,7-dimethoxycoumarin, 6,7-dimethylaesculetin, cholesterol, campesterol, stigmasterol and β-sitosterol (Rastogi & Mehrotra ed. 1990-1993).

C. sinensis has yielded *narcotine*, *tryptamine* [0.00001% in fruit pulp], *tyramine* [0.001% from fruit pulp, 0.0006% (w/w) from leaf], N-methyltyramine [0.0007% (w/w) from leaf, 0.0001% from fruit], synephrine [0.016-0.032% (w/w) from leaf, 0.0019-0.148% from fruit (decreasing with maturity), up to 61mg/L in juice, up to 29.8mg/6oz in juice concentrate (highest levels in Murcott variety)], and *norepinephrine* (Dragull et al. 2008; Rimpler 1965; Smith 1977a; Stewart 1963; Udenfriend et al. 1959; Wheaton & Stewart 1970); peel contains 6,7-dimethoxycoumarin (Tatum & Berry 1977); fruit has also yielded up to 0.000188% MTCA, as well as THCA (Herraiz 1999); fruit juice [orange juice] was found to contain 0.02-0.063mg/L trans-1,2,3,4,5-pentahydroxypentyl-THβC-3-carboxylic acid, and 0.1-0.28mg/L of the cis-isomer (Herraiz & Galisteo 2002). The essential oil contains limonene and other terpenes (Erickson 1976). Flowers of the 'Valencia' orange variety yielded c.0.0003% [bud 8mm diam.] to 0.0062% *caffeine* [fully opened flower]; leaves yielded c.0.0006% (Stewart 1985).

C. trifoliata flowers yielded purine alkaloids as for C. limon, but in lesser quantities (Kretschmar & Baumann 1999).

C. unshiu leaf has yielded *bufotenine*, 5-OH-*N*-*methyltryptamine*, (-)-synephrine, (-)-stachydrine, *adenosine*, rutin, narirutin, hesperidin, vicenin-2 and (+)-chiro-inositol. This mixture of compounds acts as an oviposition-stimulant in female 'swallowtail butterflies', Papilio xuthus [see *Endnotes* for chemistry of some Papilio spp.], which feed on some Rutaceous plants (Ohsugi et al. 1991). Fruit juice yielded 54.5-160.2mg/L synephrine (Dragull et al. 2008).

Citrus spp. fruits also contain vitamin C and other nutrients, as well as pectin. *Citral*, found in most Citrus spp. essential oils, can be condensed with olivetol to produce Δ-1-*THC*, when *citral* is present as the trans-isomer [*citral* A, or geranial (not gerianiol)] (Mechoulam et al. 1972).

Citrus reticulata is a small, spreading tree; twigs with single spines in leaf axils, slender. Leaves alternate, simple, coriaceous, thin, narrowly elliptical, lateral veins few; petioles distinctly winged and articulated with the lamina. Flowers usually all hermaphrodite, actinomorphic, solitary or in small axillary clusters, white; sepals 4-5; petals (4-)5(-8); disc present; stamens c.4x as many as petals, free or rarely monadelphous. Ovary superior, usually 10- to 14-locular; ovules in 2 rows; styles as many as carpels, free or connate. Fruit 5-7.5cm diam., depressed-globose; rind thin, easily separated from pulp, bright orange when ripe; pulp sweet, slightly tangy; seeds surrounded by stipitate, fusiform pulp-vesicles.

Much cultivated worldwide.

Members of the genus Citrus can be quite difficult to differentiate taxonomically, particularly due to the wide range of cultivars currently being grown (Tutin et al. ed. 1964-1980). Nitrogen appears to increase synephrine production, whilst manganese deficiency abolishes it (Dragull et al. 2008).

CLAVICEPS, including some Paspalum host grasses

(Ascomycetae/Clavicipitaceae)

Claviceps africana *Frederickson et al.* – African sorghum ergot
Claviceps fusiformis *Loveless* – Pennisetum ergot, bajra ergot, pearl millet ergot
Claviceps gigantea *Fuentes et al.* **(**imperfect stage known as **Sphacelia sp.)** – corn ergot
Claviceps paspali *Stevens et Hall* – Paspalum ergot
Claviceps purpurea *(Fr.) Tul.* – ergot of rye, rye smut, spurred rye, blight kernels, horn seed, mother of rye, mutterkorn, tollkorn ['mad grain'], seigle ivre ['inebriating rye']
Claviceps sorghi *Kulkarni et al.* – sorghum ergot
Claviceps sorghicola *Tsukiboshi et al. sp. nov.* – sorghum ergot
Claviceps spp. – ergots

(Gramineae)

Paspalum dilatatum *Poir.* – paspalum, water couch, caterpillar grass
Paspalum paspaloides *(Michx.) Scrbn.* **(P. distichum** *auct. non L.***)** – jointgrass, knotgrass
Paspalum scrobiculatum *L.* **(P. orbiculare** *Forst. f.***; P. polystachyum** *R. Br.***)** – kodo millet, kodrava, jome
[note: P. distichum *L.* is now considered to be a name not clearly attributable to any particular species (Samorini 2001)]

'Ergots', the best known species being C. purpurea, are fungal parasites on grasses, described by the Assyrians [who knew of its abortive properties] in 600BC as a "noxious pustule in the ear of grain". European midwives have long used it as a uterotonic to bring on birth contractions; ergot has since fallen into disrepute for this purpose due to its toxicity, but ergot alkaloids are still used as vasoconstrictors to stop post-partum haemorrhage. Cases of ergot-poisoning ['ergotism'] have been reported since the Middle Ages, when rye was introduced to Europe as a food crop [C. purpurea being parasitic on rye]. Ergot-infected grains were commonly milled in with 'clean' grains when making flour for bread-making. Those who consumed the resultant bread over time were struck by a violent poisoning manifesting in two forms. 'Convulsive ergotism' included symptoms such as nervous convulsions and epileptic fits; sometimes called 'Saint Vitus' Dance', that name now generally refers to the convulsive symptoms of chorea. 'Gangrenous ergotism' ['ignis sacer' – 'holy fire'] included gangrene, atrophy, and sometimes the loss of extremities. Both usually also involved 'delirium and hallucinations', and were often fatal. The gangrenous form of ergotism was also called 'Saint Anthony's fire', after a hermit who was considered the saint of infection, eplilepsy and fire. Those affected would often make pilgrimages to his shrines to seek a cure. Since the cause of ergotism was discovered, outbreaks have been much less common (Hofmann 1978; Ott 1993; Schultes & Hofmann 1980, 1992). Convulsive ergotism generally develops only in those who also have vitamin A deficiency, or in children, who are more susceptible. Gangrenous ergotism may develop instead in people with adequate vitamin A levels (Spanos & Gottlieb 1976). Lesser poisonings may result in nausea, vomiting, diarrhoea, thirst, restlessness, vertigo, headache, 'heaviness of the head', confusion, vasoconstriction, tachycardia, stimulation or depression of the cardiovascular system, and sometimes coma. Ergot should be avoided by people with liver impairment, hyperthyroidism or sepsis; in pregnancy, it should only be used by professionals in the third stage and not before (Felter & Lloyd 1898; Hobbs 1995).

Convulsive ergotism has been suggested as the cause of the symptoms leading to the infamous Salem witch trials of 1692 (Caporael 1976), though closer inspection of the evidence shows that this is an unlikely explanation (Spanos & Gottlieb 1976). C. purpurea ergot growing on Elymus arenarius [Leymus arenarius], or possibly on imported rye grain, is also suspected of being involved in similar events leading up to the Finnmark [Norway] witch trials in the 1600's. Interestingly, historical periods of epidemic ergotism in Europe coincide with "surges of Jewish mystical movements" (Alm 2003). Ergot has also been considered the cause of a mass-poisoning in France, in 1951 [see **Aspergillus**], despite evidence to the contrary (Ott 1993).

The ancient Greek Mysteries at Eleusis were a yearly initiation ceremony associated with the goddess Demeter, which could be attended only once in a lifetime. They were a sacred ritual celebration of agriculture and fertility, which appear to have been adopted from the Egyptian Isis cult, via Crete. The Lesser Mysteries took place in February at Agrai, where candidates for initiation witnessed re-enactments of myths related to Persephone's kidnapping by Hades [see also **Narcissus**, **Pancratium**]; a psychoactive mushroom appears to have been involved [see also **Amanita**, **Panaeolus**]. The ritual culminated 6 months later in the Greater Mysteries at Eleusis, based around Persephone's rebirth from the underworld. The rites continued for 2,000 years until the 4th century, when they were suppressed by the Christians. Attendees were required to speak Greek, and to stay in Athens for more than half a year and be able to pay for a sacrificial pig and the wages of the guides and priests, before joining the procession of initiates along the Sacred Road to the sanctuary at Eleusis. Once there, the rites took place in a hall ['telesterion'], where the initiates were served a potion [the 'kykeon' – roughly, 'mixture' or 'that which is mixed' in Greek] and beheld wondrous visions, accompanied by physical symptoms of fear, trembling, nausea, vertigo, and cold sweat. Once the initiates had 'seen', they were to tell no-one of what transpired, other than to say they had seen 'the holy'; the price of loose-lips in this case was death. Many great philosophers of science attended the Mysteries, including Plato and Aristotle. C. paspali or a similar visionary ergot-fungus has been proposed to have been the major active ingredient of the Eleusinian kykeon, a possibly 'beer-like' concoction thought to have contained a water infusion of C. paspali infected grain, barley, Mentha aquatica or M. pulegium ['stream mint', 'pennyroyal' – possibly to counteract nausea produced by ergot-alkaloids] and perhaps **Papaver** somniferum. In essence this use of ergot may be feasible, as the more psychoactive and less toxic chemicals of C. paspali are water soluble, whereas the toxic components are not, to any appreciable degree, and Paspalum paspaloides grass infected with C. paspali still grows in the area (Ott 1993; Riedlinger 2002; Samorini 2001; Wasson 1961; Wasson et al. 1978). However, it is now known that P. paspaloides was not introduced to Europe until after Columbus (Heinrich et al. 1999a), so either another grass-host bearing C. paspali was used [unlikely due to the lack of native Paspalum spp., the only known hosts to C. paspali], or other plant/s or fungi were responsible for the entheogenic effects of the kykeon. The central involvement of some kind of ergot does, however, still seem likely based on the known evidence to date (Samorini 2001).

Although no one has reported preparing a theoretical kykeon beverage using ergot, either for chemical analysis or bioassay, it has been proposed that a 'safe' kykeon could have been prepared for the original Eleusinian Mysteries using C. purpurea, generally considered too toxic to ingest. The proposition rests on the observation that hydrolysis of ergot alkaloids in basic solution converts the more toxic ergot-peptides into a mixture of *ergine* and isoergine. This could have been achieved in ancient Greece by boiling the ergot infusion with wood ashes [a source of potassium carbonate]. Excess basicity [which would hinder consumption] could have been neutralised by adding wine or vinegar, or by letting the mixture stand for several days. It was also suggested that fasting before the Greater Mysteries could have increased the subjective CNS effects of such a brew rich in *ergine* and isoergine, which are normally not particularly psychedelic in effect (Webster, P. et al. 2001). Another suggested method involves a beer brewing method thought to have been used in ancient Egypt, except stopping short of fermentation [alcohol was forbidden from the Mysteries]. A blending of two separate concoctions - one consisting of an infusion of malted grain, the other a boiled brew of ergotised grain - strained and drunk shortly after preparation may have produced an active beverage with enough tannin to bind to and inactivate the toxic alkaloids, hopefully leaving the desired alkaloids in solution and not being so rich in tannin to be undrinkable (Riedlinger 2002).

The closest examples we have of humans relatively safely consuming ergot extracts mainly come from the medical literature in days when ergot was still used therapeutically. A tincture of ergot and sodium phosphate used medicinally in the 19th century was found to produce pleasant psychotropic effects when given in moderate doses [5g tincture of ergot, 15g of 1/10 solution of sodium phosphate, poured into sugar water and consumed during a fast]. This may perhaps involve similar chemical conversions to those just mentioned. Oddly, this combined tincture was reported to only reliably produce these effects in women, "especially those of a nervous temperament." It was claimed that the resistence of males to the effects of moderate doses was "in consequence of their being more accustomed to alcohol." Effects were compared to "the slight intoxication produced by light wines and champagne", with "the most exhilarating effects, exciting loquacity and irresistible laughter, which lasted for several hours" (Anon. 1881c). Other medicinal preparations included tincture of ergot [250g powdered ergot to 1 pint proof spirit], ammoniated tincture of ergot [a more complicated, basified extract], infusion of ergot [7g powdered ergot to c.280ml boiling distilled water], fluid extract of ergot [an acidified alcohol extract], extract of ergot [the fluid extract reduced to a thick consistency] and wine of ergot [150g powdered ergot to 150cc alcohol and enough white wine to bring the whole to 1000cc]; these fluid extracts were generally strained of residue before being bottled and stored. Doses were different for different preparations, and depending on what purpose they were being used for, but were generally kept as low as possible, eg. 5-10 drops (Felter & Lloyd 1898). Medicinal doses of the freshly powdered fungus itself may range from 150-500mg (Hobbs 1995). One person with an LSD-tolerance consumed a few sips of a homemade ergot wine, made by infusing ergot in wine and ageing for 10 years or more; its maker did not divulge the quantity of ergot used and was [worryingly] casual and vague about dose. The effects were reported as broadly LSD-like, but with a heavy body load, particularly on the cardiovascular system, and with other side effects reminiscent of those of morning glory seeds [see **Argyreia**, **Ipomoea**, **Turbina**], and afterwards, weakness lasting for

around 10 days (Cole 2005).

Incidentally, ergot-infected specimens of the grasses Eleusine coracana ['finger millet', 'soma'] or Paspalum scrobiculatum ['kodo millet', 'kodrava'] have been proposed as possible identities of the Vedic soma [see **Amanita**]; Setaria indica ['sayamaka'] is also sometimes known as 'soma' in India, and S. italica has reportedly been used as a soma substitute (Ott 1998b). The Indian Pennisetum typhoides ['bajra', 'pearl millet'], a commonly cultivated food plant, is sometimes infected with ergot [often C. fusiformis], and human intoxications from such 'ergoty' bajra have been reported in the state of Maharashtra. Symptoms included "giddiness, nausea, vomiting, diarrhoea, and dehydration", and some fatalities have resulted (Bhat et al. 1976).

In Paraguay, an intoxicating beer is made by the Macai, using honey collected from bees that have fed on the 'honeydew' secretions [see below] of C. paspali infecting Paspalum plicatilum and P. unispicatum. The beer is reported to have 'disruptive effects', and to cause 'vertigo, headaches and drunkenness' (Rätsch 1998; Samorini 2001). P. scrobiculatum, which grows in moist or shady places in tropical and subtropical zones, is known to be toxic after rains, and may cause "deliriums and violent tremors"; it is said that elephants have died from eating it [presumably in large amounts]. The carefully dehusked grains are cooked and eaten as a rice-substitute in India. In West Africa, the plant grows as a weed of rice crops, and is similarly eaten (De Wet et al. 1983; Nadkarni 1976). The Lodha of the Midnapur district, w. Bengal, know P. scrobiculatum as 'jome', and they consume the outer covering of its dehusked grains for "hallucination" (Pal & Jain 1989); it is most likely infected with C. paspali. Dried ethanol extracts of the seed husk have been used to treat 'acutely disturbed schizophrenics' and 'psychotics', and have also been taken by the researchers involved. They found that 20-70mg of the extract was tranquillising and hypotensive, and had low toxicity – some tremors and rigidity occurred for short periods (Deo & Bhide 1961; Deo 1964).

In Queensland, Australia, Paspalum scrobiculatum [as P. orbiculare] has been shown to be infected by an indigenous species, C. queenslandica, as well as by C. paspali. Australian P. dilatatum is frequently found to be infected with C. paspali [but not C. queenslandica] (Langdon 1963), and has been responsible for cattle intoxications (Noble 1985).

Claviceps spp. are very variable in alkaloidal yield and composition, depending on the strain, the host grass and environmental variables. Some contain no alkaloids at all, such as French C. purpurea growing on Glyceria fluitans (Reicher et al. 1983). The alkaloids usually encountered include the ergolines [such as *ergine*, *ergonovine*], clavines [such as *agroclavine*, *chanoclavine*, *elymoclavine*], and ergot-peptides [such as *ergotamine*, ergosine, and including the 'ergotoxines' ergokryptine (ergocryptine), ergocristine, ergocornine]. These alkaloids [particularly the lysergic acid amides] are generally well-known for their potent *serotonin*-antagonist properties, though at levels required for such activity, the peptide alkaloids also stimulate uterine contractions (Cerletti & Doepfner 1958). The ergolines are often used as precursors in the licit or illicit synthesis of d-lysergic acid diethylamide [LSD, LSD-25]. Indeed, it was this factor that brought ergot back into the spotlight last century, ever since Albert Hofmann first synthesised LSD in 1938, in his search for medically-useful ergot-derivatives. LSD itself has not yet been found to occur naturally. For more discussion on some of these alkaloids, see also **Ipomoea** and the *Chemical Index*.

C. africana is an African species, parasitic of Sorghum bicoloris (Frederickson et al. 1991) and S. vulgare; it has recently also been found in India, Thailand, Japan, Australia, and the Americas (Bogo & Mantle 1999). The sclerotia has yielded 0.2-0.5% alkaloids, mostly dihydroergosine, as well as *chanoclavine*, *festuclavine*, and dihydro-*elymoclavine* (Frederickson et al. 1991); dihydroergosine antagonises *serotonin* [with slightly over twice the potency of ergosine] (Cerletti & Doepfner 1958), decreases brain *serotonin* turnover, enhances convulsive effects of picrotoxin in rats, decreases them in mice, shows antiaggressive and possibly antidepressant activity, and appears to act on *GABA* and BZ receptors (Peričić& Manev 1990).

C. fusiformis has been shown to form *agroclavine* [major alkaloid], *elymoclavine*, *chanoclavine*, *festuclavine*, 2-bromo-*festuclavine*, lysergene, isolysergene and 6-nor-*agroclavine* in culture (Banks et al. 1974; Eich & Sieben 1985). See also under C. purpurea below.

C. gigantea growing on corn [Zea mays] in Mexico has yielded 0.026-0.03% alkaloids, which was made up of 65-68% *festuclavine*, 15% dihydro-*elymoclavine*, 7-11% *chanoclavine*, 1.5-3% pyroclavine, 3% *agroclavine*, 0.5% *elymoclavine*, and traces of unidentified clavine alkaloids (Agurell & Ramstad 1965; Agurell et al. 1963).

C. paspali from Australia growing on Paspalum dilatatum yielded 0.001-0.005% alkaloids, consisting of *chanoclavine*, *ergonovine* and *ergine*; American samples from this grass yielded only 0.1-0.25 times this amount. C. paspali growing on P. paspaloides near Rome contained *ergine*, isoergine, lysergic acid methyl carbinolamide and its iso derivative (Gröger et al. 1961); lysergic acid N-1-hydroxyethylamide has also been found (Bock & Parbery unpubl.). Submerged cultures of strain MG-6 from P. dilatatum near Rome yielded 8-OH-*ergine* and 8-OH-erginine during the post-production phase (Flieger et al. 1989), as well as 10-OH-cis- and 10-OH-trans-paspalic acid amide (Flieger et al. 1993). The fungus has also yielded isolysergic acid, lysergic acid α-hydroxyethylamide, its iso derivative, dihydrochanoclavine I, its iso derivative, clavicepamine, paliclavine, paspaclavine, paspalic acid, paspalicine, paspaline [tremorgen], paspalinine [tremorgen], paspalitrems A-C [tremorgens] and aflatrem (Buckingham et al. ed. 1994; Cole et al. 1977). This fungus has been responsible for causing an intoxication known as 'Paspalum staggers' amongst stock animals feeding on infected P. dilatatum; once the animals begin eating it, they develop a liking for it. The mature ergots in this case are considered less toxic than when still in the 'honeydew' stage [see below] (Cole et al. 1977; Hungerford 1990).

C. purpurea has yielded 0.01-0.4% alkaloids [or more], often mainly [c.80%] *ergotamine*, ergokryptine, ergocornine and ergocristine, with smaller amounts of ergosine [*serotonin* antagonist (Cerletti & Doepfner 1958), peripheral vasoconstrictor, raises body temp., inhibits ovulation, oxytocic (Porter et al. 1979)], ergosinine, ergometrinine, ergoptine, ergostine, ergokryptinine, ergobine, ergonine, ergobutine, ergobutyrine and ergovaline; lysergic acid amides represent c.20% or less of the alkaloids, consisting mainly of *ergonovine* [up to 0.23% has been isolated in India] and small amounts of *ergine* and isoergine. Strains vary in their ability to produce decent yields of alkaloids, and also vary in the alkaloids present and their relative proportions. Many other compounds have been found, such as *acetylcholine*, *choline*, histidine, thiolhistidine, *histamine*, *tryptophan*, *tryptamine*, tyrosine, *tyramine*, *phenethylamine*, clavine, clavicepsin, betaine, cadaverine, putrescine, isoamylamine, trimethylamine, agmatine, ergotic acid, ergosterol, ergochrysin, ergoflavin, fungisterol, endocrocin, clavorubin, scelerythin and inorganic salts (Annis & Panaccione 1998; Bruneton 1995; Henry 1939; Lundstrom 1989; Morton 1977; Smith 1977a, 1977b; Taber & Vining 1958).

C. purpurea growing on Arthraxon lancifolius was adapted to grow on rye [Secale cereale], and thus yielded 0.5% alkaloids, consisting of 33% *ergonovine*, 22% ergokryptine, 18.7% ergocornine and 17.6% *ergotamine*. Sclerotia that were slender and elongated yielded [as % of total alkaloids] 59.6% ergokryptine and 11.2% ergocornine (Janardhanan et al. 1982a). Canadian sclerotia on rye yielded 0.011-0.452% alkaloids, consisting mainly of *ergotamine* and ergocristine, as well as *ergonovine*, ergosine, ergocornine and ergokryptine (Young 1981a). Canadian sclerotia on wheat [Triticum vulgare] yielded 0.013-0.307% alkaloids, consisting mostly [46%] of ergocristine and ergocristinine, as well as *ergotamine* [17%], *ergonovine* [7%], ergokryptine [12%], ergocornine [11%] and ergosine [5%] (Young 1981b). Canadian sclerotia on barley [Hordeum vulgare] yielded 0.082-1.04% alkaloids, of similar composition to the above Canadian C. purpurea on wheat (Young & Chen 1982). Dutch C. purpurea growing on a variety of grasses was studied for alkaloids – Dactylis glomerata [0.481-0.753%; 30-40% ergosine, 5-30% *ergotamine*, 10-20% ergocristine, 1-5% *ergonovine*], Arrhenatherum elatius [0.323%; 30-40% ergosine, 20-30% ergocornine, 5-10% *ergonovine*], Molinea caerulea [0.549-0.658%; 30-40% ergocristine, 20-30% ergosine, 5-20% *ergonovine*], Secale cereale [0.321%; 20-30% ergocristinine, 10-20% each of ergocristine and ergotaminine, 5-10% *ergonovine*], **Festuca** arundinacea [0.206%; 20-30% ergocornine, 10-20% ergosine, 5-10% *ergonovine*], **Lolium** perenne [0.221-0.317%; 30-40% ergocornine, 10-20% each of ergosine and α-ergokryptine, 1-10% *ergonovine*] and **Phalaris** arundinacea [0.458%; 30-40% ergosine, 20-30% ergocristine, 5-10% *ergotamine*, 1-5% *ergonovine*] (Reicher et al. 1983). Indian ergot of rye and wheat have yielded 0.07-0.092% alkaloids, consisting mainly of *ergotamine*, as well as *chanoclavine* and ergobasine. A strain of ergot which may have been C. purpurea [more recently claimed to be C. fusiformis – see above], growing on Pennisetum typhoides ['pearl millet'], yielded 0.032-1% alkaloids, comprised of 47.9% *elymoclavine*, 47.6% *agroclavine*, 1.55% *chanoclavine*, 1.3% isochanoclavine, 1.3% *penniclavine*, and 0.07% isopenniclavine (Bhat et al. 1976; Hofmann et al. 1957). Ergot growing on rye [hence probably C. purpurea], Agropyrum spp., Elymus spp. [see *Endnotes*], **Phalaris** spp. and **Phragmites** spp. yielded *chanoclavine* and *festuclavine* (Abe & Yamatodani 1963). Saprophytic cultures of 'Agropyrum-type ergot' [which was originally found growing on Agropyrum semicostatum, **Festuca** rubra and Trisetum bifidum in Japan] yielded *elymoclavine*, *agroclavine*, *festuclavine*, *chanoclavine*, isochanoclavine, pyroclavine and costaclavine (Spilsbury & Wilkinson 1961). Ergot infecting Calamagrostis epigeios, near the Baltic Sea, yielded 0.6% alkaloids, consisting of ergosine [46.6%], ergocornine [38.8%], ergokryptine [14.5%], and traces of water-soluble alkaloids (Kaczmarek et al. 1968). C. purpurea infecting **Lolium**, **Festuca** and other grains has caused intoxications in stock animals (Hungerford 1990).

C. sorghi is a possibly extinct species from India, which grows on Sorghum spp.; sclerotia from archives was shown to contain *caffeine* (Bogo & Mantle 2000). No ergoline alkaloids have been detected in sclerotia, though traces of *agroclavine* have been found in cultured mycelium, and in Burmese herbarium specimens (Frederickson et al. 1991).

C. sorghicola, another parasite of Sorghum spp. [originally from Japan], was cultivated on S. bicolor, and the sclerotia shown to contain [w/w] 0.03% *caffeine*, and [from different specimens] 0.0002% of an unidentified "clavine-like" alkaloid (Bogo & Mantle 2000).

An unidentified Claviceps sp. ['feather ergot'] growing on Spartina alterniflora, S. cynosuroides and S. patens yielded 0.2-1.23% alkaloids, consisting of 25-88% ergokryptine, 9-50% ergokryptinine, 2-20% lysergylvalylmethyl ester, and 1-5% clavines (Eleuterius & Meyers 1977). Another undientified Claviceps sp., growing on Cynodon dactylon ['Bermuda grass'], yielded *ergonovine* [30% of total alkaloids], ergovinine [22% of total alkaloids], *penniclavine* and *chanoclavine* in liquid culture. This grass, when infected with Claviceps sp., has caused an intoxication in cattle known as 'Bermuda grass tremors', symptomised by nervousness and twitching, sometimes accompanied by an apparent inability to walk or stand (Porter et al. 1974). An unidentified Claviceps sp., growing on Panicum antidotale and P. repens in India, yielded 0.68-0.71% alkaloids, consisting mainly of *agroclavine*, *chanoclavine* and *festuclavine* (Janardhanan et al. 1982b).

Paspalum paspaloides from Castlemaine, Victoria [Australia] tested positive for alkaloids (CSIRO 1990).

P. scrobiculatum seed [presumably ergot-infected] tested positive for alkaloids (Fong et al. 1972).

Remember, ergots can be very toxic, and should be handled with great care. Some of their alkaloids may be absorbed through the skin. There are, to my current knowledge, no reports of modern-day ingestion of Claviceps spp.; if you wish to experiment, the fungus should never be ingested directly – rather, a cold-water infusion should be made, and this should be finely filtered before consumption. Be **very careful** with dosage, as unless you have access to testing equipment, you will have very little idea of the concentration or type of alkaloids present. C. paspali would probably be preferable to C. purpurea for experimentation.

Claviceps paspali has yellowish to grey sclerotia, globose, roughened when mature, c.3mm diam., 1-several stromata per sclerotium; stroma erect, capitate-stipitate, fleshy, head of stroma dull yellow; stipe short to medium, 3-15mm; perithecia completely covering head, numerous, ovoid, 340 x 119µ; asci cylindric, unitunicate, 15-175µ long, with a thickened apical cap, 8-spored; spores hyaline, filiform, 101 x 0.5-1µ, multiseptate upon discharge.

Parasitic on Paspalum spp.; has been reported on P. ciliatifolium, P. dilatatum, P. floridanum, P. intermedium, P. laevae, P. langei, P. longipilum, P. notatum [rarely observed], P. paspaloides, P. plicatilum [not forming sclerotia], P. pubescens, P. pubiflorum, and P. urvillei. USA, Central & South America, Hawaii, Australia, New Zealand, China (Hanlin 1990; Langdon 1963; Lefebvre 1939; Sprague 1950), India, Mediterranean.

Claviceps purpurea is parasitic on a large variety of grass spp. – including Agropyrum, Agrostis, Alopecuris, Andropogon, Avena ['oats'], Bromus, Calamagrostis, Dactylis glomerata ['cock's foot'], Elymus [Leymus], **Festuca**, Glyceria, Hordeum ['barley'], **Lolium**, **Phalaris**, **Phragmites**, Poa, Secale ['rye'], **Stipa**, Triticum ['wheat'] and many others (Pammel 1911; Sprague 1950).

An Australian species temporarily named Claviceps phalaridis *Walker*, but not considered to be a true Claviceps sp., has been observed on **Phalaris**, as well as on Dactylis glomerata, Danthonia spp. ['wallaby grass'], Vulpia bromoides ['rat's tail fescue'] and **Lolium** rigidum ['Wimmera rye grass']. The sclerotia are inconspicuous, and therefore difficult to detect in the field without close examination (Walker 1970).

Heavy infestations of ergot occur more frequently in periods of humid but cool weather (Morton 1977). The sclerotia, formed in the inflorescence of the host-grass out of a sticky 'honeydew' phase, falls to the ground when mature in autumn, where it lays dormant until spring ['overwintering']; after a period of cold weather, it sprouts tiny fruiting-bodies, which release spores to re-infect host-grasses and renew the cycle.

CLEMATIS

(Ranunculaceae)

Clematis hirsutissima *Pursh* **(C. douglasii** *Hook.***)** – sugar bowls
Clematis triloba *Heyne.* – moravela, laghukarni
Clematis virginiana *L.* **(C. canadensis** *Mill.***; C. holosericea** *Pursh***; C. lingusticifolia** *Nutt.***; C. missouriensis** *Rydb.***)** – virgin's bower, lady's bower, love vine, traveller's joy
Clematis vitalba *L.* – traveller's joy, vezzandro, hexenfinger ['witches fingers'], hexenhaar ['witches hair'], hexenseil ['witches rope'], hexenwinde ['witches wind']
Clematis spp. – traveller's joy, old man's beard

In Germany, C. vitalba has several common names [see above] that are suggestive of past magical uses (De Vries 1991). In Tuscany, Italy, a decoction of the shoots is sometimes used as a body wash to prevent the 'evil eye' (Pieroni & Giusti 2002). As a Bach Flower Remedy, the herb is used to counter absent-mindedness. The plant juice is said to relieve headaches if taken nasally, but is considered caustic and toxic, and is probably dangerous taken internally (Chevallier 1996). In e. Australia, C. glycinoides ['headache vine'] is sometimes used to treat headaches, by crushing the leaves between the palms of the hands, holding them briefly to warm them, and inhaling the fumes of the plant. However, those with sensitive skin may suffer irritation and sometimes blistering, from crushing the vegetation with bare hands. Of the headache cure, it has been said that "the patient immediately forgets the headache as a minor ailment compared with the sensation of exploding head, smarting nose and watering eyes, which fortunately lasts only momentarily". Sometimes there is no effect, suggesting variation in chemistry due to undetermined factors (Cribb & Cribb 1981).

In India, C. triloba leaves are infused as a sedative and antipyretic (Nadkarni 1976). In Greece, a Clematis sp. [probably either C. cirrhosa or C. sylvestris] was reported to cure a case of epilepsy that had resisted all other treatments (Felter & Lloyd 1898).

C. virginiana and C. recta have been used medicinally in N. America; the fresh bark, leaves, and flowers are the parts used, in the form of a tincture or infusion. In this form they have been taken internally as diuretics and sudorifics, as well as to relieve insomnia, neuralgia, toothache, cystitis, gonorrhoea, and numerous other complaints. An infusion of the dried leaves of C. virginiana has been used as a "nervine in uterine diseases" (Felter & Lloyd 1898). The Iroquois of North America use a stem decoction of C. virginiana as a body-wash, to 'induce strange dreams'. The Nez Perce of n.w. US were reported in the 19th century to insert a peeled root of C. hirsutissima into the nostrils of their horses, as a stimulant to revive the exhausted animals during strenuous races. The Teton Sioux also used the root for their horses, administering it as a snuff when being chased by foes (Morgan 1981; Ott 1993).

This stimulant action may be merely due to the irritant action of the protoanemonin in these plants, in low doses. Many Clematis spp., including C. vitalba, contain the lactinic glucoside ranunculin, which is enzymatically converted to protoanemonin [isomycin; 5-methylene-2(5H)-furanone; 4-OH-2,4-pentadienoic acid γ-lactone] when the fresh plant is bruised. Protoanemonin is a bitter γ-butyrolactone derivative, which causes blistering on contact [see also **Ranunculus**] (Budavari et al. ed. 1989; Chevallier 1996; Harborne & Baxter ed. 1993; Turner & Szczawinski 1991). The irritant/blistering properties are lost when the herb is dried. On drying, protoanemonin is converted to anemonin [1,2-dihydroxy-1,2-cyclobutanediacrylic acid di-γ-lactone]. The structural similarity of protoanemonin to γ-butyrolactone [GBL, which has similar effects to *GHB*] may imply that it could have similarly interesting 'narcotic' effects that could account for the psychoactivity of these plants (Budavari et al. ed. 1989; theobromus pers. comm.). Both protoanemonin and anemonin have shown sedative activity, and anemonin also acts as an antipyretic (Martin et al. 1988).

C. glycinoides from Brisbane [harv. Jul.] and Rockhampton, Queensland [harv. Jan.] [Australia] was found to contain alkaloids in the leaves (Webb 1949).

C. hirsutissima was found to contain anemonin (Kern & Cardellina 1983).

Clematis virginiana is a perennial with stems climbing 2-3m high. Leaves usually trifoliate; lateral and terminal leaflets similar, ovate, acuminate, rarely entire, commonly coarsely toothed with mucronate teeth, occasionally lobed, the uppermost smaller and sometimes simple; petiolules of roughly equal length. Flowers in panicles from many axils, roughly equalling the subtending leaves; sepals white or dull white, commonly 4, oval or oblong, 10-15mm long, pubescent on back, glabrous or pubescent on upper side; petals none; stamens numerous. Ovule 1; style elongate, flexuous, strongly plumose, 2-4cm long. Fruit a flattened achene, terminated by the style, numerous in a globose head, pubescent, c.4mm long.

N.w. United States (Gleason 1952).

Seeds should be sown soon after collection; may also be cultivated by layering, or from cuttings taken before the late spring flowering period (Burras ed. 1994).

CLERODENDRUM [Clerodendron]

(Verbenaceae)

CLERODENDRUM FLORIBUNDUM

Clerodendrum floribundum *Hort. ex Schau.* **(C. emirnense** *Bojer ex Hook.***)** – buwatanganing, dutji, milorrk, marbordalla, lollybush, smooth spiderbush, smooth clerodendrum
Clerodendrum glabrum *E. Mey.* **(Siphonanthus glabra** *(E. Mey.) Hiern***)** – Natal glory bower, white cat's whiskers
Clerodendrum ovalifolium *Engl.* – ngula
Clerodendrum polycephalum *Baker* – fani koron lafra
Clerodendrum serratum *(L.) Moon* **(Rotheca serrata** *(L.) Steane et Mabb.***; Volkameria serrata** *L.***)** – bharangi, bala, kaattu yerukku, neera thekku, siru thaeku
Clerodendrum trichotomum *Thunb.* – chou-wu-tong, kusagi, harlequin glory bower, peanut butter tree

In Australia, C. floribundum and C. ovalifolium are mixed with ashes and chewed as stimulants. The former is used as such in the Northern Territory, and the latter in n.w. districts of Western Australia. C. floribundum has also demonstrated many medicinal uses, differing slightly from tribe to tribe. Generally, a decoction is made from 3-6 young leaves, which is then applied externally for sores or itchy skin, or taken internally to treat headache, backache, internal pains, diarrhoea, colds and bronchial congestion. The plant has shown analgesic, decongestant, antidiarrhoeal and antipruritic effects (Aboriginal Communities 1988; Lassak & McCarthy 1990; Low 1990).

Many other Clerodendrum spp. are used medicinally in the regions where they grow, particularly in Asia and s.w. Pacific. Uses include treatment of fevers, malaria, dropsy, venereal diseases, scabies and internal parasites (Lassak & McCarthy 1990; Low 1990).

In n. Thailand, C. serratum is used by hill tribespeople as an aphrodisiac stimulant (Anderson 1993). The roots of this species have been used as an analgesic, antiinflammatory and antipyretic, activites which have also been demonstrated in animal studies (Narayanana et al. 1999). The leaves of C. trichotomum are used medicinally in China as an antihypertensive, sedative, analgesic and antinflammatory. They have been used to treat rheumatic arthritis, asthma and bronchitis (Zhu et al. 1996a). In S. Africa, C. glabrum is known to be soporific, and the leaf is used by the Lobedu to relieve convulsions in children (Watt 1967). The Fang of Guinea use C. splendens leaf in the form of nose drops, to treat cerebral malaria (Akendengué 1992). The Yoruba used C. polycephalum leaves as a 'virility medicine' (Verger 1995).

C. floribundum was chemically screened, but no alkaloids, essential oil or saponins were found in leaf or stem of the samples examined. The leaves contained 1% tannin, but no active principles were isolated (Aboriginal Communities 1988).

C. indicum and C. infortunatum leaves have yielded scutellarein-7-O-glucuronide and hispidulin-7-O-glucuronide (Subramanian & Nair 1973).

C. multiflorum leaves have yielded scutellarein [6-OH-*apigenin*; see **Scutellaria**], 4',6-dimethylscutellarein [pectolinarigenin] and (24S)ethylcholesta-5,22,25-trien-3β-ol (Rastogi & Mehrotra ed. 1990-1993).

C. tomentosum leaf from Rockhampton, Queensland [Australia], harvested in January, tested positive for alkaloids [HCl extract]; leaves harvested from Jandowae, Qld [harv. Jun.] gave negative tests [Prollius fluid extract] (Webb 1949).

C. trichotomum has yielded the indole alkaloid trichotomine from its fruits [bronchodilator, hypotensive, sedative], as well as diterpenoids and flavonoids. Extracts have shown binding to opiate, 5-HT1, *adenosine*-1, α-2-adrenergic, *histamine*-1 and *GABA* receptors (Harborne & Baxter ed. 1993; Kapadia et al. 1977; Zhu et al. 1996a, 1996b).

Extracts of C. bungei and C. mandarinorum root barks [from s.w. China] have been screened for receptor-site binding. Both extracts showed binding at α-1 and α-2 adrenergic, 5-HT1, 5-HT1a, 5-HT2, *dopamine*-1, *adenosine*-1, *GABA*a, *GABA*b, and opiate receptor sites; C. mandarinorum also exhibited β-adrenergic, *dopamine*-2 and *histamine*-1 binding (Zhu et al. 1996a, 1996b).

Clerodendrum floribundum is a small, sparse tree to 5m tall; bark light grey to brown, corky, fissured. Leaves opposite, broadly ovate-elliptic, widest near base, prominent central and lateral veins, 3-15 x 3-10cm; petioles 7cm long. Inflorescences many-flowered terminal or axillary cymes; calyx red, fleshy, 5-lobed, lobes 4-6mm long, persistent, spreading; corolla salverform, tube narrowly cylindric, straight or incurved, +- equal in diameter throughout, limb 5-parted, spreading or subreflexed; stamens 4, exserted, didynamous, alternate with corolla lobes, involute in bud; anthers opening by longitudinal slits. Ovary imperfectly 4-celled, 4-ovulate; pistil 2-carpellary; stigma shortly 2-fid. Fruit a drupe, shiny, black, 1cm diam., globose or ovoid, usually 4-sulcate, exocarp +- fleshy, endocarp bony, separating at maturity into 4 pyrenes, or sometimes cohering in pairs.

In a range of habitats, including monsoon vine thickets, open forest and woodland; all regions of Northern Territory [Australia] (Aboriginal Communities 1988; Gleason 1952 [for some genus detail]).

COFFEA

(Rubiaceae)

Coffea arabica *L.* – Arabian coffee, Abyssinian coffee, Brazilian coffee
Coffea brevipes *Hiern*
Coffea canephora *Pierre ex Froehner* **(C. arabica var. stuhlmannii** *Warb.***; C. canephora var. robusta** *(Linden) A. Chev.***; C. maclaudi** *A. Chev.***; C. robusta** *Lind.***)** – Congo coffee, robusta coffee, Rio Nunez coffee
Coffea canephora var. nganda *Haarer* **(C. kouilouensis** *Pierre***)** – Nganda coffee
Coffea dewevrei *De Wild. et Dur.* – rainforest coffee
Coffea kianjavatensis *Leroy*
Coffea liberica *Bull ex Hiern* **(C. abeokutae** *Cramer***; C. excelsa** *A. Chev.***)** – Liberian coffee, Monrovia coffee, Lagos coffee, abeokuta coffee, shari coffee, large-seeded coffee, bawfili, coocoon
Coffea mauritiana *Lam.* **(C. sylvestris** *Willd. ex Roem. et Schult.***)** – café marron, café pays, kafe pei
Coffea racemosa *Lour* – inhamban coffee
Coffea stenophylla *G. Don* – bush coffee, Sierra Leone mountain coffee, narrow-leaved coffee

Coffee may have been cultivated [and its berries chewed] in Ethiopia as early as c.500AD. Yemeni sufis were said to have discovered the technique of roasting the beans; they still value it to maintain concentration in long prayers or other rites, and to aid in entering 'ecstatic' states. Early on, coffee was often drunk with other herbs that added to its flavour and stimulating effect, such as 'cardamom' [Elettaria cardamomum], 'betel' [see **Areca**], 'cinnamon' [see **Cinnamomum**] and 'ginger' [see *Endnotes*]. Some Bantu-speaking peoples use it as a ritual drink, and it is often taken with **Cannabis**. In Ethiopia, C. arabica is taken by poor people as a leaf or seed-epidermis infusion, and in Tanganyika, the plant matter of C. canephora is chewed. C. arabica supplies c.80-90% of the world's coffee, and is cultivated in tropical regions all over the world; C. canephora and C. liberica supply much of the remainder. The cheaper C. canephora is usually used to make instant coffees, and C. liberica, which makes a bitter brew, is largely used as a filler in blends of different types of coffee. In Africa, many species are used locally as well to make coffee, including C. brevipes, C. canephora var. nganda, C. dewevrei, C. racemosa and C. stenophylla (Briandet et al. 1996; Burkill 1985-1997; Rätsch 1998). The beverage prepared from C. mauritiana is claimed to be bitter and intoxicating (Iricaf undated).

Coffee berries are harvested when deep red, and are initially put in water to separate the over-ripe berries [which float]. The remaining berries are gently 'pulped' to release the beans, which are soaked for 24 hours to remove the slimy coating; they are then rinsed thoroughly and dried to a water content of c.11%, and then dehusked before roasting. Sometimes

beans are stacked to ferment earlier in the process, and drying/fermenting may be carried out in the sun. Fermentation is said to improve the flavour of the resultant coffee; it also increases the *caffeine* content through metabolism of nucleic acids. Beans may be roasted at up to 200°C for c.15 minutes, then cooled rapidly, left to stand overnight, and packed for storage. In roasting, beans should be heated evenly; also, temperatures should be kept as low as possible, and roasting as brief as possible, so as not to burn or over-roast. Instant coffees are mostly made from low grade C. canephora beans; they are usually manufactured by drying a liquid concentrate of freshly brewed coffee (Dowell & Bailey 1980; Lehane 1977; Schapira et al. 1975; Suzuki et al. 1992). Coffee beans must be ground for use, and then they may be decocted or percolated; some finely ground coffees can simply be steeped to brew an inferior beverage ['plunger coffee']. Alternately, if you really love the taste of coffee, you can chew the beans. Chocolate-coated coffee beans [see **Theobroma**] are also widely available and very popular with students in Melbourne, Australia (pers. obs.).

Coffee is a CNS-stimulant, vasodilator, bronchodilator, respiratory and circulatory stimulant, local irritant [due to the volatile oil], diuretic and laxative. It interferes with digestion, but can allay nausea in moderate amounts; it also can increase the effects of some analgesics, possibly due to the enzyme P450-inhibiting capacity of *chlorogenic acid*, caffeic acid, and some related polyphenols. Recently inhibition of MAO-A and B has been noted. Excessive doses [more than several cups in one sitting] can cause nervous agitation, insomnia, hypertension, nausea, sweating, confusion, and even indistinct colour hallucinations. Heavy coffee users [5 or more cups a day] report less insomnia when drinking it at night than lighter users; they also experience greater withdrawal symptoms, such as irritability, nervousness, lethargy, headache and inability to concentrate (Bremness 1994; Goldstein & Kaizer 1969; Herraiz & Chaparro 2006; Lehane 1977; McManamy & Schube 1936; Morton 1977; Rätsch 1992; Teel & Huynh 1998; pers. obs.). Coffee is sometimes administered by enema – there are reported deaths from frequent coffee enemas in people undergoing special diets (Eisele & Reay 1980).

A cup of coffee brewed from ground beans may contain 39-190mg of *caffeine*; a cup of instant coffee 29-99mg; and a cup of decaffeinated coffee 0-75mg (Gilbert et al. 1976). Freeze-dried instant coffee has yielded 4.5-5.1% *caffeine* and 5.2-7.4% *chlorogenic acid* [NOT per cup] (Briandet et al. 1996). Brewed coffee of various kinds may contain up to 210µg/l β-carbolines, mostly *norharman* with smaller amounts of *harman*; these appear to be formed during roasting (Alves et al. 2007; Herraiz 2002, 2004; Herraiz & Chaparro 2006).

Roasted coffee beans of unspecified origin have yielded 0.8-1.5% *caffeine*, 2-4% *chlorogenic acid*, 1% trigonelline, 0.02% *choline*, and 2% essential oil (Lindner 1956). Green coffee beans may contain c.8% non-volatile acids, c.7% of which is *chlorogenic acid*, as well as citric, tartaric, malic and oxalic acids; roasting decomposes c.40% of this, and also gives c.5% caffeic acid, 0.5% quinic acid, 0.35% acetic acid, 0.1% propionic acid, 0.2% butyric acid and 0.2% valeric acid as by-products (Morton 1977). The green beans also contain 0.2-0.3% 'coffee wax' externally, which was found to contain Nβ-alkanoyl-*serotonin* [C-5-HT], which was in turn found to consist of C-5-HT homologues [Nβ-arachidoyl-*serotonin*, Nβ-behenoyl-*serotonin* and Nβ-lignoceroyl-*serotonin* in a ratio of 12:12:1]. A stearoyl-homologue was also mentioned as being found, but not included in this ratio calculation. The wax was also found to contain traces of Nβ-(20-OH-arachidoyl)-*serotonin*, Nβ-(22-OH-behenoyl)-*serotonin* and *caffeine* (Folstar et al. 1979, 1980). Sucrose and trigonelline are largely degraded during roasting, and nicotinic acid is formed. Severe roasting may result in a loss of c.5.4% of the *caffeine* present (Trugo & MacRae 1989).

Leaves of unspecified commercial Coffea sp. have yielded 0.087-0.86% *caffeine* (Power & Chesnut 1919a). Species which contain *caffeine* contain it throughout the plant – average concentrations have been given as 0.3% in leaf, 0.04% in twig, 0.01% in stem, and 0.01% in root (Burkill 1985-1997).

C. arabica beans have yielded 0.72-3% *caffeine*, *theobromine*, xanthine, *guanine*, trigonelline, mannitol, caffetannic acid, sitosterol, kahweol, tannin, sucrose and fats [also other compounds – see above and below]; pericarp has yielded 0.35% *caffeine*. Leaves and fruits contain xanthine, hypoxanthine, *guanine*, adenine, vernine, and small amounts of *caffeine* [0.8% has been found in leaves of Egyptian trees]; stalks and small branches have yielded 0.15% *caffeine*; flowers may contain up to 0.9% *caffeine* (Balbaa et al. 1976; Chopra et al. 1965; Morton 1977; Schermerhorn et al. ed. 1957-1974).

C. canephora beans have yielded 2-3.21% *caffeine* (Burkill 1985-1997; Morton 1977). They can be distinguished from C. arabica in commercial samples by the presence of 16-O-methylcafestol, which is not found in C. arabica; also, C. canephora roasted beans contain higher levels of *caffeine*, *chlorogenic acid* (Briandet et al. 1996) and β-carbolines (Alves et al. 2007).

C. kianjavatensis beans have yielded 0.55-0.81% *caffeine*, 5.9% caffeoylquinic acids and 0.69% dicaffeoylquinic acids (Clifford et al. 1991).

C. liberica beans have yielded 1.4-1.6% *caffeine* (Burkill 1985-1997; Gilbert 1986); they have an inferior taste (Dowell & Bailey 1980).

C. mauritiana beans have yielded 0.07% *caffeine* (Clifford et al. 1991).

Coffea arabica is a glabrous evergreen shrub or small tree to 5m; branchlets compressed. Leaves evergreen, opposite (rarely in threes), 10-20cm long, shining, with conspicuous lateral veins, oblong-elliptic, apex shortly acuminate; stipules broad, interpetiolar. Flowers clustered in leaf axils, or in condensed 1-2-nate axillary cymes, appearing with leaves, white, fragrant, tubular; bracteoles often connate; calyx-tube short, limb short, often glandular, persistent; corolla 85-130mm long, 5-lobed, lobes 10-15mm long, spreading, twisted in bud; anthers 4-7, sessile, often recurved or twisted. Ovary 2-celled; style slender, bifid at apex; ovules solitary in each cell, peltate on septum. Drupe oblong, 1.3-1.9cm long, red when ripe, skin smooth, glossy, tough, flesh soft, mucilaginous; containing 2 plano-convex or ventrally concave hard pyrenes, or beans, to 1.3cm long, flattened and grooved on inner side, grey-green or grey-blue, enclosed in silvery, membranous testa (Chopra et al. 1965; Morton 1977).

C. arabica requires moderate rainfall, and a temperature +- constant at around 30°C. Flowers open 3-4 years after planting, and berries ripen 6-9 months later. C. canephora is more adaptable, and more resistant to insects and diseases. It gives larger yields than C. arabica, but the berries take longer to ripen [2-3 months more], and do not drop from the tree even when over-ripe; the taste is said to be inferior, as stated above.

Coffee trees can be grown from cuttings, but seed propagation is the usual method. Seeds germinate in 4-8 weeks [up to 3 months according to other sources]; they may be sown where they are to grow, in prepared ground, or they are grown in nurseries and transplanted when 6-24 months old. Spacing is 1.5-3m apart. Unshaded trees give higher yields, and regular fertilisation and weeding are needed.

The soil around a coffee tree gradually becomes rich in *caffeine* from fallen plant matter; thus the soil is rendered +- toxic, and coffee plantations degenerate after 10-25 years or more for this reason (Gilbert 1986; Morton 1977).

COLA

(Sterculiaceae)

Cola acuminata *(P. Beauv.) Schott et Endl.* **(Sterculia acuminata** *P. Beauv.***)** – cola nut, kola nut, guru nut, bissy nut, obì, abata

Cola anomala *K. Schum.* – Bamenda kola

Cola ballayi *Cornu ex Heckel*

Cola cordifolia *(Cav.) R. Br.* **(Sterculia cordifolia** *Cav.***)** – ntaba, bambana taba

Cola nitida *(Ventenat) Schott et Endl.* **(C. acuminata var. latifolia** *K. Schum.***; C. vera** *K. Schum.***; Sterculia nitida** *Vent.***)** – cola nut, kola nut, guru nut, bissy nut, obì

Cola verticillata *(Thonn.) Stapf ex A. Chev.* **(Sterculia verticillata** *Thonn.***)**

The cola [also spelled 'kola'] nut, an important stimulant in w. Africa, was said to have been brought to earth long ago by the creator, who on one visit left behind a piece he had been chewing. This was noticed by a watching man who, despite the warnings of a woman, placed it in his mouth and began to enjoy it. The creator came back soon after to look for the missing cola nut, and forced the man to give it back by pressing his finger against the man's throat – this is said to be why men have a projecting larynx (Rätsch 1992).

In their natural range of tropical Africa the nuts [or rather, the embryo of the seeds] of C. acuminata or C. nitida are chewed fresh or boiled into a drink that acts as a tonic, stimulant, aphrodisiac and diuretic. They are known to relieve fatigue, depression and headaches, give stamina, improve digestion, stimulate the cariac and respiratory systems, and allay appetite and thirst. The nuts are often preferred over coffee [see **Coffea**] and tea [see **Camellia**] as a stimulant. Taken with alcohol, a single nut is reputed to prevent drunkenness. Sometimes they are used as divinatory objects, as currency, as gifts for the gods, or as simple gifts to friends. Exchange or splitting of nuts is usually seen as a special gesture of friendship. Amongst the Yoruba of w. Nigeria, priests of Ifà [god of divination] use the nut for divination by splitting it into its four cotyledons, then throwing them to the ground. The number of pieces falling hollow side up determines the reading – 4 signifying good luck, 3 signifying wealth, 2 signifying scattering, 1 signifying health and success, and 0 signifying impending opposition. The nuts also yield a red dye (Bremness 1994; Burkill 1985-1997; Christy 1883; De Smet 1998; Emboden 1979a; Rätsch 1992; Verger 1995). The Yoruba also use C. verticillata as a stimulant, though they prefer C. acuminata. In general, older nuts are held in higher esteem, as are white or pink nuts which are kept to give to special guests. The Nso of the highlands of Cameroon have reportedly made extensive use of C. anomala nuts, in the same manner as other cola nuts. It was often consumed in palm-wine [see *Methods of Ingestion*] drinking sessions (De Smet 1998). The introduction of cola trees to India has led to their use as a stimulant nervine tonic there, as well (Nadkarni 1976).

In Sierra Leone, C. nitida leaves are macerated with salt and infused to treat asthma and diarrhoea (Lebbie & Guries 1995). C. cordifolia is

used as a remedy for leprosy (Watt & Breyer-Brandwijk 1962). C. acuminata and C. nitida nuts are much used in flavouring throughout the world [though nowadays synthetic flavours are more often substituted], and flavour Coca-Cola™, along with coca-leaf extract [see **Erythroxylum**].

Cola nuts from C. acuminata or C. nitida may contain [1.5-]2.35-3[-3.5]% *caffeine* [2.2%, based on dry weight, in fresh seed; 2.24% in dry seed; 2.38% in lyophilised fresh seed], 0.2-0.9% *theobromine*, 5% 'kola red' [an anthocyanin pigment], d-catechol, l-epicatechol, d-gambir-catechol, dl-gambir-catechol, 0.25% betaine, dextrose, cycloartenol, 24-methylenecycloartenol, 1.28-3% fixed oil, a volatile oil, and tannins. Fresh seeds contain greater amounts of catechins, which alter the effects. When dried, a small portion of the *caffeine* becomes bound with catechin and tannins; when fresh seeds are lyophilised, most of the *caffeine* present becomes bound. Administration of a fresh seed extract to rats caused EEG frequencies to predominate in the 7-10Hz spectrum, whilst *caffeine* alone caused dominance in the higher frequencies (Lindner 1956; Maillard et al. 1985; Nadkarni 1976; Rastogi & Mehrotra ed. 1990-1993; Schermerhorn et al. ed. 1957-1974; Vaille et al. 1993; Watt & Breyer-Brandwijk 1962).

C. ballayi nuts contain *caffeine* (De Smet 1998). Due to their uses, it is likely that C. anomala and C. verticillata nuts also contain *caffeine* (pers. obs.).

C. cordifolia has been found to contain *caffeine* (Watt & Breyer-Brandwijk 1962).

Cola acuminata is a forest tree, very similar to C. nitida, up to 22m tall. Leaves alternate, entire, oblanceolate to narrowly oblong or elliptic, sometimes narrowly obovate, up to 22 x 8cm, apex gradually long-acuminate, acumen often twisted downwards, base cuneate or rounded. Indumentum on inflorescence often comparitively sparse and free; inflorescence puberulous, up to 9cm long; flowers hermaphrodite or unisexual, actinomorphic, up to 2(-3)cm long, whitish, in dense clusters; sepals valvate, mostly partly connate or rarely spathaceous; petals 5, or absent, contorted-imbricate, often hooded; stamens free or connate into a column, sometimes with staminodes; anthers 2-celled, in 2 whorls. Ovary superior, of 2-12 united carpels or of 1 carpel; ovules on axile placentas; style simple or rarely free to the base. Fruiting carpels russet-brown or olivaceous, rough to touch due to minute indumentum, not nobbly, up to 20 x 6cm, narrowed to apex, upper suture not conspicuously ridged, apex not deflexed; seeds up to 14 per carpel, each seed with (2-)3-4(-6) cotyledons.

Sometimes cultivated; native to Togo (Hutchinson & Dalziel 1954-1972).

COLEUS [including Plectranthus, Solenostemon]

(Labiatae/Lamiaceae)

Coleus aromaticus *Benth.* **(C. amboinicus** *Lour.***)** – asmantaka, patherchur, patharkuchi, amlakuchi, amroda, kurpurvalli, country borage, Indian borage

Coleus blumei *Benth.* **(C. atropurpureus** *Benth.***; C. scutellarioides** *(L.) Benth.***; Plectranthus blumei** *(Benth.) Lawnert***; Solenostemon blumei** *(Benth.) Maza***; S. scutellarioides** *(L.) Codd.***)** – el nene ['the child'], el ahijado ['the godson'], maconha, cimorilla, timorilla, painted nettle, many cultivar names incl. 'Flame dancer'

Coleus forskohlii *(Poir.) Briq.* **(C. barbatus** *Benth.***; Plectranthus barbatus** *Andr.***)** – gurmal, garmalu, mainmul, makandi, boldo, boldo falso

Coleus pumilus *Blanco* **(**often referred to as **C. pumila; C. acuminatus** *Benth.***; C. rehneltianus** *Berger***)** – el macho ['the male']

[Note – many, if not all, Coleus spp. have recently been transferred to Plectranthus and Solenostemon]

Introduced to the Americas at an early date, C. blumei and C. pumilus attracted attention during field investigations into the use of **Salvia** divinorum in Oaxaca, Mexico. A Mazatec informant reported that C. pumilus, and two varieties of C. blumei ['el nene' and 'el ahijado'], were used for the divinatory properties of their leaves, in the same manner as **Salvia** divinorum. Later field work failed to find confirmation for this use, and researchers were told the plants were only ornamental (Schultes & Hofmann 1980, 1992; Wasson 1962). It would not seem unlikely if Mazatec people who knew of the use of Coleus had since decided not to divulge any more information. It is to be remembered that in cases where the indigenous use of sacred plants has been reported [such as with **Psilocybe** and **Lophophora**, both prominent Mexican examples], an influx of drug-enthusiasts has often followed, creating unwelcome disruption of the small communities where such use is often based, as well as inviting police harassment.

Apparently, as 'maconha', C. blumei is smoked as a **Cannabis** substitute by the Macumba of Brazil in their ceremonies, the purpose of which is to enter a trance in order to open one's self up to their deity (Rätsch 1992). In n.e. Peru the leaves are used externally as an antiinflammatory, but are believed to be too toxic to take internally (De Feo 2003). It is also used in Samoa as a remedy for elephantiasis (Ott 1993), and it treats dysentery and digestive problems in Ayurvedic medicine, along with C. aromaticus and C. malabaricus. Coleus spp. are known collectively under Ayurveda as 'pashanabhedi', and may treat asthma, coughs, slow and painful urination, piles, convulsions, heart diseases and insomnia, amongst other uses. The tuberous roots of C. forskohlii are pickled and eaten as a condiment in India (Nadkarni 1976; Perry & Metzger 1980; Valdés et al. 1987b), as are the leaves. The plant is antispasmodic, dilates bronchioles and blood vessels, increases circulation to the brain, lowers blood pressure, and acts as a heart tonic. The leaves and roots are harvested in autumn (Ammon & Muller 1985; Bone 1996; Chevallier 1996). As C. barbatus, it has been used to procure abortion; this has also been demonstrated as effective in rats (Almeida & Lemonica 2000).

C. aromaticus is known to be intoxicating, stimulant and antispasmodic in India, and the leaves are also used there in a popular culinary dish called 'bajeh'. In China, the plant is used to treat epilepsy and convulsions (Kirtikar & Basu 1980; Nadkarni 1976; Perry & Metzger 1980). In Tanganyika, C. kilimandschari is used by the Shambala to treat convulsions in children (Watt 1967). In New Britain, Papua New Guinea, C. atropurpureus is used in rain magic (Paijmans ed. 1976). A closely related plant, tentatively identified as a Plectranthus sp., is used by the Nkopo of PNG in rituals to create harmony with natural forces (Schmid 1991). Sap from the closely-related Solenostemon latifolius is used in the Congo as a cardiac sedative, and to ensure nightmare-free sleep. In Tanganyika, the leaves are used for 'reviving' (Burkill 1985-1997), presumably for those who have fallen unconscious or stuporous.

Few people have tried ingesting Coleus spp. for psychonautic purposes, and of those who have, there are conflicting reports. Most people swear that Coleus spp. are inactive, some swear that they can be psychoactive. Most experiments have centred on C. blumei, which exists in many horticultural forms, and may be expected to exist in different chemical races. Also, the mode of administration may have been inappropriate in some instances, as the leaves do not seem to be noticeably active via the oral route. They may show activity with sublingual administration [keep 1 or more large, thoroughly chewed leaves under the tongue for 20-30min.], or with smoking. Myself, and some others, have had definite psychoactive results. My single experiment involved smoking a dried alcohol extract, which had been evaporated onto a small amount of the original leaf as a binder. The solution had been left for 3 days with occasional shaking; the amount of dried extract smoked was the size of a small pea. Effects were much milder than those of **Salvia** divinorum, though I felt strongly 'stoned' for at least 30 minutes (pers. comms.; pers. obs.).

C. aromaticus leaf has yielded 0.3% essential oil, consisting mostly of carvacrol [60.1%] and β-caryophyllene [20.6%], as well as 5.3% p-cymene, 4.3% γ-terpineol, 3.2% humulene and traces of other compounds; *eugenol* and *methyleugenol* have also been reported, but not from Javan plants (Bos et al. 1983). As C. amboinicus, the leaves yielded the flavonoids *apigenin*, salvigenin, luteolin, quercetin, taxifolin, 6-MeO-genkwanin, chrysoeriol and eriodyctiol (Brieskorn & Riedel 1977). The chewed fleshy leaves had a mild stimulating and euphoric effect in one psychonaut, which he compared to the effects of *borneol* (theobromus pers. comm.).

C. blumei has yielded rosmarinic acid (Buckingham et al. ed. 1994), 5,6,7-trihydroxyflavone, scutellarein [6-OH-*apigenin*], cyanidin-3,5-diglucoside, pelargonidin-3-glucoside, nonacosane, hentriacontane, dotriacontane, tritriacontane, pentatriacontane, β-sitosterol and stigmasterol (Rastogi & Mehrotra ed. 1990-1993). In the process of analysis for *salvinorin A*, the leaf extract was shown to be rich in components, but their identities were not pursued as none were similar to *salvinorin A* (Gruber 1997).

C. forskohlii tubers have yielded c.0.1-0.3% [c.0.05% in whole plant] of the diterpene forskolin [coleonol], which has spasmolytic, bronchodilating, cerebral-vasodilating, hypotensive, and cardiotonic activity. It lowers intraocular pressure, inhibits platelet aggregation, and activates the enzyme adenylate cyclase, causing increased thyroid secretion, adrenal steroid synthesis, and *adrenocorticotropin* release from pituitary (Ammon & Muller 1985; Bone 1996; Valdes et al. 1987b). Forskolin is reputed to be psychoactive, in a similar way to other diterpenoids found in **Salvia** and **Scutellaria** (friendly pers. comm.).

Coleus blumei (generally) is an annual herb or shrubby perennial, 30cm to 3m or more; stems and branches square, slightly succulent, often coloured (usually pale translucent green), angles generally obtuse, joints often hairy. Leaves rhomboid-ovate, deltoid-ovate, linear to lanceolate, 0.5-25cm wide, 1-30cm long, becoming smaller and cuspidate ascending upper flowering stems, margins incised or serrate, sometimes digitately lobed, sometimes entire, apex acuminate to acute, base attenuate to cordate, membranaceous, pubescent or subglabrous on both surfaces, green or yellow-green, frequently blotched, spotted or striate with purple, brown, red, pink, white, often uniform purple on underside; principal nerves partially raised on underside only; petioles usually pubescent at sides, 0.5-8cm long. Inflorescence terminal whorled racemes, panicles or cymes, sometimes branched, 10-60cm long, with bracts, shedding after

pollination; calyx 2-3mm long, oval, broader at base, bell-shaped, usually very pubescent outide, glabrous inside, upper lobe entire and oval with downturning edges, lower lip 3-parted, middle lobe parted into 2 triangular pointed teeth protruding beyond the other, side lobes shorter and oval-ended, closing inwards and retaining nutlets after pollination; corolla violet, very occasionally bluish-white, funnel-shaped, protruding downwards, curved or more often sharply bent and refracted, 4-6mm long, limb double lipped, upper lip short and broad, erect, 3-cleft, lower one extended, boat-shaped, bearing stamens and style; stamens 4, united into a tube for more than ½ their length, encompassing the style; style protruding beyond the anthers, bearing a 2-fid stigma. Nutlets 4, black or dark brown flattened spheres, c.1mm diam. (Pedley & Pedley 1974).

Native to Java; widely cultivated as an ornamental. Much variation exists in appearance due to the many different cultivars. This species itself is apparently a hybrid of other species – today, many people do not even consider C. blumei to be a valid species designation.

Grows best in strong, indirect light in warm, rich, loose, well-drained moist soil. Start seeds indoors in flats of fine soil covered with glass or plastic; sow thinly and cover with a thin soil layer. Transplant to pots or garden when large enough to handle. Can also be grown from cuttings. Frost- and shock-sensitive. Needs high-N fertilisation in spring and summer, though do not overfertilise. The combustion fumes of city life often contribute to excessive leaf-dropping (Pedley & Pedley 1974; pers. exp.).

CONIUM

(Umbelliferae/Apiaceae)

Conium maculatum *L.* **(C. cicuta** *Neck.***; C. maculosum** *Pall.***; Cicuta major** *Lam.***; Ci. officinalis** *Crantz***; Coriandrum cicuta** *Crantz***; Cor. maculatum** *Roth***; Selinum conium** *Krause***; Sium conium** *Vest***)** – koneion, hemlock, spotted sorobane, spotted hemlock, poison hemlock, poison parsley, winter fern, herb bonnet, beaver poison, Musquash root, kurdumana, wašia, kex [a name for all similar Umbelliferae in Lincolnshire, UK]

Hemlock is an ancient poisoner's herb, sacred to Hecate [Greek goddess of magic, who protects travellers at night]. It has been used since ancient times as a medicine, anaphrodisiac and incense. A decoction of the unripe seeds in wine or opium wine [see **Papaver**] was a means of execution [either official or illicit] with the ancient Greeks. Socrates was said to have chosen hemlock as his drink of death. Besides having been an ingredient in some witches flying ointments [see *Methods of Ingestion*], hemlock has been used magically to induce astral projection, and in spells to banish sexual desires. Its juice was also rubbed on ritual knives and swords to empower and purify them before use. A German folk tradition tells that hemlock was home to a toad [see **Bufo**], which lived under the plant and sucked its venomous properties from it. In the Middle Ages, the sedative action of hemlock was used to counter conditions such as epilepsy, mania, and 'St. Vitus' Dance' [an old term for the convulsive stage of ergot poisoning – see **Claviceps**; today it refers to the symptoms of chorea]. In India, the plant is considered aphrodisiac [in contrast to the anaphrodisiac properties the herb is usually known for – perhaps a matter of dose?], and is used to treat painful skin conditions. The root has been recommended for gout, but today is given only in homoeopathic doses for prostate problems and thickened arteries (Bremness 1994; Cunningham 1994; Jordan 1992; Nadkarni 1976; Rätsch 1992). The Tarahumara of n. Mexico know this introduced plant as 'wašia', and use a small portion of the root [from the flowering plant] to stun fish. They only use it in slowly moving water, never in pools (Pennington 1958).

C. maculatum is sedative, analgesic, antispasmodic, and often fatal (Bremness 1994). Animals including humans have suffered from hemlock poisoning, though animals are rarely stupid enough to eat it (Lamp & Collet 1989; McBarron 1983). Sometimes people mistake it for 'wild parsley' [see **Petroselinum**] or 'wild carrot' [see **Daucus**], or have consumed the tubers believing them to be 'wild parsnip', Pastinaca sativa [see *Endnotes*].

C. maculatum contains a mixture of 5 very toxic piperidine alkaloids [0.01-0.15% in stem; 0.03-0.6% in leaves; 0.09-0.24% in flowers; 0.73-0.98% in unripe fruit; up to 3.6% in ripe dried fruit; root low in alkaloids], which are *coniine*, γ-coniceine, N-methyl-*coniine*, conhydrine and pseudoconhydrine (Blackwell 1990; Henry 1939; Pammel 1911). γ-Coniceine is usually the major alkaloid, except in maturing fruits, where it is mostly converted to *coniine*. A mixture of unidentified compounds [several amino acids and two alkaloids] was found in leaf, fruit, and root, at all stages of development. Seedlings and young leaves contain predominantly γ-coniceine, with *coniine* levels increasing as the leaves mature. Seedlings harvested 2 weeks after the opening of the first 'true' leaves contained γ-coniceine and traces of conhydrine, but no *coniine* or N-methyl-*coniine*; seedlings harvested 1 week later contained only γ-coniceine [in addition to the unidentified mixture mentioned above]. In roots, alkaloids are +- absent when the plant is actively growing. In flowers, alkaloid levels are minimal in the first week. In the fruits, alkaloids are most concentrated in the endocarp ['*coniine* layer'] and the pericarp cells directly beneath ['beaker-cell layer']. Alkaloid levels peaked in the fruits after 4-5 weeks of development; the highest yield obtained was c.3%. γ-Coniceine was the major alkaloid, until 5-6 weeks of development, when it is largely replaced by *coniine*. Shortly after, there was again a small rise in γ-coniceine levels. Alkaloid yields, and relative proportions of *coniine*/γ-coniceine, were observed to fluctuate widely throughout the course of a day [samples taken 4-hourly], with highest overall levels at 4am, 4pm, and 12 midnight, and lowest at 8am and 12 midday, in weeks 4 and 5. In a study done of the next year's crop, fruits in week 5 [sampled 2-hourly over a 14 hr period] did not vary as widely, and gave lower yields per fruit; lowest levels were at midday, with slight peaks at 8am, and 4-6pm. Aborted fruits were shown to consistently bear higher alkaloid concentrations, compared to normal fruits. In rainy weather, γ-coniceine is the main fruit alkaloid. Sunny and dry weather seems to encourage development of larger fruits, with higher levels of alkaloid per fruit (Fairbairn & Challen 1959; Fairbairn & Suwal 1961).

All of the alkaloids in this plant are considered toxic, and some may cause birth defects. *Coniine* in small doses is similar to *nicotine* in overdose – paralysis of the motor nerves occurs, as well as stimulation then depression of the CNS; nausea and vomiting also occur. In higher doses, heart action is slowed, numbness and paralysis spread from the lower limbs to the arms and chest, and death usually occurs from paralysis of the diaphragm. Lower doses are said to produce a sensation of flying. *Coniine* may be toxic at doses as low as 60mg. *Coniine*, and perhaps the other alkaloids, lose their toxicity on drying or from heat (Blackwell 1990; Bremness 1994; Foster & Caras 1994; Harborne & Baxter ed. 1993; Henry 1939; Lamp & Collet 1989; Pammel 1911; Rätsch 1992; Wexter ed. 1998). The plant is said "to be nearly harmless in the spring but very dangerous afterwards" (Pennington 1958).

The related 'water hemlock' [Cicuta virosa] is also highly toxic, with ingestion of the root causing burning in the mouth, "prolonged vomiting and violent convulsions". It has yielded cicutoxin, cicutol, falcarindiol, and other similar compounds. 'Hemlock water dropwort' [Oenanthus crocata] causes similar symptoms from the consumption of the root; the main toxic principle in this case is oenanthotoxin, an unstable polyenyne (Bruneton 1995).

Conium maculatum is an erect annual or biennial herb to 3m tall; stems freely branched, glabrous, longitudinally grooved and spotted purple, hollow except at nodes. Leaves alternate, glabrous, 20-50cm long, broadly triangular-ovate in general outline, 3-4 times pinnately compound, ultimate divisions ovate-oblong, 4-10mm long, toothed or incised; petioles deeply cupped at base surrounding the stem, hollow. Flowers numerous in dense terminal umbels, white, 2-4mm diam.; petals 5. Fruits grey-brown, broadly ovoid, c.3mm long, consisting of 2 sections, humped with 5 prominent undulate ribs. Fl. late autumn to summer.

Native to Europe, w. Asia, n. Africa; a weed of waste areas, crops and other places worldwide. Prefers to grow in humid and subhumid temperate regions in shaded sites and near streams on moist, fertile loam soils; occurs as an introduced weed in all states of Australia except Northern Territory (Gleason 1952; Parsons & Cuthbertson 1992).

CONOCYBE

(Agaricaceae/Bolbitiaceae)

Conocybe cyanopus *(Atkinson) Kühner* **(Galerula cyanopus** *Atk.***; Pholiotina cyanopoda** *(Atk.) Sing.***)**
Conocybe kuehneriana *Singer*
Conocybe siligineoides *Heim* – ta'a'ya
Conocybe smithii *Watling* **(Galera cyanopes** *Kauffman***)**

The Mazatec of Oaxaca, Mexico, reportedly used C. siligineoides in their shamanic practices (Wasson 1961). It has also been claimed that a Conocybe sp. known as 'tamu' ['mushroom of knowledge'] is used in the Ivory Coast for its entheogenic effect (Samorini 1995b, quoting Yves Soubrillard).

C. cyanopus from Norway has yielded 0.33-0.55% *psilocybin* and 0.004-0.007% *psilocin*; a fresh Finnish collection yielded 0.45% *psilocybin* and 0.07% *psilocin*; a collection from the Pacific n.w. US yielded 0.93% *psilocybin*. Canadian specimens from Vancouver have yielded also 0.03-0.1% *baeocystin*, and 0.05% was found in samples from Washington (Benedict et al. 1962, 1967; Beug & Bigwood 1982; Christiansen et al. 1984; Ohenoja et al. 1987; Repke et al. 1977). German specimens have yielded 0.84-1.01% *psilocybin* and 0.12-0.2% *baeocystin*. Cultivated mycelium has yielded 0.25% *psilocybin*. It has been suggested that this species would not be practical to consume in c. Europe due to its relative rarity and small stature (Gartz 1991). With N. American specimens, 40-50 fresh fruiting bodies may constitute an effective dose (Allen 1997). This is the only Conocybe sp. in c. and n. Europe which has a bluing stem (Gartz 1991).

C. filaris [Pholiotina filaris] from Seattle has been shown to contain the cyclopeptide α-amanitin, a toxin found in some of the deadly

Amanita spp. (Brady et al. 1975). Obviously, caution is advised with unknown Conocybe spp. There is also the possibility that such toxins will show up in Conocybe spp. known to contain *psilocybin* and/or *psilocin*. See also *Producing Plant Drugs* for discussion of a spot test for amanitins.

C. kuehneriana has yielded 0.004% *psilocin* (Ohenoja et al. 1987).

C. siligineoides has not been chemically analysed, but is thought to contain *psilocybin* and/or *psilocin* due to its purported uses, and the alkaloid content of some of its cousins (Repke et al. 1977; Schultes & Hofmann 1980).

C. smithii from Michigan has yielded *psilocybin*, as well as up to 0.08% *baeocystin* and possibly also *norbaeocystin* (Benedict et al. 1967; Repke et al. 1977).

Conocybe siligineoides has a cap 1.3-2.3cm across, 0.9-1.9cm tall, at first subhemispherical, then conic-campanulate, never spread, fawn-orange-red, near centre slightly deeper orange, glabrous, dull becoming shiny, hygrophanous, margin regularly crenate, white with darker striations. Stem slender, rigid, cylindrical, hardly swollen towards base, up to 6cm tall, 1.5mm thick, white-farinaceous at top, pale orange in upper part, cream-citrine elsewhere, tinged with dull-pink near middle, at first darker, always white at base, fistulous; growth of stem continuing after growth of cap. Flesh thin, translucent in cap, white with a slight tinge of flesh colour. Gills +- distant, rather thick, adnexed, with 2 series of very unequal, saffron-coloured or brownish-orange lamellulae. Spores polymorphic, obovoid, very slightly cylindrical, often subtly hexagonal in profile, 11-15 x 7-10 x 6-12µ, with large germinative pore, bright ochraceous or chrome yellow. Fr. Jun.-Jul.

On rotting tree trunks; Oaxaca, s. Mexico (Schultes & Hofmann 1980).

C. cyanopus is very rare in Europe, and thus should not be harvested irresponsibly, or in the immature state.

The genus Conocybe is believed to be closely related to the genera Galerina and Pholiotina [see also **Gymnopilus**, **Psilocybe**], some of which are known to be deadly poisonous.

CONVOLVULUS

(Convolvulaceae)

Convolvulus arvensis *L.* **(C. minor** *Gilib.***)** – field bindweed, lesser bindweed, European bindweed, field morning glory, wild morning glory, small-flowered morning glory, cornbine, hiranpandi, hiranpag, naranji

Convolvulus mauritanicus *Boissier* **(C. sabiatus** *Viviani***)** – vilucchio della riviera

Convolvulus pluricaulis *Choisy* **(C. microphyllus** *Sieb. ex Spreng.***)** – sankhapuspi, sankpuspi, dodak, bephuli, gorakhpinaw, poprang, porprang

Convolvulus sepium *L.* **(Calystegia sepium** *(L.) R. Br.***)** – greater bindweed, Rutland beauty, villucione, campanelle, zaunwinde, grand liseron

Convolvulus tricolor *L.* **(C. minor** *Hort. ex Mill.***)** – dwarf morning glory, villucio tricolor, bunte ackerwinde, dreifarbige winde

Convolvulus spp. – bindweeds

Dioscorides wrote that ingesting the seeds of C. sepium could cause "many and troublesome dreams" (Gunther ed. 1934; Ott 1993). It is regarded as poisonous, and has cathartic properties (Hurst 1942). In n. India, C. pluricaulis [whole plant] is used "as a brain tonic, in the treatment of some forms of insanity and neurasthenia". The herb is harvested when in flower. In animal experiments, the alcohol extract has been shown to potentiate the hypnotic effects of barbiturates, potentiate *acetylcholine* response in skeletal and tracheal muscle, and exhibit a spasmolytic effect in smooth muscle other than the tracheal (Barar & Sharma 1965; Rastogi & Mehrotra ed. 1990-1993). The herb has proven very effective as a brain tonic taken with equal parts of **Bacopa** monnieri and Celastrus paniculatus seed-oil [see *Endnotes*] (friendly pers. comm.).

C. scammonia has been used as an abortifacient and to treat headaches (Ott 1993). The fresh root [gathered in June, in the northern hemisphere] is cut near the apex, and the milky sap collected and dried, to prepare the drug 'scammony'. One imitation scammony originating from s. France was made from the root sap of Cynanchum monspeliacum [Asclepiadaceae]. Scammony is mainly used as a powerful purgative [said to be safe even in large doses], and for such purposes it is sometimes mixed with unskimmed milk, sweet almonds, sugar, and/or ginger (Felter & Lloyd 1898). C. arvensis was said to quicken birth, and has been used as a topical haemostatic (Ott 1993). Resin obtained from the leaves of C. arvensis has been used as a gentle purgative (Chiej 1984), and the roots are also used as a purgative in India (Nadkarni 1976). This plant has caused purging in stock animals who have eaten the tuber, and is also suspected of causing photosensitisation in some animals (Parsons & Cuthbertson 1992). All parts of C. arvensis, C. sepium, and C. soldanella contain resins with purgative activity (Erspamer 1947). The tubers of C. erubescens may be eaten safely, though they are fibrous and have little flavour (Low 1989). In NSW, Australia, a decoction of the whole plant is used by some indigenous people to treat indigestion, stomach aches, and diarrhoea (Cribb & Cribb 1981).

C. arvensis aerial parts yielded 0.017% crude alkaloids [w/w], mostly pseudotropine, with traces of tropine, tropinone, meso-cuscohygrine and hygrine; α-amyrin, campesterol, stigmasterol, sitosterol, alkanes and alkanols were also found. The roots yielded cuscohygrine and calystegines [polyhydroxytropanes] (Todd et al. 1995), and calystegines are also found in the herb and flowers (Schimming et al. 1998) – calystegines have glycosidase-inhibitory activity (Drager et al. 1995). The plant has also been shown to contain *scopoletin*, umbelliferone and isoferulic acid (Rastogi & Mehrotra ed. 1990-1993).

C. erinaceus roots yielded c.2% alkaloids, consisting mostly of cuscohygrine (Aripova et al. 1972).

C. krauseanus aerial parts have yielded convolvine [3α-veratroyloxy-nortropane, or veratroyl-nortropine], convolamine [veratroyltropine], convolidine [3α-vanilloyloxy-nortropane], convolicine [3α-veratroyl-N-acetylnortropine] and phyllalbine (Aripova & Yunusov 1980).

C. lanatus roots have yielded c.0.11% alkaloids, consisting mostly of cuscohygrine; the roots have purgative activity (Hilal et al. 1986).

C. lineatus flowering aerial parts have yielded 0.03% alkaloids, including convolvine, convolamine, and 4 other unidentified alkaloids (Israilov et al. 1965), as well as umbelliferone and *scopoletin* (Festi & Samorini 1999b).

C. mauritanicus seeds were found to contain 0.009% ergoline alkaloids (Taber et al. 1963a); flowers contain 3 calystegines (Schimming et al. 1998).

C. pluricaulis has yielded an alkaloid, sankhpuspine (Basu & Dandiya 1948); two unidentfied bases were isolated, only one of which was pharmacologically-active, showing hypotensive actions in dogs (Rakhit & Basu 1959). Also found were 6-MeO-7-OH-coumarin, 0.76% chloride, 3,4-dihydroxycinnamic acid, kaempferol [MAOI, potential neuroprotectant (Sloley et al. 2000)], kaempferol-3-glucoside, sterols, sugars and starch (Deshpande & Srivastava 1970; Rastogi & Mehrotra ed. 1990-1993).

C. sepium has yielded calystegines from all parts (Drager et al. 1995; Schimming et al. 1998), though some specimens contained none; seeds did not contain ergoline alkaloids; roots yielded cuscohygrine, and 2-7% of a toxic glucoside (Festi & Samorini 1999b).

C. subhirsutus roots yielded 0.43% alkaloids, consisting mostly of convolvine (Aripova et al. 1972), as well as convolamine (Yunusov et al. 1959), convolidine, phyllabine, confoline [N-formyl-convolvine] and an unidentified alkaloid (Sharova et al. 1981); aerial parts have yielded up to 0.406% alkaloids, and seeds up to 0.5% alkaloids, consisting of convolvine, convolamine, convolvidine and convolicine. Aerial parts from young plants yielded up to 2.08% alkaloids (Yunusov et al. 1959). Young plants contain mainly convolvine in aerial parts [c.91% of alkaloids] and roots [c.0.68% of alkaloids]; as the plant matures, the convolvine content declines in the aerial parts, replaced by a large increase in convolamine levels (Aripova et al. 1983).

Seeds of one batch of Danish C. tricolor 'Fine Mix' were once found to yield 0.001% alkaloids and 6.1% lipids [w/w] (Genest & Sahasrabudhe 1966), though this was later doubted due to possible seed contamination by **Ipomoea** spp. (Ott 1993), as most C. tricolor seed has tested negative for alkaloids (Der Marderosian & Youngken 1966; Hahn 1990). However, others have detected lysergic acid and clavine alkaloids in seeds of C. tricolor [0.011% in 'Cambridge Blue'; 0.021% in 'Royal Marine'], C. 'Lavender Rosette' [0.014%] and C. 'Royal Blue' [0.018%] (Taber et al. 1963a).

Calystegines have also been found in the herbage of C. caput-medusae and roots of C. cneorum (Schimming et al. 1998), and in the closely related Calystegia soldanella and Calystegia sylvatica (Festi & Samorini 1999b).

Convolvulus tricolor is an annual herb, often branching from the base and spreading as a ground cover c.60cm across; stems trailing, ascending 15-30cm, angulate, brownish, villous. Leaves alternate, exstipulate, narrow-oblong or subspatulate, obtuse or rounded at apex, pubescent or sometimes glabrous, ciliate towards base. Peduncles 3-flowered, usually exceeding the leaves; calyx persistent, 5-parted, without bracts, sepals ovate, acute, villous; corolla campanulate or funnelform, c.3.75cm across, with azure-blue limb and yellow throat margined with white, limb plicate, 5-angled; stamens 5, inserted near base of corolla, included, filaments often dilated at base. Ovary 2-celled, 4-ovulate; stigmas 2, oblong or linear. Blooming continuously throughout summer, flowers remaining open all day in pleasant weather. Some varieties have striped or spotted flowers, or white only. Capsules globose, opening by 4 valves or bursting irregularly; seeds glabrous.

Southern Europe (Bailey 1968).

CORDYCEPS [including Elaphomyces]

(Ascomycetae/Clavicipitaceae)

Cordyceps barnesii *Thwaites ex. Berk. et Broome* – xiang bang chong cao
Cordyceps capitata *(Holmskjold ex Fries) Link* – tlakatsitsin ['little men'], hombrecitos, niños
Cordyceps hawkesii *(G.R. Gray) Cooke* **(Sphaeria hawkesii** *G.R. Gray***)** – huokesi chong cao, yaxiang bang chong cao
Cordyceps liangshanensis *Zang, Liu et Hu* – liang shan chong cao
Cordyceps militaris *(Fr.) Link* **(Sphaeria militaris** *Fr.***)**
Cordyceps ophioglossoides *(Ehrenberg ex Fries) Link* – tlakatsitsin, deer fungus parasite
Cordyceps sinensis *(Berk.) Sacc.* – yarsagumba, tung chung hsia tsao, dong chong xia cao, kurki, jivanbuti, thokre chyau, winter worm summer grass, cordyceps
Cordyceps shanxiensis *Liu, Rong et Jin* – jinbangbang chong cao
Cordyceps spp.

(Elaphomycetaceae)

Elaphomyces cervinus *(L. ex Gray) Schlechtendal* – hexenspitzel ['witch informer', hart's truffle, puffball]
Elaphomyces granulatus *Fr.* – false truffle, deer truffle, su mondo
Elaphomyces variegatus *Vittadini* – false truffle, su mondo

Cordyceps spp. are a group of ascomycetes that parasitise other species, ranging from subterranean truffles to insects, overcoming the host with their sclerotia and fruiting from the ground. C. capitata and C. ophioglossoides grow on the truffles Elaphomyces granulatus and E. variegatus, which are known as 'su mondo' ['its world']. In Tlanixco [Mexico], these 'little men' are ritually consumed paired with specimens of the 'little women', **Psilocybe** wassonii ['siwatsitsintli'], sometimes apparently for analgesic and anti-rheumatic effects, according to Heim (1963b). C. capitata is believed to possess visionary properties which augment the effect of the **Psilocybe** mushrooms, and might possibly also contribute a tonic effect, given the medicinal properties of some other Cordyceps spp. E. granulatus and E. variegatus are consumed in the Alta Mixteca of Oaxaca as rejuvenatives, and to treat serious wounds (Heim 1963b; Guzmán 1990; Tamm 1962; Wasson 1961). E. granulatus has been claimed to have aphrodisiac properties (Norland 1976), and Elaphomyces spp. are sold in British markets as aphrodisiacs (theobromus pers. comm.). Incidentally, E. cervinus has been known in Germany as hexenspitzel ['witch informer'], hinting at some kind of interesting past use (De Vries 1991). It has been observed to act as an aphrodisiac for stags, bulls and boars, but not humans (Rätsch 1990). See also Tuber spp. truffles in *Endnotes*.

C. sinensis is a highly prized tonic in TCM. In ancient China, it was very scarce [as it still is], and used only in the Emperor's palace. The fungus grows on moth larvae of the order Lepidoptera, especially on Hepialus armoricanus ['sphinx moth']. Himalayans compete with the local yaks for the fungus, harvesting it just before the yaks migrate into the steep ravines to eat it, which they do regularly in spring before returning to the lowlands for mating. Likewise, in Nepal, it is used as an aphrodisiac. C. sinensis is usually prepared by roasting or baking it inside a duck, the duck flesh then being endowed with the properties of the fungus and eaten over a week or so; it may also be decocted in water [in a dose of 3-9g], or infused in alcohol. The herb has an affinity for the lungs and kidneys, and is considered a tonic for these organs; it reinforces vital energy, stimulates the immune system, stimulates the endocrines, reduces stress, reduces excess phlegm, helps build bone marrow, replenishes sperm, treats impotence, spermatorrhoea, neuraesthenia and backache, and has sedative, antitumour, antibacterial, antifungal, antiasthmatic [by relaxing smooth muscle and dilating bronchii] and *epinephrine*-potentiating properties. C. ophioglossoides also stimulates the immune system, as well as stimulating circulation and regulating menstruation. C. cicadae has antitumour properties. C. barnesii, C. hawkesii, C. liangshanensis and C. militaris may have similar effects to C. sinensis, due to sharing similar chemistry [see below]. A new species, C. shanxiensis, is said to have greater medicinal virtues than any other Cordyceps sp. (Hobbs 1995; Hsu et al. 1986; Huang 1993; Pegler et al. 1994).

Recently, it was found that Nepalese shamans in the upper Kalinchok region use C. sinensis for shamanic travelling; it is ground and mixed with **Nicotiana** or **Cannabis**, then either smoked or added to 'rakshi' liquor and drunk (Müller-Ebeling et al. 2002). A Cordyceps sp. extract, as well as soup made from the whole fungus, has caused mild 'LSD-like' symptoms in some individuals when taken in large quantity [doses unspecified]. It is unknown whether the actual identity of the fungus was C. sinensis, or another related species (Trout pers. comm.). A commercially-available alcohol extract of C. sinensis mycelium [1:1], taken in a dose of 15ml, resulted in mild euphoria and closed-eye visuals in one psychonaut. The same person later consumed the same dose of the extract, in combination with c.330mg dried **Psilocybe** semilanceata. The effects of the **Psilocybe** were altered and intensified, with similarities to the combination of **Psilocybe** and **Peganum** harmala seeds, but more subjectively 'sensual' (theobromus pers. comm.).

C. barnesii contains alkaloids, sterols [including 1.18% ergosterol], 8.73% d-mannitol, proteins, organic acids, and amino acids, of similar composition to C. sinensis, which it has been proposed as a substitute for (Yang et al. 1985, 1987).

C. capitata has yielded 0.004% of an unidentified indole derivative, as well as c.1% fatty oil (Tamm 1962).

C. cicadae has yielded galactomannans [CI-P and CI-A], which have shown hypoglycaemic activity in mice (Hobbs 1995).

C. hawkesii contains d-mannitol, alkaloids, sterols [including ergosterol], amino acids, organic acids and vitamins, of similar composition to C. sinensis, except with lower d-mannitol content; it has been proposed as a substitute for C. sinensis (Guo et al. 1990; Huang, H.-T. et al. 1981; Huang, H.-Y. et al. 1981).

C. liangshanensis contains d-mannitol, ergosterol, organic acids [including stearic acid], amino acids, and alkaloids, of similar composition to C. sinensis, which it has been proposed as a substitute for (Tan, Z. et al. 1985, 1987).

C. militaris contains cordycepin, d-mannitol, ergosterol, β-sitosterol, adenine, *adenosine* (Liu et al. 1990), homocitrullylamino-*adenosine*, and 3'-amino-3'-deoxy-*adenosine* (Buckingham et al. ed. 1994).

C. ophioglossoides contains ophiocordin, and 3 protein-bound polysaccharides [CO-N, SN-C and CO-1] with antitumour activity (Hobbs 1995). In a screening of fungi, it tested weakly positive for the presence of unidentified alkaloids (Spilsbury & Wilkinson 1961).

C. sinensis contains cordycepin, cordycepin 3'-deoxy-*adenosine*, cordycepic acid, ophiocordin, uridine, uracil, d-mannitol [7.83% in one analysis], adenine, *adenosine*, *tryptophan* [and other amino acids], sterols [including ergosterol – 1.1% in one analysis], fatty acids and coarse protein. Many of these compounds have antifungal, antibacterial, antitumour and/or immunostimulating properties (Bok et al. 1999; Hobbs 1995; Hsu et al. 1986; Huang 1993; Huang, H.-T. et al. 1981; Yang et al. 1985). A commercial C. sinensis extract was shown to inhibit MAO degradation of *phenethylamine*, in rodent brains (Xu et al. 1988). It appears to be relatively non-toxic (Huang et al. 1988).

Cordyceps capitata fruiting body is divided into a spherical fertile head, and a spherical cylindrical stalk; head 6-10mm, yellow-brown, sometimes with olive tint, with fine dark punctation from the projecting ostioles of the perithecia, roughened by ostioles when dry; stalk offset sharply, 50-80 x 8-10mm, thick below but tapering upwards, deep to pale yellow, smooth, without yellow mycelial strands; perithecia immersed; asci cylindrical, c.15µ wide, 8-spored; spores filiform, breaking up when mature into many smooth, hyaline, rod-like spores with a few drops, 16-21(-25) x 2-3µm. Fr. Sep.-Oct.

Singly to clustered, in coniferous forests among mosses and needle litter, parasitic on Elaphomyces spp. growing underground, not common (Breitenbach & Kranzlin 1984; Dennis 1968) to common; N. America [common in n. California & Pacific n.w.], Asia, Europe (Hobbs 1995).

Cordyceps militaris grows on submerged caterpillars, and is found in N. America, Asia, England and Australia [NSW, Vic.] (Hobbs 1995; Phillips 1981; Young, T. 1994).

Cordyceps sinensis is found over Asia, especially on mountain tops above 3000m in cold and snowy grasslands in China (Hobbs 1995; Pegler et al. 1994).

Cordyceps hawkesii has been reported from eastern Australia, though there is some doubt regarding its true identity here. A number of other species grow in Australia – C. aphodii, C. bicephala, C. brittlebankii, C. coxii, C. cranstounii, C. dovei, C. aff. entomorrhiza, C. furcata, C. gunnii, C. meneristitis, C. robertsii, C. scottiana and C. taylori (Willis 1959).

CORIANDRUM

(Umbelliferae/Apiaceae)

Coriandrum sativum *L.* **(Selinum coriandrum** *Krause***)** – coriander, Chinese parsley, cilento, kottmir, kustumbari, kusbara, kushniz

Coriander, cultivated for at least 3,000 years, is mentioned in many ancient writings [such as the Egyptian Ebers papyrus from c.1500BC, and Sanskrit texts], and is compared to 'manna' ['food from heaven'] in the bible. Originating in North Africa and the Mediterranean, it was spread north through Europe by the Romans, who combined it with cumin and vinegar as a meat preservative. The Egyptians used it as an aphrodisiac, a trend continuing until the Middle Ages. The Greeks added it to their wine [see *Methods of Ingestion*]; added to warm wine, the powdered fruits are said to make an effective 'lust potion'. The Chinese believed coriander gave immortality. The fruits are used in TCM to treat stomach ache, nausea and measles, and in Ayurveda to treat indigestion, sore throat, burns, allergies and urinary tract infections. In India, it is said to reduce the effects of alcohol. In the Philippines, the aroma of the crushed fruit is inhaled to relieve dizziness. The fruits are also known to relieve flatulence and headaches, and have sedative-hypnotic properties. The essential oil of

the fruit is used in toothpaste, perfumes and massage oils, and the fresh leaves and crushed fruits are popular as a cooking herb/spice (Bremness 1994, 1998; Cunningham 1994; Mabey et al. ed. 1990; Nadkarni 1976; Perry & Metzger 1980; Polunin & Robbins 1992).

C. sativum fruits [sometimes referred to as the seeds] have yielded 20-25% fatty oils, and up to 2.17% essential oil, the latter containing 33-81.6% d-linalool [sedative, antiseptic, fungistatic], 1-7.3% limonene [sedative, expectorant, skin-irritant], 1.8-31.5% α-*pinene*, 0.1-1.2% β-*pinene*, 1.9-6.6% *camphor*, 0.4-6.1% camphene, 0.4-3.4% myrcene, 0.2-1.6% p-cymene, dipentene, 0-0.7% α-terpineol, 2.5-15.4% γ-terpinene, 0.2-10.2% geranyl acetate, 0-8.2% geraniol, 0-0.9% decanal, 0-1% decanol, 0-0.5% E-2-dodecenal, 0-1.2% sabinene and 0-0.7% undecanal [these last 2 both tentatively identified] (Harborne & Baxter ed. 1993; Karow 1969; Smallfield et al. 2001). Also present in the fruit are flavonoids [such as quercetin, kaempferol (MAOI (Sloley et al. 2000)) and *apigenin*], coumarins, and phenolic acids, such as caffeic acid [analgesic, antibacterial, antioxidant, antiinflammatory, antifungal, antiviral] and *chlorogenic acid* (Harborne & Baxter ed. 1993; Polunin & Robbins 1992).

Coriandrum sativum is a glabrous annual herb rising from a taproot, 20-70cm tall. Basal leaves forming a rosette, ternately or pinnately lobed to pinnately compound, ovate, 3-15 x 2-10cm; leaflets flabelliform-cuneate, 1-2 x 0.5-1cm, toothed or incised; upper cauline leaves pinnately dissected, the ultimate divisions linear to filiform, 2-15 x 0.5-1.5mm; petioles 1-15cm long. Flowers in lax, compound umbels; peduncles terminal and lateral, 3-10cm long or occasionally abortive, rays 2-8, 1-2.5cm long, pedicels 2-5mm long, involucel dimidiate, bractlets linear, 2-4mm long; calyx teeth ovate-lanceolate, 0.5-0.8mm long; petals white or rose, 5, bilobed, oblong with a narrower inflexed apex, outer petals radiant; styles slender, stylopodium conical; carpophore 2-parted. Fruit 1.5-5mm diam., globose, subterete, mericarps boat-shaped, glabrous, not readily separating at maturity, primary ribs 5, filiform, secondary ribs filiform or obscure, vittae absent; seed face concave. Fl. summer.

Native to Mediterranean region (Simonetti 1990; Wagner et al. 1990).

CORIARIA

(Coriariaceae)

Coriaria arborea *Lindsay* **(C. sarmentosa** *Forst. f.***; C. tutu** *Lindsay***)** – tutu

Coriaria atropurpurea *DC.*

Coriaria japonica *A. Gray*

Coriaria myrtifolia *L.* – dyer's bush, gerberstrauch, redoul

Coriaria sinica *Maxim.* **(C. nepalensis** *Wall.***)**

Coriaria thymifolia *Humb. et Bonp. ex Willd.* **(C. lurida** *Kirk***; C. microphylla** *Poir***; C. ruscifolia** *L.***)** – shanshi, tutu, tutu-papa, tutu-heu-heu, pohou, tupakihi, ink plant

'Shanshi', C. thymifolia, is used by sorcerers in the Ecuadorian Andes for its psychoactive berries, which are said to induce a sensation of flying. They are still collected in the mountain forests by the Sibundoy. The berries, known as 'piñan', have produced intoxications in children who have eaten them; human deaths have occurred with overdose, and the plant has also poisoned stock animals. C. atropurpurea has also been reported as being intoxicating, and has been suggested to have been the Aztec 'tlacopétatl' [this might be a spelling error]. It is known in Mexico as a toxic cardiac stimulant and convulsant (Diaz 1979; Montgomery 1997a, 1997b; Ott 1993; Schultes & Hofmann 1980, 1992; Usher 1974).

In parts of S. America, the juice of the flower petals of C. thymifolia has been used as an ink, known as 'chanchi'. Maoris of New Zealand are also known to use juice from Coriaria spp. as an ink for tattooing. In New Zealand, intoxications have occurred with Coriaria spp. ['tutu poisoning'], especially C. arborea, as well as C. thymifolia. Here, C. thymifolia and C. ruscifolia have sometimes been separated, on the basis of the former being a shrub, and the latter a bush or small tree [possibly a confusion with C. arborea]. Sometimes the intoxications result from consumption of the berries, though the Maoris are known to make a "non-intoxicating drink" from the fruits (Ford 1910/1911a). Another source reported the juice of the fleshy petals to be the part used for these beverages (Cheeseman 1906). In Spain, C. myrtifolia is known as 'emborracha cabras' ['inebriates goats'] (theobromus pers. comm.).

Intoxications occur from ingestion of honey made from the honeydew-secretion of the leaf-hopper Scolypopa australis, which feeds on these plants. The young shoots and berries are considered the most toxic parts (Palmer-Jones 1965). In animals, symptoms of poisoning include "stimulated and then impaired respiration, tetanic convulsions and coma", with death usually following within a few hours. In sublethal doses, animals recover completely from the intoxication with no lasting damage evident. In humans, however, there is usually complete recovery, though memory impairment has been reported. The toxins do not easily deteriorate from boiling. Lime [not the **Citrus** fruit] has been suggested as an antidote to tutu poisoning, as alkalis are known to destroy the toxins in vitro (Ford 1910/1911a), though I can not imagine how it would be feasible to consume adequate quantities of lime without painful burning of the alimentary tract, unless it were encapsulated.

C. arborea leaves and berries contain the picrotoxin-like sesquiterpene lactone *tutin* [causes extreme CNS-excitation, stimulates respiratory, vasomotor and cardioinhibitory systems]. The leaf-hopper insect Scolypopa australis metabolises *tutin* to hyenanchin [mellitoxin; 4-OH-*tutin*], which has similar effects.

C. japonica and C. myrtifolia have yielded *coriamyrtin*, which has similar effects to *tutin*; leaves of C. japonica also contain the tannin coriariin A, which has antitumour properties (Harborne & Baxter ed. 1993; Palmer-Jones 1965).

C. sinica has yielded *tutin*, *coriamyrtin*, corianin, and coriatin; a mistletoe [see *Endnotes*] that parasitises this species, Taxillus yadoriki, has been shown to accumulate up to 10 times the concentration of these compounds from the host plant (Chang & But ed. 1986).

C. thymifolia aerial parts [from Chile] yielded 0.042% *coriamyrtin*, 0.021% quercetin, 0.017% quercetin-3-O-galactoside, 0.01% quercitrin, 0.007% avicularin, 0.021% β-sitosterol and 0.035% ursolic acid; fruits also contained *coriamyrtin*, β-sitosterol, ursolic acid (Reyes et al. 1980), ellagic acid 3,3'-dimethylether, and corianin (Valencia et al. 2001).

Coriaria thymifolia is a small, glabrous, suffruticose or herbaceous plant 15-20cm or more tall; rootstock often stout, woody, much-branched; stems and branches slender, with winged angles, often flattened in one plane. Leaves frond-like, +- pinnate, opposite or rarely in whorls of 3, entire, exstipulate, variable in size, 3-26mm, oblong-ovate or lanceolate, acute or acuminate, sessile or very shortly petioled, glabrous or slightly pubescent. Axillary racemes 2.5-10.2cm long, slender, spreading, pubescent; flowers less than 3mm diam., often unisexual, strongly proterogynous; sepals 5, imbricate, persistent, broadly ovate, subacute; petals 5, hypogynous, smaller than sepals, keeled within, enlarged after flowering and becoming thick and fleshy and embracing the fruit; stamens 10, hypogynous; filaments short, elongating after fertilisation; anthers large; disc absent. Carpels 5-10, free, 1-celled, whorled on a short conical receptacle; styles as many as carpels, free, thick, elongated, covered for whole length with stigmatic papillae; ovules solitary, pendulous from top of cell. Fruit globose, purplish-black, of 5-8 cocci enveloped by persistent enlarged juicy petals, 1-celled, 1-seeded; seed with membranous testa.

North and south Islands of New Zealand, in mountainous districts from Taupo and the east Cape southwards, 300-1500m (Cheeseman 1906); also native to Peru and Ecuador (Bailey & Bailey 1976; Schultes & Hofmann 1980).

Cultivate from seed in early spring, or from cuttings or layers in midsummer. Grows well in well-drained soil in a sunny position (Grubber 1973).

CORNUS

(Cornaceae)

Cornus amomum *P. Mill.* – knob-styled dogwood, cawaruc ['deer feed']

Cornus racemosa *Lam.* **(C. paniculata** *L'Her***)** – panicled dogwood, northern swamp dogwood, masigusge ['arrow wood']

Cornus rugosa *Lam.* **(C. circinata** *L'Her.***)** – Alder leaved dogwood, rough leaved dogwood, broad leaved dogwood, round leaved cornel, silky cornel, rugisucje ['smoking bark']

Cornus stolonifera *Michaux* **(C. sericea ssp. stolonifera** *(Michx.) Fosberg***; Thelycrania sericea** *(L.) Dandy***)** – western red osier dogwood, red willow, rose willow, swamp dogwood, silky cornel

In Pacific northwest N. America, the inner bark of C. stolonifera is smoked as a 'kinnikinnick' [see **Arctostaphylos** and *Endnotes*] by Plains Indians; it is said to produce an opium-like effect [see **Papaver**]. The root bark is generally preferred over the stem bark. Conversely, the North Carrier Indians decoct the bark as a stimulant. Perhaps the discrepancy lies with differences in dosage and route of administration. The Winnebago smoke the bark of C. amomum, C. racemosa and C. rugosa as kinnikinnick; in British Columbia, leaves of Cornus spp. are smoked instead, by the Thompson Indians. C. racemosa is said to have a flavour similar to, but milder than, **Arctostaphylos** (Felter & Lloyd 1898; Kindscher & Hurlburt 1998; Ott 1993; Winter 1998). Bark of C. florida and other Cornus spp. have been used medicinally as quinine substitutes, and to relieve headache from quinine, also acting as a tonic and mild stimulant [dose c.1.3-3.9g]. The flowers have been used as a chamomile substitute [see **Anthemis**, **Matricaria**], and tinctures of the ripe fruit in brandy or whiskey have been a popular bitters with some rural folk (Felter & Lloyd 1898). The Cherokee use Cornus spp. for medicine – C. alternifolia and C. florida barks are used as a tonic, stimulant, antiseptic, astringent, antipyretic, anthelmintic, antidiarrhoetic and analgesic. These species, as well as C. stricta, are used to treat lost voice (Hamel & Chiltoskey 1975).

In Central America, C. excelsa [C. declinata, C. tolucensis; 'tepeacuilotl'] root bark is used as a tonic. C. mascula ['cornelian cherry'] fruits

are eaten for their sweet taste in Eurasia, and in France they are made into an alcohol called 'Vin de Cornoulle' (Usher 1974). In TCM, C. officinalis fruits ['shan-chu-yu' or 'shan zhu yu'] are used as a "long-life medicine" (theobromus pers. comm.), and in a dose of 3-10g as an astringent tonic, to treat impotence, spontaneous ejaculation, vertigo, night-sweats, infrequent urination, tinnitis, impaired hearing, and other disorders. The fruits are considered incompatible with **Asarum** sieboldii, **Siler** divaricatum, and Platycodon grandiflorus, and have shown anti-*histamine* activity (Hsu et al. 1986; Huang 1993; Keys 1976).

I have been unable to find any chemical studies of most of these plants, though C. alba ssp. tartarica and C. sanguinea have yielded *phenethylamine* (Lundstrom 1989). C. officinalis fruits have yielded cornin, loganin, morroniside, 7-O-methylmorroniside, and sweroside, and the leaves have yielded longiceroside (Hsu et al. 1986; Huang 1993).

Cornus stolonifera is a shrub 1-3m tall, often forming dense thickets; younger branches red; pith white and large. Leaves opposite, commonly 5-10cm long, 1/4-2/3 as wide, lanceolate to elliptic or ovate, gradually acuminate, acute to broadly rounded at base, distinctly whitened beneath, pubescence of lower leaf surface appressed to spreading, the hairs all or mostly 2-pointed, inserted near their middle, rarely as much as 0.5mm long; lateral veins on well-grown leaves 5-7 pairs. Inflorescences flat or slightly convex open cymes; sepals rarely as much as 1mm long; petals 4, small, white, purple or yellow, valvate in bud, spreading or revolute at anthesis; stamens 4; filaments long and slender; anthers versatile. Ovary 2-celled; ovule 1 in each cell; style elongate; stigma capitate. Fruit a white drupe, 7-9mm diam., the hard endocarp 2-celled but often only 1-seeded.

A complex and highly variable species.

C. stolonifera forma interior [west US, east to Michigan and Indiana] – the pubescence of the young stems and inflorescence is dense and tomentose.

Ranging from Newfoundland to Alaska, south to Pennsylvania, Indiana and Illinois, west to n. Mexico (Gleason 1952).

CORYNANTHE [including Pausinystalia]

(Rubiaceae)

Corynanthe johimbe *K. Schum.* **(Pausinystalia yohimbe** *(Schum.) Pierre ex Beille***)** – johimbe, yohimbe, idágbon

Corynanthe macroceras *K. Schum.* **(Pausinystalia brachythyrsa** *De Wild.***; P. macroceras** *(K. Schum.) Pierre ex Beille***)** – nikiba, eyamonet, abo idágbon ['female johimbe']

Corynanthe pachyceras *K. Schum.* **(C. africana** *R. Br.***; Pausinystalia pachyceras** *(K. Schum.) De Wild.***; Pseudocinchona africana** *A. Chev. ex E. Perrot***; Ps. pachyceras** *(K. Schum.) A. Chev.***)** – mbarakun, pramprama, gauhele, bopat, nkaka, kobri

Corynanthe paniculata *Welw.*

Pausinystalia angolensis *Wernham*

The inner bark shavings of C. johimbe are a famous aphrodisiac, perhaps the only one with a proven aphrodisiac action. Its use is well-established in Gabon, Nigeria and e. Cameroun, where it is chewed as a stimulant tonic and aphrodisiac. When taken too often, it is said to disturb one's sanity. It is used by the Bantu of tropical w. Africa in fertility orgies that may last up to 15 days, with the herb being consumed in ever greater quantities over this period. It may also be generally consumed as an aphrodisiac tonic. Some tribes are reported to consume it in combination with **Tabernanthe** iboga during initiation rites. In Gabon, the bark is cooked with meat or fish and fed to hunting dogs as a stimulant, and the plant is also used as a fish-poison. C. macroceras is used in Congo as a strong aphrodisiac stimulant, and anti-hypnotic; it is also used in Cameroun in the same way as C. johimbe. Bark of C. pachyceras is also considered aphrodisiac in this part of the world, and may be added to sorghum beer [see *Methods of Ingestion*] to increase its potency. In Congo, it is taken 'as a stimulant to prevent bad dreams'. In Ivory Coast, it is macerated or chewed as an antitussive, antipyretic, and to ease nausea. Near the Liberia/Ivory Coast border, the bark is used as an arrow-poison ingredient (Burkill 1985-1997; Miller 1985; Oliver-Bever 1986; Rätsch 1990, 1992).

Today in the west, quality 'yohimbe' has been at times difficult to obtain, yet it and its main active constituent *yohimbine* [an indole alkaloid] have attracted interest as male aphrodisiacs, and extracts are sometimes available in health shops and pharmacies. Commercial yohimbe may sometimes be adulterated with other Corynanthe spp., which may be low or deficient in *yohimbine*.

Dose suggestions for C. johimbe bark vary widely and it would be wise to establish individual tolerance before trying high doses. Some suggest using 2-4g (Torsten pers. comm.), though Miller (1985) suggested 30g! I suspect this latter figure may be due to the use of low-quality bark. Bark shavings are prepared non-traditionally by bringing 2 cups of water to a boil, reducing to a simmer, adding the juice from ¼ of a lemon or lime [see **Citrus**] or c.1g ascorbic acid, and then adding the powdered root bark and simmering for a further 10 minutes. This brew is then filtered through coffee-filter papers while still hot, then cooled to room temperature for consumption. The material may be more effectively extracted by soaking in alcohol for c.8 hours, before straining and evaporating the alcohol to leave a crude alkaloidal residue. The purpose of adding a source of vitamin C is to increase the absorption of *yohimbine* and other alkaloids, as well as reducing the time to onset of effects. The tea is quite bitter, and ascorbic acid also reduces the likelihood of nausea. It is reported to be best consumed as quickly as possible. Effects of plain tea may be felt in 30-60 minutes; the alcohol extract in 10-20 minutes. Effects include warm tingles up the spine, relaxation of limbs, hypertension, mental stimulation, mild perceptual alterations in higher doses, and often a spontaneous erection lasting several hours, due to stimulation of the spinal ganglia which control penile erectile tissue. Lower doses of *yohimbine* are more effective for sexual purposes than higher doses. When used as a sexual tonic, 250-500mg may be taken every morning after food. Due to *yohimbine*'s MAOI activity, it should not be taken with *amphetamine*s or *tyramine*-rich foods; also should not be taken by those with kidney, liver or heart problems, or by diabetics or hypoglycaemics. Combined with tricyclic antidepressants, dangerous hypertension may result (Crenshaw & Goldberg 1996; Fugh-Berman 2000; Miller 1985; Rätsch 1992; Torsten pers. comm.). Yohimbe can also interact dangerously with dextromethorphan [DXM] (pers. comm.).

It is suggested that blood-sugar levels be kept high when consuming yohimbe, to reduce the incidence of unpleasant reactions. Drinking a glass of milk immediately before consumption has also been suggested to minimise unwanted side-effects (Torsten pers. comm.). Chocolate [see **Theobroma**] should not be consumed, even with small doses of yohimbe. Ginseng [see **Panax**] also interacts with yohimbe so that only ¼ of the usual yohimbe dose may be needed for the same level of effect (theobromus pers. comm.).

C. johimbe bark has yielded tannins, and 1-15% alkaloids [with higher levels in 15-20 year-old trees], consisting mostly of *yohimbine*, α-*yohimbine*, and β-*yohimbine*, as well as pseudoyohimbine, alloyohimbine, yohimbiline, *ajmalicine*, corynantheine and dihydrocorynantheine (Bruneton 1995; Buckingham et al. ed. 1994; Burkill 1985-1997; Henry 1939; Meulen & Kerk 1964); corynanthine [rauhimbine] has also been reported from the plant, and is an α1-adrenoceptor antagonist (Buckingham et al. ed. 1994), mild local anaesthetic, and in dogs [0.1-0.2mg/kg i.v.], stimulated erection and ejaculation. Corynanthine is 4-5 times less toxic than *yohimbine*, and its sympatholytic activity is twice as strong (Oliver-Bever 1986). Concentration of *yohimbine* and related alkaloids in bark was found to increase from the base to the top of the tree; leaves and branches contained only small amounts of alkaloids (Paris & Letouzey 1960).

C. macroceras bark has yielded 4% alkaloids – 60-65% *yohimbine*, 8% α-*yohimbine*, 7% *ajmalicine*, 7% (-)-calycanthine [see **Calycanthus**], 5% corynantheine [AChEI] and 1.5% β-*yohimbine* (Leboeuf et al. 1981; Orgell 1963a); trunk bark has yielded up to 1% alkaloids, mostly *yohimbine*, as well as saponins and tannins (Burkill 1985-1997). Corynanthine has also been reported from the plant (Buckingham et al. ed. 1994).

C. pachyceras bark has yielded 5-6% alkaloids, including corynantheine, corynanthine, corynanthidine and corynantheidine (Burkill 1985-1997).

C. paniculata bark was found to contain *yohimbine*, β-*yohimbine*, alloyohimbine, pseudoyohimbine, and an unidentified alkaloid (Meulen & Kerk 1964).

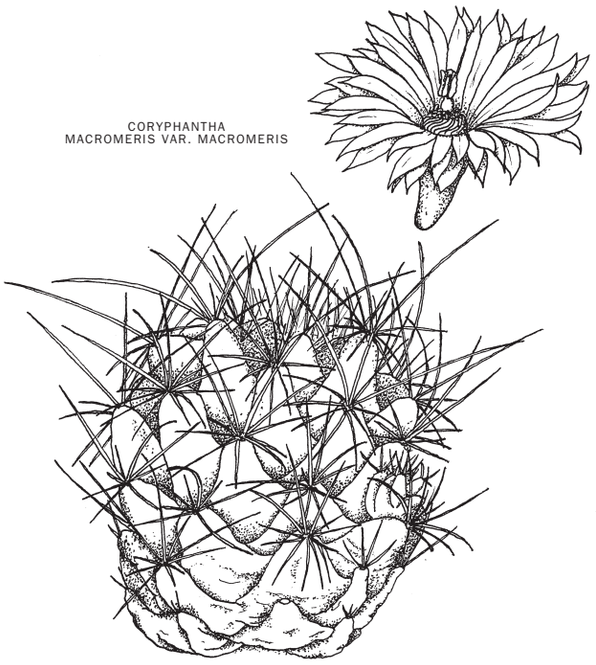
P. angolensis bark was found to contain *yohimbine*, α-*yohimbine*, β-*yohimbine*, alloyohimbine, pseudoyohimbine, corynantheine, and an unidentified alkaloid (Meulen & Kerk 1964).

Corynanthe johimbe is a forest tree 6-28m tall, trunk straight to the first main branches, without buttresses. Leaves opposite, elongate-obovate or oblanceolate, narrowed to the usually auriculate base, very shortly and obtusely acuminate, 13-35 x 5-11.5cm, with 10-16 main lateral nerves on each side of midrib, prominently venose-reticulate above, margins often undulate; petioles up to 7mm long. Inflorescences panicles up to 18cm long, glabrous, flowers in paniculate clusters; flowers 4-merous; calyx adnate to ovary; corolla epigynous, +- tubular, rarely campanulate, corolla-lobes valvate with filiform appendages c.1.5cm long; stamens epipetalous, as many as and alternate with the corolla-lobes. Ovary inferior; ovules 2 or more in each cell; anthers 2-celled; styles slender. Capsules 1-1.6cm long, dehiscent; seeds winged.

In west tropical Africa [s. Nigeria, Cameroun, Equatorial Guinea, Congo] (Hutchinson & Dalziel 1954-1972).

CORYPHANTHA

(Cactaceae)



Coryphantha bumamma *(Ehrenberg) Britton et Rose*
Coryphantha calipensis *Bravo*
Coryphantha compacta *(Engelmann) Br. et R.* – bakana, bakanawa, wichuri, Santa Poli
Coryphantha cornifera *(DC.) Lemaire* **var. echinus** *(Engelm.) L. Benson* **(C. echinus** *(Engelm.) Br. et R.***)**
Coryphantha elephantidens *(Lem.) Lemaire* **(Mammillaria elephantidens** *Lem.***)** – peyote
Coryphantha greenwoodii *H. Bravo*
Coryphantha macromeris *(Engelm.) Lem.* **(C. pirtlei** *Werder.***; Lepidocoryphantha macromeris** *(Engelm.) Backeb.***)** – doñana, doña ana
Coryphantha missouriensis *(Sweet) Br. et R.* **(Cactus mammillaris** *Nutt.***; Ca. missouriensis** *Kuntze***; Escobaria missouriensis** *(Sweet) Hunt* **ssp. missouriensis; Mammillaria missouriensis** *Sweet***; M. nuttallii** *Engelm.***; M. simplex** *Torrey et Gray non. Haworth***; Neobessya missouriensis** *(Sweet) Br. et R.***; N. notesteinii** *(Br.) Br. et R.***; N. rosiflora** *Lahman ex G. Turner***; N. similis** *(Engelm.) Br. et R.***; N. wissmannii** *(Hildmann ex Schumann) Br. et R.***)** – Missouri pincushion, Kansas pincushion
Coryphantha palmerii *Br. et R.*
Coryphantha pectinata *(Engelm.) Br. et R.* **(C. echinus** *(Engelm.) Orcutt***)**
Coryphantha ramillosa *Cutak*
Coryphantha rosea *Clokey* **(C. vivipara var. rosea** *(Clokey) L. Benson***; Escobaria vivipara** *(Nutt.) Buxbaum* **var. rosea** *(Clokey) D.R. Hunt***)**
Coryphantha runyonii *Br. et R.* **(C. macromeris var. runyonii** *(Br. et R.) L. Benson***; C. macromeris ssp. runyonii** *(Br. et R.) Taylor***; Lepidocoryphantha runyonii** *(Br. et R.) Backeb.***)**
Coryphantha scolymoides *(Scheidw.) Berg.* **(C. cornifera** *(DC.) Lem.* **var. scolymoides** *(Scheidw.) Börg.***)**

The Tarahumara respect and fear C. compacta as a kind of 'peyote' [see **Lophophora**], and it is used by their shamans as a "powerful medicinal plant" (Bye 1979b; Diaz 1979); sometimes it is made into a beer-like drink (Rätsch 1998). Its common names, 'bakana' and 'bakanawa', are shared with the **Scirpus** used by the Tarahumara. C. palmerii has also reportedly been used as a 'narcotic' plant in Mexico (Dominguez et al. 1970; Hornemann et al. 1972). C. rosea has also been hinted by reliable sources to be psychotropic. C. elephantidens has been observed to be sold as 'peyote' in a Mexico City market, though this may be only for medicinal purposes (Smith 2000).

C. macromeris, known as 'doñana' in n. Mexico, was reported by Schultes & Hofmann (1980) to possibly "still be used in this area as a ritual hallucinogen" (Schultes & Hofmann 1980), though this claim appears to be without foundation (Smith pers. comm.; Trout pers. comm.). C. macromeris is thought to have been used by N. American psychonauts since at least the early 1970's as an experimental intoxicant, as promoted by numerous underground publications still being reprinted and widely read (eg. Gottlieb 1992 and earlier editions). The promotion of its use appears to be based on assumptions gleaned from Hodgkins et al. (1967), who reported that *macromerine* [a major constituent of C. macromeris] showed what they regarded as "hallucinogenic reactions" in cats and squirrel monkeys (Hodgkins et al. 1967). C. macromeris has also reportedly "been declared as a sacrament" and cultivated for use by a Californian 'psychedelic church' (Schultes & Hofmann 1980).

The effects from one bioassay of C. macromeris [which used "several hundred grams fresh"] were described as "very mild and very strange, with many waves of intense nausea and extremely persistent after-effects, such as distorted vision and a very weird feeling of unreality lasting for weeks after its use" (Trout ed. 1997a; Trout pers. comm.). A dose of 8-12 de-spined cacti, eaten or decocted for 1hr and drunk on an empty stomach, has been suggested (Gottlieb 1992). However, it is likely that the comments by Gottlieb are not based on any personal experience, and it appears that few people have ever actually ingested this species (Trout pers. comm.).

The active chemicals in many Coryphantha spp. have been considered to be *macromerine* and *normacromerine*, which were claimed to be psychoactive in animals, but are less potent than *mescaline* by weight. The purported activity of *normacromerine* in rats was compared to *mescaline* and *psilocybin* (Bourn et al. 1978; Hodgkins et al. 1967). Of course, it would be better if the rats could tell us what they thought! Both alkaloids have also been reported to be non-psychoactive in rats (Vogel et al. 1973), but the tests used to reach this conclusion were inadequate (Bourn et al. 1978). If these alkaloids do indeed act as so-called 'hallucinogens', like *mescaline* and *psilocybin*, this would be unusual, as N-methylated *phenethylamines* usually lack such activity. However, this does not necessarily imply a lack of psychoactivity (Nichols & Glennon 1984). The β-OH-4-MeO-*phenethylamines* found in the genus inhibited the oxidation of *tyramine* [but not *tryptamine*] by MAO in vitro, whilst those lacking the β-OH group inhibited MAO oxidation for both (Keller & Ferguson 1976b). Such MAO-inhibition might possibly account for the psychoactivity of some of these cacti, given the low potency of *macromerine* and *normacromerine* alone. Also widespread in the genus are other *phenethylamine* [PEA] derivatives, including synephrines.

C. bumamma was found to contain 0.01-0.05% alkaloids [w/w], consisting of *hordenine* [>50%], N-methyl-4-MeO-*PEA*, and N-methyl-*DMPEA* (Bruhn et al. 1975); (-)-β-O-methyl-*normacromerine* [calipamine] has also been reported (Ranieri et al. 1976).

C. calipensis has yielded 0.14% alkaloids [w/w], including 0.0053% (-)-*normacromerine* [10-50% of total alkaloids, in one test], calipamine, 0.0016% N,N-dimethyl-3,4-trimethoxy-*PEA*, 0.0082% coryphanthine [β-MeO-dehydroxycandicine; β-MeO-N,N,N-trimethyl-*PEA*], N-methyl-3,4-dimethoxy-β-MeO-*PEA*, N,N-dimethyl-3,4-dimethoxy-β-MeO-*PEA*, and traces of N-methyl-*DMPEA*, N,N-dimethyl-*DMPEA*, N-methyl-*tyramine* and *hordenine* (Bruhn & Agurell 1974; Bruhn et al. 1975; Lundstrom 1989; Shulgin & Shulgin 1997).

C. compacta has reportedly yielded N-methyl-*DMPEA* (Diaz 1979), though this may have been in error. I have been unable to find any primary reference for the analysis of this species.

C. cornifera yielded N-methyl-*tyramine*, *hordenine*, synephrine, N-methyl-*DMPEA*, 4-MeO-*PEA* and β-OH-4-MeO-*PEA* (Hornemann et al. 1972).

C. cornifera var. echinus has yielded *macromerine*, 0.0002% N-methyl-*tyramine*, 0.0001% *hordenine*, synephrine, 0.0001% β-O-methyl-synephrine, 0.0002% N-methyl-4-MeO-*PEA*, β-OH-4-MeO-*PEA*, and 0.0007% N-methyl-*DMPEA*.

C. durangensis yielded N-methyl-*tyramine*, N-methyl-*DMPEA*, *hordenine* and synephrine.

C. elephantidens has yielded *macromerine*, N-methyl-*tyramine*, *hordenine*, synephrine, β-OH-4-MeO-*PEA*, and N-methyl-*DMPEA* (Hornemann et al. 1972; Shulgin & Shulgin 1997).

C. greenwoodii yielded 0.043% (-)-*normacromerine*, 0.034% calipamine, 0.0095% N-methyl-*DMPEA*, N,N-dimethyl-*DMPEA*, N-methyl-3,4-dimethoxy-β-MeO-*PEA*, N,N-dimethyl-3,4-dimethoxy-β-MeO-*PEA*, dl-synephrine, dl-β-O-methylsynephrine, *hordenine*, 0.022% [w/w] (+)-coryphanthine, and 0.0157% [w/w] O-methylcandicine [N,N,N-trimethyl-4-MeO-*PEA*] (Bruhn et al. 1975; Meyer et al. 1983; Ranieri et al. 1976).

C. macromeris has yielded 0.16% *macromerine* (Brown et al. 1968, 1972; Hodgkins et al. 1967); references to other alkaloids in this species by Buckingham et al. (1994), Keller et al. (1973a, 1973b), and Shulgin & Shulgin (1997) are in error and should refer to C. runyonii [C. macromeris var. runyonii]. Other unidentified alkaloids have, however, been observed in C. macromeris, and more detailed analysis is needed.

C. missouriensis yielded 0.39% *hordenine*, 0.013% N-methyl-*tyramine*, and traces of *tyramine* and N-methyl-*DMPEA* (Pummangura et al. 1981).

C. ottonis yielded N-methyl-*tyramine*, *hordenine*, synephrine and 4-MeO-*PEA* (Hornemann et al. 1972).

C. palmerii yielded a crude alkaloid, as well as 0.003% β-sitosterol, eicosanol and dotriacontane (Dominguez et al. 1970). An unclear remark

by Gennaro et al. (1996) suggested that this species may contain traces of *mescaline*.

C. pectinata has yielded *macromerine*, *tyramine*, N-methyl-*tyramine*, *hordenine*, synephrine, β-O-methylsynephrine, β-OH-4-MeO-*PEA*, N-methyl-4-MeO-*PEA*, and N-methyl-*DMPEA* (Hornemann et al. 1972; Shulgin & Shulgin 1997).

C. poselgeriana yielded N-methyl-*tyramine*, *hordenine*, synephrine and 4-MeO-*PEA* (Hornemann et al. 1972).

C. radians was found to contain 0.001-0.01% alkaloids [w/w], over 50% of which was N-methyl-*tyramine*, and 1-10% *hordenine* (Bruhn et al. 1975). An unclear remark by Gennaro et al. (1996) suggested that this species may contain traces of *mescaline*.

C. ramillosa has yielded 0.73% *hordenine*, 0.043% N-methyl-*tyramine*, 0.015% β-O-methylsynephrine, 0.0057% synephrine and 0.00092% N-methyl-4-MeO-*PEA* (Sato et al. 1973).

C. runyonii has yielded over 0.05% alkaloids [w/w] (Agurell 1969a); mostly *macromerine* [0.0021% w/w; 0.07% d/w] and *normacromerine* [0.071% w/w; 0.19% d/w], 0.0077% N-formyl-*normacromerine*, 0.0001% *tyramine*, 0.0019% N-methyl-*tyramine*, 0.0004% *hordenine*, 0.0006% N-methyl-*DMPEA*, 0.0005% N-methyl-4-MeO-*PEA*, 0.0001% synephrine, 0.0002% metanephrine, N-methylmetanephrine, *epinephrine* and *norepinephrine* (Agurell 1969a, 1969c; Below et al. 1968; Keller 1978; Keller & McLaughlin 1972; Keller et al. 1973a, 1973b; Lundstrom 1989).

C. scolymoides [fresh] has yielded 0.0004-0.0012% *mescaline* (Gennaro et al. 1996).

C. vivipara and C. vivipara var. arizonica yielded [w/w] 0.017% *hordenine*, as the only detectable alkaloid (Bruhn et al. 1975; Howe et al. 1977).

Coryphantha macromeris is a cactus branching at the base, often many-headed, up to 20cm long, clumping to 30cm across; larger stems green, cylindroid to elongate-ovoid, up to 10-15 x 5cm; tubercles large, soft, loosely arranged, elongated, 12-15mm long, c.6-9mm thick, protruding 1.5-2.5cm, grooved on upper side c.2/3 of their length; areoles c.3mm diam., usually c.12mm apart; spines 10-17, slender; radials dark to pale grey, lighter than centrals, 9-15 per areole, spreading parallel to stem surface, straight to slightly curving, the longer 20-25mm long, c.0.5mm wide at base, acicular or nearly so, nearly circular in cross-section; central spines 4-6, black or dark to pale grey or reddish-brown, lower one longer, 25-50mm long, base to 1mm thick, spreading irregularly, straight or somewhat curved or twisted, subulate, narrowly elliptic in cross-section. Flowers large, purple, 4.5-5cm long, (3-)6-8cm across; perianth segments with greenish midribs, reddish-purple margins, the larger narrowly oblanceolate, up to 25mm long, 6mm wide, apex fimbriate-ciliate; scales on tube ciliate; petals reddish-purple to rose, largest narrowly oblanceolate, to 30 x c.6-9mm, minutely fimbriate; filaments reddish-purple to rose, to 12mm long; anthers yellow, oblong, c.1mm long; style yellow, c.20mm long, up to 1.5mm thick; stigmas 7-8, c.4.5mm long, slender; ovary in anthesis c.7.5mm long, 4.5mm diam., bearing a few scales with hairy axils. Fruit 15-25 x 6-9mm, green at maturity, with fimbriate scales with wooly axils; seeds globose, brown to yellow, smooth, reticulate, c.1.25mm long, 2mm broad, 1mm thick.

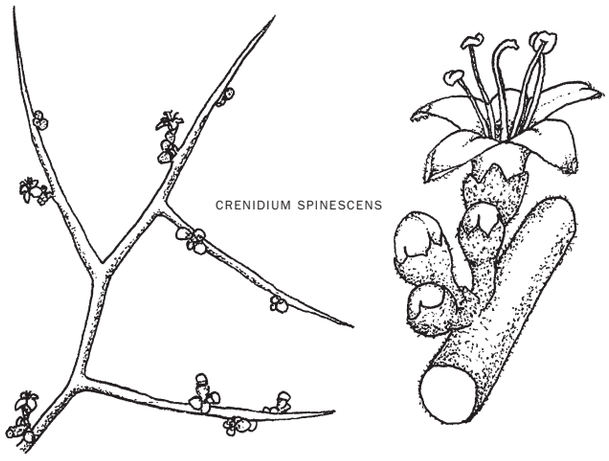
Yellow clay and gravelly soils of low hills in desert, mostly 750-1350m; s. New Mexico, w. Texas, Chihuahua south to Zacatecas, Mexico.

The groove on the upper tubercle is characteristic of the genus Coryphantha (Benson 1982; Britton & Rose 1963), and of the closely-related genera Escobaria and Neobesseya (Marshall & Bock 1941).

C. runyonii [C. macromeris var. runyonii] is similar in appearance to C. macromeris. It is distinguished by a smaller grey-green stem [to c.5-7.5cm long, 2.5-3.8cm diam.] growing in larger clumps [to 1m across], with longer tubercles [to 7.5mm long, c.4.5mm diam., protruding c.1.2cm], and different native habitat [Rio Grande Plain, Texas; near sea level] (Benson 1982).

CRENIDIUM

(Solanaceae)



Crenidium spinescens *Haegi*

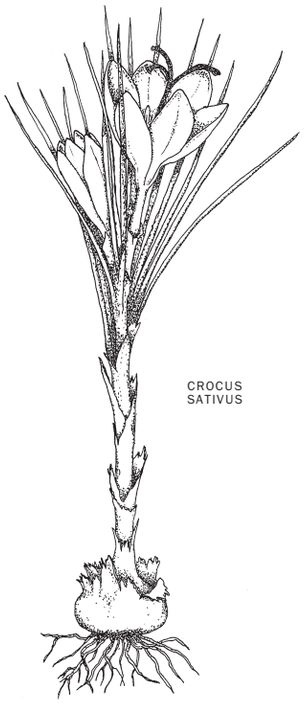
This Australian shrub has no recorded uses, yet it has been shown to be a source of hallucinogenic tropane-alkaloids and a *nicotine*-isomer. A mature, non-flowering specimen harvested in dry conditions in Western Australia [August] yielded 0.09% alkaloids from the aerial parts, consisting mostly of *hyoscyamine*, as well as *hyoscine*, tropine, 6-OH-*hyoscyamine* and *anabasine*. The roots yielded 0.21% alkaloids of similar composition, but without tropine or *anabasine* (El Imam & Evans 1984; Evans & Ramsey 1983).

Crenidium spinescens is a rounded, intricately branched shrub to 1.7m tall; branches spinescent, tomentose with non-glandular dendritic hairs, glabrescent. Leaves present only on immature parts, scattered, narrowly elliptic to linear, sessile, 3-10 x 0.5-1.5mm, tomentose, entire, margins slightly recurved. Flowers in cymose clusters at nodes, bisexual, slightly zygomorphic, each subtended by a pair of opposite bracts; pedicels 1-3mm long; calyx cupular, 5-lobed, 1.3-2mm long, tomentose, lobes minute; corolla 2.5-4mm long, tomentose outside, narrowly tubular with spreading limb, pale yellow, limb with 5 short, broad lobes, lobes ovate to broadly ovate, 1.5-2.5mm long, volutive in bud; stamens and style usually much exserted; stamens usually 4, didynamous, inserted at base of corolla tube; a staminode present or rarely fertile; anthers unilocular, not cohering, dehiscing by a semicircular slit. Ovary bilocular; stigma capitate, very shortly bilobed. Fruit a smooth ovoid capsule 4-4.5mm long, opening by 2 bifid valves, lower half enclosed by calyx; seeds subreniform, 3.5-4mm long.

In deep sand on margins of salt lakes; from Menzies to Lake Moore in s. Western Australia (Haegi et al. 1982).

CROCUS

(Iridaceae)



Crocus sativus *L.* – saffron crocus, saffran, saffer, karcom, kunkuma, kumkum pati, bhavarakta

Saffron, being the prized stigmas from C. sativus, has long been valued as a culinary and medicinal herb in the northern hemisphere, but particularly so in southern Europe and the middle east where it originated. In ancient Egypt and the Mediterranean, saffron was regarded as a powerful medicine. Greek shamans knew it as the 'blood of Hercules', and wore it as a protective amulet, as well as burning it in magical incense. The Phoenicians consumed saffron in crescent-shaped cakes, eaten in honour of the moon and Ashtoreth, their fertility goddess. It has long been associated in the east with fertility, sexual potency, strength, psychic powers and high-caste royalty. In parts of Asia, the privileged classes sometimes use it to dye their clothes a deep yellow. It may also be used to make a coloured paint for the 'third eye' spot worn on the forehead by devout Hindus. In Ayurvedic and Islamic medicine, it is used as a nerve tonic, stimulant, aphrodisiac and stomachic, and may be applied externally to treat headaches, bruises and rheumatism (Cunningham 1994; Nadkarni 1976; Rätsch 1990, 1992; Simonetti 1990). In Nepal, it is used in incenses, and the local variety has been observed to be more potently psychoactive than usual (Müller-Ebeling et al. 2002). It has been claimed that drinking an infusion of saffron can give the power "to foresee the future" (Cunningham 1994). In the Mediterranean region, saffron was once given as a tea to "put unruly children to sleep" (Emboden 1979a).

The stigmas of 1,700 flowers weigh only 25g dry (Bremness 1994), and are labour-intensive to harvest. This is the main reason why 'real' saffron is so expensive, and why false substitutes are so often encountered. 'Turmeric' [Curcuma longa] root powder is one of the more common substitutes, and in parts of Asia, turmeric is sometimes called saffron. Carthamus tinctorius ['bastard saffron', 'American saffron', 'safflower'] is also sometimes substituted for the real thing, in the form of shredded flower petals. Nowadays, saffron is mostly used to flavour saffron rice (Mabey et al. ed. 1990), though in some circles it is used as an expensive opium substitute [see **Papaver**], or as an exotic aphrodisiac, claimed to cause "long, distinctive orgasmic sensations" (Rätsch 1990).

Saffron is known to be capable of improving mood and even leading to euphoric, stimulant, 'narcotic', and perhaps mildly entheogenic effects. Besides this, it is known for its oestrogenic, analgesic, antiinflammatory, antipyretic, emmenagogic, carminative and digestive effects (Chiej 1984; Nadkarni 1976; Simonetti 1990; pers. comms.). For medicinal purposes, a standard dose may be 60-200mg. In overdose, it acts as a narcotic poison (Nadkarni 1976); 5-10g is considered sufficient to cause serious poisoning. One person who consumed 5g of saffron powder as an abortifacient collapsed, and suffered bleeding from the skin and kidney toxicity (Frohne & Pfänder 1983). Whilst 20g can kill, 1.5g may be +- safe for psychotropic use (Rätsch 1998). Saffron, in excess, can also cause headache and uterine bleeding. In small doses, however, saffron has been used to strengthen the uterus. Children have died from saffron overdose (Rätsch 1990, 1992). It has been claimed [by someone who probably never consumed toxic quantities] that eating too much saffron would cause one to "die of excessive joy" (Cunningham 1994)!

In animal studies, saffron has been shown to improve impairments in learning and memory induced by ethanol; these effects have been attributed largely to the crocin content of the stigmas. Also demonstrated are sedative, antitumour, and free-radical scavenging effects, which have been attributed largely to the crocetin content (Abe & Saito 2000; Zhang et al. 1994). Although early workers reported the isolation of crocetin in various forms from saffron (eg. Karrer & Helfenstein 1930), later analysis with more sophisticated equipment did not reveal crocetin itself (Tarantilis et al. 1995).

C. sativus stigmas contain mainly carotenoid glycosides, cis- and trans-derivatives of crocin, which are glycosides of crocetin; also present are safranal [a monoterpene aldehyde], picrocrocin [a glycoside, and precursor to safranal; the bitter component of saffron], picrocrocin aglycone, kaempferol diglycoside [kaempferol is an MAOI (Sloley et al. 2000)], isophorone, isophorone glycoside, 3,5,5-trimethyl-4-OH-1-cyclohexanon-2-ene, 3,5,5-trimethyl-1,4-cyclohexadione, 3,5,5-trimethyl-1,4-cyclohexadion-2-ene, 3,5,5-trimethyl-2-OH-1,4-cyclohexadion-2-ene, 2,6,6-trimethyl-4-OH-1-cyclohexene-1-carboxaldehyde, 2,4,4-trimethyl-3-formyl-6-OH-2,5-cyclohexadien-1-one (Karrer & Helfenstein 1930; Tarantilis et al. 1995; Zarghami & Heinz 1971a), *pinene*, cineole (Hilger 1900), naphthalene, 2-phenylethanol, 2-butenoic acid lactone, palmitic acid, stearic acid, oleic acid, linoleic acid and linolenic acid (Zarghami & Heinz 1971b). The essential oil has been claimed to contain *safrole* as a major constituent (Emboden 1979a), though this may be in error. The essential oil is obtained in a yield of 8-10% (Mabey et al. ed. 1990). Saffron is also rich in riboflavin [vitamin B2] (Rätsch 1992).

Crocus sativus grows from a usually symmetrical corm, enclosed by several tunics of variable texture and colour, tunics without rings, outer tunics fibrous in part, laciniate at base, fibres finely to coarsely reticulate, sometimes obscurely so; cataphylls up to 5, sheathing the aerial shoot. Leaves usually present at anthesis, appearing with or after flowers, all basal, flat or canaliculate on upper surface, lower surface usually strongly keeled, usually with 2 grooves; scape absent. Flowers 1-several, each on a short, subterranean pedicel which is sometimes subtended by a membranous, sheathing prophyll; bract membranous, bracteole similar or reduced, both white-membranous, rather flaccid, not closely sheathing at perianth tube; perianth regular, petaloid, 6-partite, deep lilac-purple with darker veins, white, or white with a purple base, segments 3.5-5cm, equal or subequal, tube long and narrow, glabrous, or with a ring of hairs in throat at insertion of filaments, throat glabrous or pubescent, white or lilac; anthers yellow, extrorse; stamens 3, opposite the outer perianth segments; stigmas 3. Ovary subterranean, inferior; style deeply divided into 3 simple branches, not at all subdivided at apex, style-branches 2.5-3.2cm. Capsule cylindrical or ellipsoid, maturing at or above ground-level by elongation of the pedicel. Fl. Sep.-Jan.

This plant is a sterile triploid, and is not known in a truly wild state; partially naturalised in some areas. It is very similar to the wild species C. cartwrightianus, which grows on rocky hillsides in the s. Aegean region (Tutin et al. ed. 1964-1980).

C. sativus also looks similar to the poisonous Colchicum autumnale ['meadow saffron', 'autumn crocus'], which does not have 3 stigmas (Bremness 1994).

Prepare harvested stigmas by sun-drying (Rätsch 1990).

CROTALARIA

(Leguminosae/Fabaceae)

Crotalaria juncea *L.* **(C. benghalensis** *Lam.***; C. fenestrata** *Sims***; C. porrecta** *Wall.***; C. sericea** *Willd.***; C. tenuifolia** *Roxb.***; C. viminea** *Wall.***)** – Bombay hemp, Sunn hemp, ghore-sun, pulivanji, mustanpat, shanabo

Crotalaria longirostrata *Hook. et Arn.* – long-beaked rattlepod, chipilin, chapilin, chiplino, chipil, tcap-in, chop, parrajachel, cascabell de vibora ['rattlesnake rattle'], tronador, garbancillo

Crotalaria mucronata *Desv.* – zhu zi tou

Crotalaria saggitalis *L.* **(C. belizensis** *Lundell***; C. fruticosa** *Mill.***; C. lunulata** *Raf.***; C. mathewsana** *Benth.***; C. parviflora** *Roth***; C. pilosa** *Raf.***; C. platycarpa** *Link***; C. pringlei** *A. Gray***; C. saggitatas** *Hill***; C. tuerckheimii** *H. Senn***)** – rattlebox, cascabelito, chinchin, chiplin de Montana, Chiplin de Monte, cohetillo, espadilla, guache, Trebol Silvestre

Crotalaria verrucosa *L.* **(C. acuminata** *(DC.) G. Don.***; C. angulosa** *Lam.***; C. arnottiana** *Benth.***; C. caerulea** *Jacq.***; C. coerulea** *Beddome***; C. coerulea** *Jacq.***; C. flexuosa** *Moench***; C. hastata** *Steud.***; C. mollis** *Weinm.***; C. paramariboensis** *Miq.***; C. semperflorens** *Vent.***; C. verrucosa var. acuminata** *DC.***; C. verrucosa var. genuina** *Stehle***; C. verrucosa var. obtusa** *DC.***; C. wallichiana** *Wight et Arn.***; Anisanthera hastata** *Raf.***; A. versicolor** *Raf.***; Phaseolus bulai** *Blanco***; Quirosia anceps** *Blanco***)**

Crotalaria spp. – rattlepod, rattlebox

In many parts of Central America [Guatemala, El Salvador, Honduras] young leaves and shoots of C. longirostrata are cooked in various forms and eaten with other food as a soporific. Raw leaves are emetic and purgative; in Guatemala, the root mixed with cornmeal is used as a bait to kill dangerous animals (Morton 1994). In North America, the Delaware-Okl use the root of C. saggitalis as a 'very strong narcotic' (Ott 1993). The Indian C. juncea, which is known as a type of 'hemp', has been said to be smoked as an inebriant (Nadkarni 1976), though this might be a confusion with the drug properties of **Cannabis** ['true' hemp]; C. juncea is primarily used for fibre. C. verrucosa is used by the Karen of n. Thailand as a tonic sedative (Anderson 1993). In Paraguay, C. incana pods [which, when ripe, rattle when shaken] are said to be blessed with the power of speech, and are used as a 'magic' plant to help children to speak properly. Facing the sun at sunset, the child's mother breaks one or more unripe pods in the child's mouth. The pods are then thrown towards the sunset, and the process repeated every day until it has proven effective (Hirschmann et al. 1987).

In TCM, the whole plant of C. mucronata is used to relieve insomnia [with **Ziziphus** spinosa], mental stress, and frequent urination (Huang 1993). In n. Western Australia, C. cunninghamii [C. sturtii] is used by indigenous peoples for fibre, and as a medicine. A leaf decoction relieves sore eyes and headache [externally]; sap from bruised leaves is used to treat earache; and a bark decoction is used as an external wash for swellings (Cribb & Cribb 1981; Lassak & McCarthy 1990). Many species are used as manure and fibre sources (Usher 1974).

Crotalaria spp. are known for their hepatotoxic alkaloids, particularly of the pyrrolizidine-type, and are known to cause stock poisonings (Keeler 1975). The major compound often responsible is the hepatotoxic carcinogen monocrotaline, found in 20% of the genus [which consists of c.600 species], though so far confirmed only in the section Calycinae and subsection Crotalaria, with one occurrence in section Dispermae (Pilbeam et al. 1983).

C. incana unripe pods yielded [w/w] 0.0034% pyrrolizidine bases, and 0.002% reduced N-oxides (Hirschmann et al. 1987).

C. juncea seed was found to produce HCN (Watt & Breyer-Brandwijk 1962); monocrotaline was not detected in seeds [detection limit 0.5%] (Pilbeam et al. 1983).

C. longirostrata has yielded γ-glutamyltyrosine, and traces of α-amino-α-oxalylaminopropionic acid (Morton 1994); monocrotaline was not detected in seeds [detection limit 0.5%] (Pilbeam et al. 1983).

C. mucronata has yielded the alkaloids mucronatine, mucronatinine, nilgirine, retrorsine and usaramine, and the flavonoids vitexin, vitexin-4-O-xyloside and *apigenin* (Huang 1993).

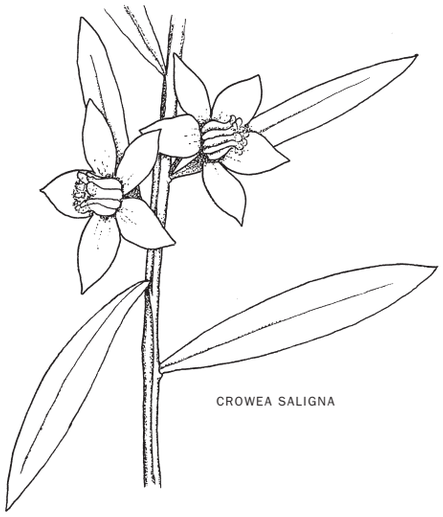
C. saggitalis pods have yielded monocrotaline and monocrotaline N-oxide (International... 1994); one study found no alkaloids in seeds [detection limit 0.5%] (Pilbeam et al. 1983).

Crotalaria saggitalis is an annual or short-lived perennial with a taproot; pubescence spreading-hirsute; stems ascending, 10-50cm tall. Leaves all simple, lanceolate or linear to elliptic, 3-8cm x 8-15mm; stipules usually present, triangular, very narrowly decurrent on stems for c.1/2 the length of the internode. Racemes 2-4-flowered; bracts ovate-lanceolate, slender-stalked; floral cup c.2mm long; calyx gamosepalous, tube often obliquely campanulate, lobes often free and often subequal, with spreading hairs, 1-2mm long, the unequal lobes lanceolate to linear; corolla +- as long as calyx, yellow; banner often with red diffused in the yellow, orbicular to ovate, longer than the wings or keel, external in bud; wings oblong; keel often scythe-shaped, sometimes beaked; stamens 10, monadelphous. Ovary nearly sessile, less commonly short-stiped. Pod oblong, glabrous, 20-35(-40)mm long, c.1cm thick. Fl. Apr.-Sep.

In sandy soils; east half of Texas, west to Parker, Bastrop & Wilson counties; e. & c. U.S. (Correll & Johnston 1970), Mexico, Caribbean, Belize, Costa Rica, El Salvador, Guatemala, Panama, Bolivia, Colombia, Peru and Venezuela (International... 1994).

CROWEA

(Rutaceae)



Crowea angustifolia *Smith* – swamp Crowea, narrowleaf Crowea, pink Crowea, pink stars
Crowea exalata *F. Muell.* – common Crowea
Crowea saligna *Andrews* **(Eriostemon crowei** *F. Muell.***)**

The essential oil from the leaves and terminal branchlets of the Australian shrub C. saligna was first analysed in 1922, after it was observed that the aroma of the crushed leaves suggested the presence of *safrole* (Penfold & Morrison 1922). Although the genus has since seen very little chemical analysis, Crowea spp. appear to be a rich source of interesting phenylpropenes.

C. angustifolia var. angustifolia has yielded an essential oil containing 68% γ-*asarone*, 13% *exalatacin* and 7% *croweacin* (Brophy et al. 1997).

C. exalata has yielded 0.3-1% essential oil. Five chemotypes were found within this species – one dominant in *safrole* [81.88%]; one rich in (E)-*carpacin* [47-51%] and (E)-*methylisoeugenol* [18-25%]; one rich in (E)-*methylisoeugenol* [29-46%], *safrole* [27-35%], and α-*pinene* [12-25%]; one rich in *asaricin* [57-74%] and *safrole* [6-29%]; and one rich in *exalatacin* [30-43%] and *croweacin* [10-20%] (Brophy et al. 1997).

C. saligna [originally analysed as Eriostemon crowei] yielded 0.4% essential oil, containing mostly the new compound *croweacin* [90%], as well as d-α-*pinene*, a sesquiterpene, a paraffin and an unidentified chemical; notably, *safrole* was absent (Penfold & Morrison 1922). However, later research found traces of *safrole* in the essential oil from C. saligna, along with *croweacin* [84-94%] and terpenoids (Brophy et al. 1997). The plant has also yielded croweacic acid (Buckingham et al. ed. 1994). To confuse matters a little, the plants originally analysed by Penfold & Morrison were said to be quite common throughout eastern NSW and some parts of Victoria (Penfold & Morrison 1922). However today, this does not correspond to the range of E. crowei [C. saligna], but does correspond to the range of C. exalata. Index Kewensis equates C. exalata with C. saligna, yet Harden (ed. 1990-1993) describes them as two obviously different members of the same genus!

C. exalata x saligna essential oil was similar in makeup to that from C. saligna, and was also rich in *croweacin* [82%] (Brophy et al. 1997).

Crowea exalata is a shrub to 1m tall; branchlets slender, scarcely angled, slightly hairy, obtusely angled or +- terete. Leaves alternate, oblong-cuneate to spathulate, 1.5-5cm x 1-6mm, apex rounded to obtuse and apiculate, base gradually attenuate, glabrous. Flowers bisexual, terminal or in upper axils on a short axillary shoot with few leaves; pedicel 2-4mm long, fleshy towards apex; sepals 5, free, 2-2.5mm long, slightly hairy to glabrous, finely ciliate; petals 5, imbricate, persistent in fruit, narrow- to broad-ovate, 5-12mm long, pink to pale mauve (sometimes green in fruit); stamens 10, slightly imbricate, sterile apices gradually spreading, free but with contiguous or imbricate filaments, pyramidally arranged and incurved over ovary; carpels 5, basally fused, lacking a sterile apex; styles fused, arising subterminally on carpels; stigma globose; ovules 2 in each carpel. Fruit of 1-5 cocci, cocci +- erect, c.7mm long, with rounded apices, not transversely ribbed; seeds released forcibly from dehiscing cocci, shiny, brown. Fl. sporadically throughout the year.

Widespread in dry sclerophyll forest on sandy soils, south from Deepwater, NSW, through much of eastern NSW, also eastern highlands of Vic. [such as Mt Howitt and Pine Mountain] and the Bendigo area (Costermans 1992; Harden ed. 1990-1993).

CUSCUTA

(Convolvulaceae/Cuscutaceae)

Cuscuta australis *R. Br.* **(C. cordofana** *(Engelm.) Yunck.***; C. hygrophilae** *Pearson***; C. kawakamii** *Hayata***; C. millettii** *Hook. et Arn.***; C. obtusiflora var. australis** *(R. Brown) Engelm.***; C. obtusiflora var. cordofana** *Engelm.***)** – tu szu tzu, tu si zi ['jade woman'], yeh hu sse ['wild fox silk'], Australian dodder

Cuscuta chilensis *Kerl-Gawl* – cabello de angel

Cuscuta chinensis *Lam.* **(C. chinensis** *C. Wright***)** – tu szu zu, tu si zi, yeh hu sse

Cuscuta japonica *Choisy* **(Monogynella japonica** *(Choisy) Hadacβ. et Chrtek.***)** – tu szu tzu, tu si zi, yu nu, yeh hu sse

Cuscuta micrantha *Choisy* – cabello de angel

Cuscuta monogyna *Vahl* **(C. astyla** *Engelm.***; Monogynella monogyna** *(Vahl) Hadacβ. et Chrtek.***)**

Cuscuta reflexa *Roxb.* **(C. gigantea** *Griff.***; Monogynella reflexa** *(Roxb.) Holub***)** – amaravela, akasbel, tukhm-i-kasusa

Cuscuta spp. – dodders, cabello de angel

The dodders are fairly common parasitic plants the world over, and have varied medicinal uses. C. australis, C. chinensis and C. japonica are all used in similar ways in TCM, and share the same Chinese names. The dried, ripe seeds are considered to have pungent, sweet, and neutral properties, with an affinity for the kidneys and liver. Decocted in doses of 7-15g, they are said to be a stimulant and nutritive sexual tonic, used to tonify the kidneys and liver, nourish semen, improve vision, retard ageing, strengthen the urinary tract, strengthen bone and sinew, control diarrhoea and prevent miscarriage. They have been shown to have cardiotonic, hypotensive and uterine-stimulant actions, and also decrease spleen size and inhibit intestinal activity. Prolonged use may retard the healing of open sores, though [especially when given with 'wild yam' – see **Dioscorea**] they are said to give longevity when used for extended periods (Hsu et al. 1986; Keys 1976; Reid 1995). A friend finds that when used regularly, they enhance "perceptions both of the physical and the nonphysical" (Trout pers. comm.). Interestingly, C. australis is reported to have been used as an arrow-poison in Australia (Pammel 1911).

In India, dodder seeds are considered to be purgative, and the plant juice is used to staunch bleeding and reduce inflammation. In Ayurvedic medicine, C. reflexa is said to be aphrodisiac, alterative, tonic, astringent to bowels, acrid and bitter; it is also useful in diseases of the eye and heart, and in treating biliousness (Kirtikar & Basu 1980; Nadkarni 1976). C. europea has strong cathartic properties (Pammel 1911). The Mapuche of Chile have used Cuscuta spp. ['cabello de angel'] as a 'love elixir', as well as to treat inflammatory tumours. Mixed with parsley seed [see **Petroselinum**], they have been used to procure abortion. The only species reported from this area are C. chilensis and C. micrantha (Ruben Garcia et al. 1995).

It is worth noting that in Germany, Cuscuta spp. have been known by various names denoting an association with witches – 'hexengarn' ['witch yarn'], 'hexenhaar' ['witch hair'], 'hexenseide' ['witch silk'] and 'hexenwirbel' ['witch tears']; C. epithymum is known as 'hexenklee' ['witch clover'] (De Vries 1991).

C. americana contains *GABA* (Durand et al. 1962).

C. australis has yielded β-carotene [vitamin A], α-carotene, 6-epoxide, taraxanthin, cuscutin and lutein (Hsu et al. 1986; Reid 1995).

C. chilensis [growing parasitically on **Sophora** macrocarpa] yielded quinolizidine alkaloids derived from its host plant; proportionally, they consisted of 78.61% matrine, 2.98% sophoranol and 1.32% methyl-*cytisine* (Ruben Garcia et al. 1995).

C. chinensis has yielded cuscutin, as well as sugars and a resin (Hsu et al. 1986; Reid 1995).

C. europaea tested positive for the presence of c.0.001% alkaloids (Hultin & Torssell 1965).

C. japonica has yielded vitamin A, cuscutin and sugars (Hsu et al. 1986; Keys 1976; Reid 1995).

C. micrantha [growing parasitically on **Convolvulus** arvensis] yielded 0.1% kaempferol [MAOI (Sloley et al. 2000)] and lesser amounts of kaempferol-3-O-β-glucoside (Ruben Garcia et al. 1995).

C. monogyna is of primary interest because its seeds yielded 0.015% (-)-*agroclavine* (Ikan et al. 1968). However, another investigation, examining seeds of a specimen grown on **Artemisia** maritima [selected due to supporting the most vigorous growth of hosts tested] in a greenhouse in London [it did not produce seed outdoors], found no ergoline or clavine alkaloids (Mantle 1972). It may be likely that the host plant influences the alkaloid content, as with C. chilensis. The host of the specimen analysed by Ikan et al. was not reported.

Alkaloids were detected in the stems of an unidentified Cuscuta sp. in Yarraman, Queensland [Australia], harvested in October (Webb 1949).

Cuscuta monogyna is a herbaceous parasite, usually annual; stems twining, with haustoria. Leaves reduced to minute scales. Flowers 3-4mm, (3-)4-5-merous, small, white, yellowish or reddish, sessile or shortly pedicellate, in spike-like inflorescences of 1-4-flowered cymules; calyx campanulate, 2/3 as long as corolla-tube or equalling it in length; lobes orbicular-ovate, obtuse, overlapping, somewhat carinate and with crenulate margins; corolla lobes ovate, obtuse, crenulate, erect, about ½ as long as tube; corolla tube cylindrical; stamens inserted in throat of corolla tube; hypostaminal scales attached at base of corolla tube, dentate, nearly reaching stamens. Ovary globose-conical, 2-celled, each cell containing 2 anatropous ovules; style 1, in fruit about as long as stigma, free or united; stigmas capitate or elongate. Fruit a circumsessile capsule dehiscing by a line near base, or remaining closed, capped by the detached corolla; seeds 4 or fewer, 3-3.5mm.

Mainly on shrubs and trees; s.e. Europe, extending locally westwards to Portugal (Tutin et al. ed. 1964-1980) and east to Afghanistan, also n. Africa (Mantle 1972).

CYMBOPETALUM

(Annonaceae)

Cymbopetalum penduliflorum *(Sessé et Moçiño ex Dunal) Baill.* **(Unona penduliflora** *Sessé et Moçiño ex Dunal***; Porcelia cinnamonema** *G. Don***)** – xochinacaztli ['flower ear'], teonacaztli ['divine ear'], hueynacaztli ['growing ear' or 'big ear'(?)]

This tree was apparently used by the Aztecs for its aromatic flowers, which were drunk in 'cacao' [see **Theobroma**, also Quararibea in *Endnotes*] or smoked with tobacco [see **Nicotiana**]. As 'teonacaztli' [see also Enterolobium cyclocarpum in *Endnotes*], it was written in the Florentine Codex that "one shouldn't drink much because it comes out in people; it inebriates like the mushrooms", referring to **Psilocybe** mushrooms. The flowers are still used today as a spice in cacao; the fruit has eupeptic and anti-asthmatic properties (Diaz 1979; Ott 1993).

I am not aware of any phytochemical studies of C. penduliflorum, but C. brasiliense bark has yielded quaternary alkaloids [0.572% magnoflorine (see **Magnolia**), 0.286% tembetarine, 0.286% N-methylisocorypalmine, 0.221% colletine], and a mixture of non-quaternary alkaloids [0.13%], including (+)-reticuline, asimilobine, and (-)-norushinsunine. The quaternary alkaloids acted synergistically [the mixture was 5 times more potent than any of the alkaloids alone] to increase contractile force of isolated rat heart, and decrease blood pressure and pulse rate (Cave et al. 1984).

I haven't been able to find the description for this plant, though here are the reference citations -

Cympopetalum penduliflorum – Baill. Adansonia, viii:268 (1868); or as

Unona penduliflora – Monog. Anon., 100, t.28.

CYMBOPOGON

(Gramineae)

Cymbopogon ambiguus *(Steudel) Camus* **(C. exaltatus var. ambiguus** *(Steudel.) Domin***)** – native lemon grass, scented oil grass, aher-aher, rrwengerrweng, herre-herre, yawula, ilintjii, kalpalpi, karrinyarra, minjinpa, ampwer, pajarnpajarnpa, yayirri-yayirri

Cymbopogon densiflorus *(Steud.) Stapf* **(C. stypticus** *(Welw.) Fritsch***; Andropogon densiflorus** *Steud.***; A. schoenanthus var. densiflorus** *(Steud.) Hack.***; A. stypticus** *Welw.***)** – esakuna

Cymbopogon procerus *(R. Br.) Domin.* – wurrunjinbung, kunbong, bu, gabulurr

C. densiflorus, closely related to the common lemon grass [C. citratus], is used in Tanganyika by shamans, who smoke the flowers of the herb either alone or with tobacco [see **Nicotiana**] to induce a dream-like state where divinations may take place. Its aromatic leaves and rhizomes are also used as a tonic, and to control bleeding (De Smet 1996; Schultes & Hofmann 1980, 1992). Macerated together with **Ocimum** americanum, it is used in Zaïre to treat epilepsy (Watt 1967). The Nkopo of Papua New Guinea chew a Cymbopogon sp. ['petaong'] as a stimulant for dancing (Schmid 1991). The Warlpiri of northern Australia have a legend that tells of a wallaby with human form, who is immortal and lives on C. ambiguus. This herb is rubbed on the body and inhaled [sometimes decocted] for colds, chest complaints and other ills. A leaf decoction taken in the evening provoked "an almost continuous stream of vivid nightmares throughout the night" in one ethnobotanist (Latz 1995).

C. ambiguus leaf yielded 1.3% essential oil, which consisted of 47% camphene, 24% *borneol*, 4.3% tricycline, 5.8% α-*pinene*, 8.3% limonene, 2.5% *camphor*, 1% iso-*borneol*, 2.8% α-terpineol, and traces of other constituents (Aboriginal Communities 1988).

C. citratus essential oil may contain 90-95% *citral* (Erickson 1976).

C. densiflorus essential oil has yielded buchu-*camphor*, isopiperitinol, p-mentha-1(7),8-dien-2-ol (Buckingham et al. ed. 1994), cineole,

diosphenol, limonene, ocimene and dihydrotagetone (De Smet 1998).

C. martini essential oil ['palmarosa oil'] is rich in geraniol.

C. nardus and C. winterianus essential oil ['citronella oil'] contains 30-45% geraniol, 40-50% *citronellal* and citronellol (Erickson 1976).

C. procerus leaf yielded 0.4% essential oil; samples from one location contained predominantly *elemicin* [66% of essential oil], as well as 11% trans β-ocimene, 3.6% cis β-ocimene, 6.6% trans caryophyllene, 2.9% *methyleugenol*, 1.5% citronellyl acetate, 1.5% γ-cadinene, and traces of other constituents. A sample from a different area contained 47% camphene and 18% *borneol* as the major constituents, with no *elemicin* or *methyleugenol* (Aboriginal Communities 1988).

Cymbopogon densiflorus is a grass, usually perennial; culms erect, stout, up to 5mm diam. below, up to 8 or more noded, simple below false panicle, terete, smooth, sometimes waxy below nodes, glabrous. Leaf sheaths terete, tight, glabrous, smooth; ligules very short, truncate, glabrous; blades linear to linear-lanceolate, base usually wider and sometimes rounded, apex long and tapering to a fine point, to over 30 x 1.2-2.5cm, glaucous, glabrous, smooth except on upper margins; midrib slender, primary lateral nerves 7-11 on each side, fine, slightly raised. Spatheate panicle very dense or compact, ovoid to oblong or subglobose, 9-15cm or more x 6.3-10.2cm; lowest internodes 2.5-6.4cm long, rapidly decreasing upwards; lowest primary branches undivided at base; rays finely filiform, c.3mm long, glabrous; subtending sheaths with normal but shorter blades; spathes lanceolate, acutely and often finely acuminate, thinly subherbaceous, 7-11mm long, green then turning reddish or brownish; spatheoles similar but scarious, narrower and shorter; peduncles c.3mm long, very slender; racemes 2-nate, slender, olive-green to brownish, 0.5-1cm long, obscurely hairy, one sessile or subsessile, the other with glabrous base; fertile spikelets oblong, subobtuse, c. 2mm long, glabrous; callus very small, obtuse, minutely bearded; glumes subchartaceous, equal, lower subtruncate, back flat, with fine median groove, keels acute or obscurely winged, oil streaks on each side of the groove; upper glumes narrow in profile, acutely keeled above, 1-nerved; lower floret reduced to an oblong obtuse sub-2-nerved sparingly ciliolate valve; upper floret, valve reduced to a subchartaceous very slender stipe, usually without lobes, passing gradually into a fine bristle, including it c.3.5mm long; anthers c.1mm long; pedicelled spikelets neuter, lanceolate to lanceolate-oblong, c.1.5mm long; lower glume subherbaceous with 3-5 intracarinal nerves; upper membranous, white, 1- to sub-3-nerved; florets usually quite suppressed.

Fairly common in meadows, thickets and dry savannahs; lower Guinea, Gabon, Congo, Angola, Mozambique, Malawi (Prain ed. 1934).

CYPERUS, including BALANSIA endophytes

(Cyperaceae)

Cyperus articulatus *L.* **(C. corymbosus** *Rottb.***; C. diphyllus** *Retz.***; C. niloticus** *Forssk.***; C. nodosus** *Humb. et Bonpl. ex Willd.***; C. subnodosus** *Nees et Meyen***)** – waiyo duri, intiash piripiri, napi piripiri, cu nuni, nuni, piripiri yaca, mandassi

Cyperus digitatus *Roxb.* **(C. bourgaei** *C.B. Clarke ex Lundell***; C. mexicanus** *Liebm.***)** – chicorro

Cyperus fastigiatus *Rottb.* – mothoto

Cyperus odoratus *L.* – piripiri

Cyperus prolixus *Kunth* **(C. amplissimus** *Steud.***; C. jubaeflorus** *Rudge***)** – nuni, ta-dexka pona manise-ko, huhu diri, huhu nuni, hududi, saida nyame dudi, na'nyame dudi, na'nyame nuni ['rainbow nuni'], uchi achitiai maikiua, chicorro, piripiri yaca

Cyperus rotundus *L.* **(C. bicolor** *Vahl***; C. maritimus** *Bojer***)** – nutgrass, suad, yelka, thiang fowtse, tsin, hsiang fu, so t'sao, mustaka, muthanga, bhadramustra, junica redunda

Cyperus sp. – shako shayari, shako shejeti, anubedsetetseperi, piripiri, piripiri de brujo ['piripiri of the witch'], napi piripiri ['snake piripiri'], nuni, chicuro, chondoy, chondur, huaste, pijipíg

Cyperus spp. – sedge grass, ivenkiki

(Clavicipitaceae)

Balansia claviceps *Spegazzini* – black crust, inflorescence blight

Balansia cyperi *Edgerton*

Balansia epichloë *(Weese) Diehl*

These sedges, related to the original 'paper plant' [C. papyrus], are often infected with Balansia spp. endophytic fungi, and as such are used ritually and medicinally in Amazonia, often collectively referred to as 'piripiri' in Ecuador. In some villages, the infected sedges are cultivated in communal gardens (Plowman et al. 1990). The Jivaro of e. Ecuador attribute 'hallucinogenic' properties to these plants (Lipp 1995). Their bulbous roots are prepared in water and drunk by the Yagua of Peru for shamanic intiation, and to contact the spirit of the plant (Luna & Amaringo 1991). Shuar and Aguaruna shamans also sometimes consume a root tea for the same purposes as ayahuasca [see **Banisteriopsis**], and recognise a variety of endophyte-infected strains of C. articulatus, C. odoratus and C. prolixus, as do other groups [see below] (Bennett 1992).

The Sharanahua of the Peruvian Amazon add powdered rhizomes of a Cyperus sp. known as 'shako shayari' [probably C. digitatus or C. prolixus] to their ayahuasca brews. The Culina use a similar species, as 'anubedsetetseperi', when hunting peccaries (Pinkley 1969; Rivier & Lindgren 1972; Schultes 1972). In Peru, leaves of C. prolixus infected with B. cyperi are added to ayahuasca, and the dried rhizomes are sometimes mixed with tobacco [see **Nicotiana**] and smoked for an entheogenic effect (Plowman et al. 1990). C. digitatus may be smoked in the same way [Trout ed. 1998 notes that this information was referenced by various authors to Luna 1984, though I could find no mention of this in Luna's paper]. In Venezuela, a rhizome infusion of C. articulatus is given to children to increase their intelligence. C. articulatus has been used there [and also in Africa] to treat headaches, epilepsy, stomach ache, constipation, respiratory infections, rheumatism, oedema, problems in ovulation, and as an aphrodisiac. In Africa, the root powder is applied externally for such purposes (Bum et al. 1996; Plowman et al. 1990). This species is said to have 'intoxicating' properties (Lipp 1995).

The Yanomamo of Venezuela recognise a large variety of endophyte-infected Cyperus spp., which they cultivate and use for specific purposes. Many are used as hunting charms, the tubers heated and attached to arrows to ensure accuracy. Different cultivars are used, depending on the type of animal that is being hunted. Others are used as aphrodisiacs, stimulants, and contraceptives, amongst other uses, but the Yanomamo also know a cultivar that can kill. Piripiri varieties are used to treat fright, anger, diarrhoea, snakebites, and to counter witchcraft; they generally act as stimulants. The most widespread use is to procure abortion, due to the uterotonic action of the endophytes; piripiri is also enlisted to treat postpartum haemorrhage [due to its vaso-constrictive effects], hasten impending birth, or as a contraceptive (Lizot 1985; Plowman et al. 1990).

In Peru, a Cyperus sp. known as 'caballo piripiri' ['horse piripiri'] is mixed with Genipa americana, and the preparation poured over the body to gain strength. For this purpose, the mixture must be left on the body for at least 8 days, and the user must avoid the sun, salt, sugar, garlic, alcohol, pig fat, sex, and association with those who have been having sexual activity (Luna & Amaringo 1991). Most commonly, piripiri is prepared by grating the rhizome and infusing it in cold water; the liquid is either drunk or applied to the body as a wash (Plowman et al. 1990).

The Machiguenga of Peru know Cyperus spp. as 'ivenkiki', and like the Yanomamo, they cultivate a large variety of endophyte-infected Cyperus spp. for specific purposes. Each type of game animal has a corresponding ivenkiki cultivar, the tuber of which is chewed by male hunters when that animal is to be hunted. In the case of fishing, some of the chewed tuber may also be spat into the water, "to mesmerise the fish and focus the hunter's attention." Machiguenga women also cultivate their own Cyperus spp., used "to improve their concentration and skill spinning and weaving". Other uses for particular cultivars include treating headaches, fevers, diarrhoea, cuts, haemorrhage in childbirth, insanity, and for inciting bravery, defending babies against harmful spirits and rubbing on the hands when planting certain crops ["to make them more hardy"]. In his time with the Machiguenga, Glen Shepard Jr (1997), normally clumsy by his own admission, was temporarily able to skilfully juggle grapefruits after consuming a Cyperus sp. intended to treat his headache [which it did, incidentally] (Russo undated; Shepard 1997)!

The Chinese consider the rhizome of C. rotundus to be a tonic stimulant, properties for which it is also esteemed in Ayurvedic medicine [as well as for being an anthelmintic, diuretic, demulcent, stomachic, astringent, and vermifuge]. In Ayurveda, it is regarded as a 'jeeyanya' ['life promoter'], and is an ingredient of the Ayurvedic herbal preparation 'brahmighritham', used to control epilepsy. In Indian Unani medicine, it is reputed to improve memory and treat chronic fever, palpitations and anorexia. Tubers of the Indian C. inundatus and C. iria are also used as tonic stimulants (Nadkarni 1976; Shanmugasundaram et al. 1991). In Nepal, C. esculentus seeds ['kaancho laae' - see also **Scirpus**] may be used in ritual incense, but not by the Kirati (Müller-Ebeling et al. 2002). In southern Africa, the Basuto have been reported to use C. fastigiatus ['mothoto'] as an ingredient of a compound drug ['sehoere'] consumed in intoxicating ritual feasts [see *Methods of Ingestion*] (Laydevant 1932).

The pharmacology of the Amazonian endophyte-infected Cyperus spp. appears to be largely due to the chemical compounds produced by the endophytes in question. As many of the cultivars in use appear to be similar or identical botanically, their individualised applications are probably related to selected strains of the endophytes, that have been shown over time to produce the desired effects. These chemicals are mostly indoles similar or identical to those found in **Claviceps** ['ergot'] and **Ipomoea** ['morning glory'], for example.

B. claviceps has yielded the ergot-alkaloids *ergonovine*, ergonovinine and *chanoclavine I* (Bacon 1985; Bacon et al. 1986; Porter et al. 1978). In liquid culture, one strain of B. claviceps [219] produced 170.25mg of alkaloids per litre, consisting of *ergonovine*, ergonovinine, and *chanoclavine I*, whilst another [266] did not produce alkaloids. Both strains were orig-

inally growing on the same host species, Chasmanthium laxum (Bacon et al. 1979).

B. cyperi has yielded the ergot-type petides ergobalansine and ergobalansinine, as well as unidentified ergot-alkaloids [see **Claviceps**] (Buckingham et al. ed. 1994; Plowman et al. 1990; Powell et al. 1990).

B. epichloë, which has been implicated in stock intoxications similar to those caused by **Claviceps**, has yielded the ergot-alkaloids *agroclavine*, *elymoclavine*, *ergonovine*, ergonovinine, *penniclavine*, *chanoclavine I*, isochanoclavine I, 6,7-seco-*agroclavine*; as well as other indoles – indoleacetamide, indoleethanol, indoleacetic acid, threo-1-(3-indolyl)propane-1,2,3-triol, erythro-1-(3-indolyl)propane-1,2,3-triol, 3-(3,3-diindolyl)propane-1,2-diol, 4-(3-indolyl)butane-1,2,3-triol and 3-(3-indolyl)propane-1,2,3-triol (Bacon 1985; Bacon et al. 1975, 1986; Buckingham et al. ed. 1994; Porter et al. 1977, 1978). 'Smutgrass' [Sporobolus poiretii] parasitised by this species yielded 0.0017% alkaloids, consisting mostly of *chanoclavine I*, followed by *ergonovine*. In liquid culture, this strain of B. epichloë produced 390mg of alkaloids per litre, consisting of *ergonovine*, ergonovinine, *agroclavine* and *chanoclavine I* (Bacon et al. 1979).

B. henningsiana and B. strangulans in liquid culture produced 6.95mg and 85-158mg of alkaloids per litre, respectively; both produced only *chanoclavine I* (Bacon et al. 1979). The former species has been found on Panicum anceps (Bacon et al. 1979), P. agrostoides (Mogen et al. 1991), Andropogon spp. and Eragrostis spp. as host grasses (Bacon et al. 1975).

C. articulatus has yielded α-corymbolol, mandassidione and muskatone (Buckingham et al. ed. 1994). Extracts from rhizomes collected in Cameroon inhibited binding to the NMDA and *glycine* receptors in rats (Bum et al. 1996); a rhizome decoction [which was shown to contain flavonoids, saponins, terpenes, tannins and sugars] showed sedative activity in mice (Rakotonirinaa et al. 2001).

C. rotundus [whole plant] has tested positive for HCN (Watt & Breyer-Brandwijk 1962); it has has yielded cyperol, isocyperol, α-cyperone, *pinene*, cineole, *camphor*, glucose, fructose, and a eudalene-group sesquiterpene (Schermerhorn et al. ed. 1957-1974), as well as [w/w] 0.0091% octopamine; octopamine [0.0017%] and *tyramine* [0.001%] are also found in C. papyrus (Wheaton & Stewart 1970).

Balansia spp. – sclerotium composite, formed of the affected parts of the host embedded in a well-developed mass of fungal tissue; stroma arising from, not growing from, the sclerotium (true sclerotia with thick rinds are not formed), erect, large, stipitate and capitate or sessile, pulvinate, obovate, discoid, or separated from the sclerotium as soon as the latter is mature, stroma with distinct sterile and fertile portions, the latter often knob-like, surface lightly papillate from the projecting ostiola of the immersed scattered perithecia; asci 8-spored; spores continuous; paraphyses none; conidia, when known, an ephelis and preceeding the stroma (Sprague 1950; Stevens 1913).

Balansia claviceps produces a soft stroma on the inflorescence of the host grass, and does not produce sclerotia; spikes and rachis somewhat stunted, rachis thickened; stromata white inside, dark to black outside, hemispherical or globose, arising from spikelets, 1.5-3mm diam., stipe 1.5-3mm long, 1-1.5mm thick; perithecia subcortical in cap of stromata, densely grouped, distinctly obovate, 200-220 x 120-140μ, perforate ostiole; asci cylindrical, apices rounded, truncate, bases moderately attenuate, briefly rounded, 150-160 x 5-6μ, without paraphyses, 8-spored; ascospores filiform, fascicled, 0.6-0.8μ across, transversely septate, hyaline; conidia an ephelis.

Also infects Cenchrus echinatus, Setaria spp., Pennisetum spp.; tropics (Sprague 1950; White et al. 1995).

Balansia cyperi occurs on the surface of meristematic rhizome tissue and meristems (not growing internally), on young leaves, in the gap between the leaves in the whorl, and on aborted inflorescences as stroma, bearing abundant conidial frutifications (and, more rarely, ascostromata). Some aborted inflorescences have been observed to themselves produce miniature plantlets, which themselves would flower and produce miniature aborted inflorescences. Mycelium particularly abundant on rhizomes. Hyphae tightly packed only at very base of gap between leaves, extending upwards in loosely woven net, hyaline, thin-walled, c.2μ diam.; widely scattered patches of disarticulated and apparently senescent mycelium on surface of older leaves; mycelium proliferates around young, developing inflorescences, abundant mycelium filling all spaces between different parts of young spikes – the spike may continue to develop until initial signs of ovules appear – finally the fungal stroma completely enclose the culm apex; on stroma surface, a continuous palisade of ephelis conidiophores is formed.

Infects Cyperus spp. such as C. articulatus, C. pseudovegetus, C. rotundus, C. surinamensis and C. virens. C. rotundus uninfected by B. cyperi is usually infected by Rhizoctonia solani on the leaves (Clay 1988; Leuchtmann & Clay 1988; Plowman et al. 1990; Stovall & Clay 1991).

Balansia epichloë produces stroma on the upper leaf surface; mycelium grows intercellularly in leaf and culm tissues, as well as in pith; hyphae grow between host cells; in leaf sheaths hyphae are relatively straight.

Infects 'smutgrass' [Sporobolus poiretii], Andropogon scoparius and other Andropogon spp. [see **Cymbopogon**], Agrostis alba, Calamagrostis spp., Chasmanthium laxam, Chloris spp., Ctenium aromaticum, Eragrostis spp., Gymnopogon ambiguus, Oryzopris asperifiloa, Panicum spp., Thrasya petrosa and Triodia flava (Bacon et al. 1986; Leuchtmann & Clay 1988).

Cyperus spp. infected with Balansia spp. seem to be more vigorous than uninfected plants. Also, the same species of Balansia may produce different chemicals, or none, on a different host species (Bacon et al. 1986).

Cyperus prolixus is a perennial herb; rhizome horizontal, thick and hard, knotty, thickly fibrillose. Culms 90-150cm high, robust, obtuse triangular, smooth, base porous-thickened, lower bearing many leaves. Leaves equalling or exceeding culms, glaucous, 8-20mm wide, quite long, acuminate, margin keeled, scabrous, strongly septate-nodulose, sheath brownish and lucid. Bracts 6-10, exceeding anthelae. Anthela loose, large, radiating in many directions, rays rigid compressed-triangular, suberect, strongly inequal continuously to 30cm high, arising from prophylls, long, tubulose, brownish-green, in front truncate, at back long-bicuspidate. Anthelulae arranged bracteoles 6-8, short, mostly equal length, to 4mm wide, shortly setaceous, subtended, setaceous, suberect, firm, compressed, to 12cm long. Spikes densly multispiculose, outline oblong-elliptic; spikelets suberect, linear or linear-lanceolate, acute, 15-20mm long, 1½-2mm wide, compressed, 10-14-flowered; rachilla tenerrima flexuose, high, wings lanceolate, soon deciduous; scales scattered, when fruiting apex spreading, oblong-elliptic, obtuse, often shortly mucronate, 4mm long, green-keeled, dingy straw-yellow, 5-7-nerved, secondary nerves rusty-lineolate, margin enveloping, soon falling; stamens 3; anthers linear, apex white-setose. Style long, slender, deeply trifid; stigma strongly exserted, nearly tufted. Nut nearly equalling scales, narrowly oblong, thickened at angles, dark brown, shiny, densely punctulate, shortly apiculate.

Mexico to tropical S. America (Engler 1936).

CYPHANTHERA

(Solanaceae)

Cyphanthera albicans *(Cunn.) Miers* **ssp. albicans (C. ovalifolia** *Miers***)** – grey ray flower
Cyphanthera albicans ssp. notabilis *Haegi* **(Anthocercis albicans** *Cunn. sensu Maiden et Betche***)**
Cyphanthera anthocercidea *(F. Muell.) Haegi* **(A. anthocercidea** *(F. Muell.) Druce***; Eadisia anthocercidea** *F. Muell.***)**
Cyphanthera microphylla *Miers* **(A. microphylla** *F. Muell.***)**
Cyphanthera myosotidea *(F. Muell.) Haegi* **(A. amblyantha** *F. Muell.***; A. myosotidea** *F. Muell.***)**
Cyphanthera odgersii *(F. Muell.) Haegi* **(Anthocercis odgersii** *F. Muell.***)**
Cyphanthera odgersii ssp. occidentalis *Haegi*
Cyphanthera racemosa *(F. Muell.) Haegi* **(A. racemosa** *F. Muell.***)**
Cyphanthera scabrella *(Benth.) Miers* **(A. scabrella** *Benth.***)**
Cyphanthera tasmanica *Miers*

These Australian plants are known to produce hallucinogenic tropane alkaloids, and have no known native use. Although C. myosotidea was claimed to be "the only likely candidate" for the botanical identity of "an intoxicating root [...] used by some South Australian Aborigines", there is no evidence that it was the plant used (Peterson 1979).

All parts tested from the species below were collected in September, except for C. odgersii ssp. odgersii [Aug.] and C. tasmanica [May].

C. albicans ssp. albicans aerial parts yielded 0.05% alkaloids, consisting of *hyoscyamine*, *hyoscine*, their apo-derivatives, valtropine, valeroidine, 3-α-acetoxytropane, 3-α-isobutyryloxytropane, 3-α-isobutyryloxytropan-6-β-ol and tigloyl esters; roots yielded similar constituents, as well as 6-OH-*hyoscyamine*.

C. albicans ssp. notabilis stem bark yielded 0.01% alkaloids, most of which was *hyoscine*, with lesser amounts of *hyoscyamine*, their apo-derivatives, and tropine; leaves yielded 0.02% alkaloids of similar constituency to C. albicans ssp. albicans; roots yielded 0.07% alkaloids.

C. anthocercidea stem bark yielded 0.025% alkaloids, mostly *hyoscine*, as well as apo-*hyoscine* and an unidentified base; leaves yielded 0.21% alkaloids, mostly *nicotine*, with lesser amounts of *hyoscyamine*, *hyoscine*, their nor-derivatives, *anabasine* and tropine; roots yielded 0.07% alkaloids, mostly *hyoscine*, with less *hyoscyamine*, their apo-derivatives, *nicotine* and an unidentified pyridine derivative.

C. microphylla aerial parts yielded less than 0.01% alkaloids, which consisted of *hyoscyamine*, apo-*hyoscyamine* and unidentified bases.

C. myosotidea aerial parts yielded 0.11% alkaloids, most of which was *hyoscine*, as well as *hyoscyamine*, their apo- and nor-derivatives, 6-OH-*hyoscyamine*, scopine, tigloyl esters, and possibly 6,7-dihydroxy-3-phenylacetoxynortropane (Evans & Ramsey 1983).

C. odgersii ssp. odgersii aerial parts yielded 0.08% alkaloids, mostly *hyoscine*, as well as *hyoscyamine*, nor-*hyoscyamine*, apo-*hyoscine*, apo-*atropine*, 6-β-OH-*hyoscyamine* and tropine (El Imam & Evans 1984; Evans & Ramsey 1983).

C. odgersii ssp. occidentalis aerial parts yielded 0.1% alkaloids, mostly *hyoscine*, as well as *hyoscyamine*, their apo-derivatives, 6-OH-*hyoscyamine* and tetramethylputrescine.

C. racemosa aerial parts yielded 0.01% alkaloids, consisting of *nornicotine*, *anabasine* and an unidentified base; roots were alkaloid free to the limits of detection.

C. scabrella aerial parts yielded 0.06% alkaloids, mostly *hyoscine*, as well as apo-*hyoscine*, and possibly *hyoscyamine* and valeroidine (Evans & Ramsey 1983).

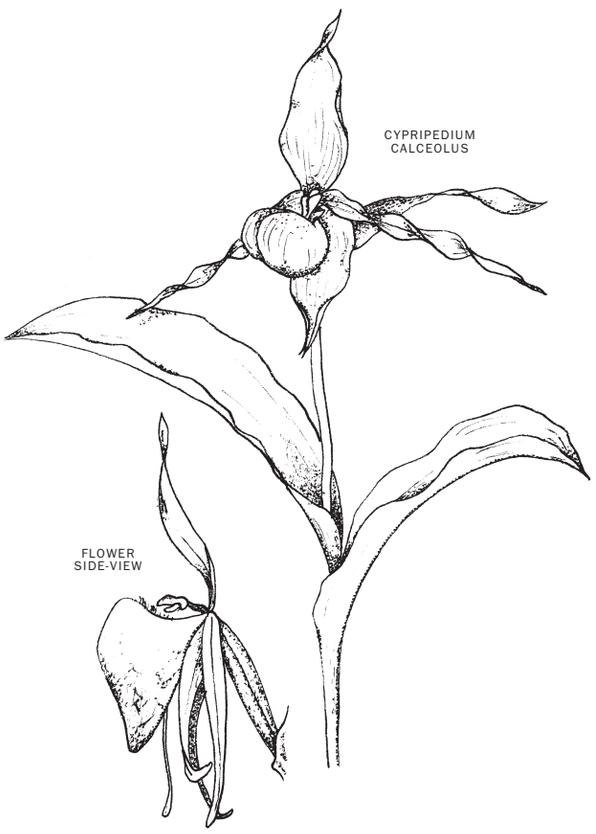
C. tasmanica aerial parts yielded 0.17% alkaloids, mostly *nicotine*, followed by *hyoscine*, as well as *hyoscyamine*/*atropine*, tropine, meteloidine and tigloidine; roots yielded 0.16% alkaloids, mostly *nicotine*, followed by *hyoscine*, as well as *hyoscyamine*/*atropine*, tropine, tigloidine and valeroidine (El Imam & Evans 1984)

Cyphanthera anthocercidea is an erect shrub to 2m tall; branches moderately tomentose. Leaves alternate, ovate to narrowly ovate, rarely ovate-elliptic, margins flat, sessile or almost so, 8-35 x 2-10mm, sparsely pubescent, midrib not indented above; young leaves up to 11 x 4cm, petioles to 15mm long. Inflorescence leafy, dense, and panicle-like, terminal or lateral; pedicels 2.5-6.5mm long, sparsely pubescent; calyx 3-4mm long, glabrous or almost so, campanulate to cupular, 5-lobed; corolla 10-14.5mm long, funnel-shaped to campanulate with spreading limb, almost glabrous, white, with purple striations in tube, limb 5-lobed, lobes ovate-truncate to linear, 4-5.5(-9)mm long, volutive in bud; stamens 4, inserted at base of corolla tube, 2-4mm long; staminode sometimes present; anthers unilocular, dehiscing by terminal, semicircular slit. Ovary bilocular; stigma capitate, very shortly bilobed. Fruit a smooth capsule, +- globose, 4-5mm diam., opening from apex by 4 valves, partially enclosed by calyx; seeds subreniform, 2.4-3.5mm long.

In rocky gullies of dry sclerophyll forest, also in sandstone-derived soil on exposed rocky spurs in shrubland; mainly in Wimmera region of Victoria (Haegi et al. 1982).

CYPRIPEDIUM

(Orchidaceae)



Cypripedium acaule *Aiton* **(C. humile** *Salisb.***; Fissipes acaulis** *(Aiton) Small***)** – stemless lady's slipper, low lady's slipper

Cypripedium arietinum *R. Br.* **(Criosanthes arietina** *(R. Br.) House***)** – ram's head lady's slipper

Cypripedium bulbosum *L.* **(Calypso borealis** *Salisb.***; C. bulbosa** *(L.) Oakes***)** – bulbous lady's slipper

Cypripedium calceolus *L.* **(C. parviflorum** *Salisb.***; C. pubescens** *Willd.***; Calceolus parviflorus** *(Salisb.) Nieuwl.***)** – yellow lady's slipper, moccasin flower, patridge moccasin, American valerian, nerve root, umbel

Cypripedium candidum *Muhl. ex Willd.* – small white lady's slipper, white-flowered lady's slipper

Cypripedium spectabile *Salisb.* – showy lady's slipper

The generic name and common name of these herbs are intertwined to some degree, with the 'lady' of the lady's slipper being Aphrodite, the Cypriot (theobromus pers. comm.). Some of these North American orchids are used by native groups as medicaments and intoxicants. The Meswaki used C. acaule root in love charms. The Menomini consume C. acaule as a nervine, and they use sacred bundles of C. calceolus to induce a shamanic dream-state. The Cherokee used C. calceolus and C. acaule in the form of a root tea to treat nerve problems, neuralgia, spasms, mania, pain, diabetes, colds, stomach ache and worms. In the 19th century, the dried rhizome of C. calceolus [and sometimes C. borealis] was used as an alcoholic tincture in Europe and N. America, primarily to treat menstrual disorders; the flower parts are thought by some to be representative of female genitalia, and the plant reputedly has aphrodisiac properties. The tincture was also used to treat nervous irritability, depression, insomnia and delirium. A syrup preparation was also given to restless children (Emboden 1979a; Felter & Lloyd 1898; Hamel & Chiltoskey 1975; Hutchens 1973; Lawler 1984; Ott 1993). Combined with equal parts of **Scutellaria** lateriflora and **Nepeta** cataria, C. calceolus roots have been decocted and used as an effective headache remedy (Felter & Lloyd 1898). The Indian C. elegans has been used for nervous disorders, as has C. luteum by native N. Americans. Leaves and roots of C. guttatum have been used to treat epilepsy in Siberia and e. Russia (Lawler 1984).

It is advisable to cultivate Cypripedium spp., as many species are rare in the wild. The roots, including rootlets, are harvested in autumn, cleaned free of dirt and carefully shade-dried. Although decoction in boiling water will extract some of the properties of the herb, extraction is best achieved with preparation of a simple alcoholic tincture, which is usually taken in a dose of c.6-20ml [concentration not noted]. The properties of all species are relatively mild, but synergise effectively with some other herbs, such as **Eupatorium** aromatica and **Scutellaria** lateriflora. All of the species listed above share similar properties, though C. acaule and C. spectabile are reputed to be more potent, particularly when found growing in dark swamps. Cypripedium spp. are said to give "a more calm and cheerful condition of the body and mind [...] consequently favouring mental tranquillity, or sleep" (Felter & Lloyd 1898; Hutchens 1973). However, handling the leaves of some species may result in 'poison ivy'-like dermatitis [see **Rhus**] (Lawler 1984).

C. calceolus has yielded the quinone cypripedin, which has been shown to cause allergic skin lesions in guinea pigs (Schmalle & Hausen 1979). A compound that has been referred to as 'cypripedin' [not the same as the aforementioned quinone] may be prepared by the addition of water to a strong alcoholic tincture of the roots, and collecting the precipitate (Grieve 1931). One psychonaut followed this procedure, drying out the precipitate to leave a powdery resinous residue. This 'cypripedin' acted as a strong sedative if eaten, but did not result in any noticeable effects when smoked, except that the psychonaut became immune to the effects of **Cannabis** for the next 3 days (theobromus pers. comm.)! Contact with the leaves and stems of Cypripedium spp. has been known to cause dermatitis, due to the glandular hairs that cover them (Felter & Lloyd 1898; theobromus pers. comm.).

In a screening for alkaloids in orchids, C. acaule, C. calceolus and C. macranthon gave negative results (Lüning 1967).

Cypripedium calceolus is a perennial herb growing from coarsely fibrous roots; stem erect, leafy, 20-80cm tall, bearing 2 or more ample leaves. Leaves +- sheathing, oval to ovate-lanceolate, 6-20cm long, about ½ as wide. Flowers 1-2, each subtended by an erect foliaceous bract; sepals (3) and petals (3) greenish-yellow to purplish-brown, ovate to linear, acute to acuminate, widely spreading; 2 lower sepals connate into 1, narrower than upper sepals, 2-toothed at apex; upper sepal ovate to ovate-lanceolate, 3-8cm long; lateral petals lanceolate, 3-8cm long, usually twisted; lip a large inflated pouch, margins +- inrolled around orifice, yellow, not cleft, usually +- veined with purple, 2-6cm long; column declined over orifice of the lip, bearing a fertile stamen on each side and a dilated staminode above; anthers 2. Ovary inferior, 1-celled; stamens 1-2, united with style and with prolongation of the central axis to form a central column bearing the stigma on its anterior face near base and anthers on its side, back or summit. Fruit a 3-valved capsule, containing many minute seeds.

In bogs and moist woods; widely distributed in Eurasia and N. America [Newfoundland to n.w. Canada, south to S. Carolina, Louisiana and New Mexico]. North American plants are represented by C. calceolus var. pubescens (Gleason 1952). Cultivate in soil with plenty of decayed leaves; can be propagated by division. Likes shade to full sun, winter min. 4°C, but doesn't grow in subtropical/tropical climates (Banks & Perkins 2005).

CYTISUS, GENISTA and SPARTIUM

(Leguminosae/Fabaceae)

Cytisus canariensis *(L.) Steud.* **(C. monspessulanus** *L.***; Genista canariensis** *L.***; G. monspessulana** *(L.) L.A.S. Johnson***; G. monspessulana** *(L.) Bolos et Vigo***; Teline monspessulana** *(L.) K. Koch***)** – Canary Island broom, canary broom, Cape broom, Montpellier broom, French broom, soft broom

Cytisus racemosus *Hort.-Cf. Marnock*

Cytisus scoparius *(L.) Link* **(Genista scoparia** *Lam.***; Sarothamnus scoparius** *(L.) W.D.J. Koch***; Spartium scoparium** *L.***)** – Scotch broom, common broom, yellow broom, giesta, retama de escobas

Cytisus spp. – brooms

Genista linifolia *L.* **(Cytisus linifolius** *Lam.***; Teline linifolia** *(L.) Webb et Berth.***)** – flax-leaved broom

Genista tinctoria *L.* – dyer's broom, dyer's greenweed

Spartium junceum *L.* **(Genista juncea** *Scop.***; G. odorata** *Moench***; Spartianthus junceus** *Link.***)** – Spanish broom, weaver's broom, retama, ginestra

The complex group of 'brooms', which are common weeds and garden plants in many parts of the world, attracted attention from people like ourselves when it was discovered that C. canariensis, an introduced plant to Mexico, was being smoked by at least one Yaqui shaman as a shamanic inebriant. The shaman interviewed in the original study claimed that he was instructed to smoke the flowers by a 'plant teacher' whilst in a trance. The flowers were prepared by ageing them for 10 days packed in a sterile, sealed glass jar, before being dried and smoked. During this ageing process, the flowers were not allowed to ferment or become mouldy, yet I have found it difficult to prevent such decompositions. Yaqui shamans may also prepare a drink from the seed capsules to facilitate divination, healing and time travel (Emboden 1979a; Fadiman 1965; Rätsch 1992; Schultes 1966). In Ecuador, dried flowers of S. junceum are smoked to treat asthma, and the root is infused to procure abortion (Schultes & Raffauf 1990). In Tuscany, Italy, stems of the wild plant are burned on Christmas eve to prevent the 'evil eye' and bring good omens (Pieroni & Giusti 2002).

Brooms get their collective name from the fact that they have been used to make brooms, due to their strong and flexible branches. In mediaeval times, the flowering plants were sometimes featured in heraldry. At one time, broom seeds were used as a coffee substitute [see **Coffea**], and the flowers pickled in wine. Perhaps more important was the widespread European use of young, green flowering tops [or occasionally the seeds] in beer brewing [see *Methods of Ingestion*], to render the drink more bitter and intoxicating. In European folk medicine, the flowers have been decocted as an aphrodisiac, and used to make a dye. The herbage was utilised in tanning leather, due to its tannin content. Medicinally, the plants have been used to treat heart, kidney and bladder problems, as well as rheumatism. The actions of the herb on the body in low doses are diuretic, purgative and weakly cardioactive; in moderate doses, they are 'narcotic', causing 'inebriation, staggering gait, and impaired vision', first with excitation, and later stupefaction; higher doses cause GI pain, diarrhoea, vomiting, sweating, and if unlucky, death by asphyxiation (Bremness 1988, 1994; Buhner 1998; Chopra et al. 1965; Rätsch 1992; Turner & Szczawinski 1991). C. proliferus is intoxicating to horses when fruiting, and C. scoparius has been toxic to sheep (Watt & Breyer-Brandwijk 1962).

Experiments have been carried out to examine the effects of the prepared, dried flowers when smoked. Subjective effects noted consisted of relaxation and a feeling of well-being; when more than one cigarette was smoked by subjects, a greater level of arousal was experienced, accompanied by mental clarity, and in some cases, greater appreciation of colour and contrast; some subjects also noted closed-eye imagery. C. canariensis was said to be the most pleasant and effective, with C. scoparius and S. junceum being less effective (Fadiman 1965). In my own experience, C. canariensis [as C. monspessulanus], C. racemosus and G. linifolia were +- equal in their mild effects.

The activity of the brooms is usually thought to be solely attributable to their *cytisine* content. However, as well as the other alkaloids, non-alkaloidal constituents such as flavonoids may also possibly contribute to overall activity.

In general, brooms contain quinolizidine alkaloids, such as *cytisine*, N-methylcytisine, sparteine, lupanine, anagyrine and many others. They should only be taken internally with caution due to their toxic nature. Sparteine, for example, has a similar action to *coniine* [see **Conium**], but is less toxic, and has little psychotropic activity, apart from CNS depression; it can paralyse motor nerves and sympathetic ganglia, as well as depressing the heart in large doses. Smaller doses stimulate heart action [see also **Lupinus**, **Sophora**] (Buhner 1998; Henry 1939; Nucifora & Malone 1971; Schmeller et al. 1994). Genistein, a flavonoid commonly found in Fabaceous legumes, has shown MAOI properties (Hatano et al. 1991), and is oestrogenic (Harborne & Baxter ed. 1993).

C. canariensis has been found to contain *cytisine*, N-methylcytisine, sparteine, lupanine, anagyrine, and other alkaloids (Harborne et al. ed. 1971; International... 1994).

C. proliferus seeds yielded 0.55% alkaloids, containing c.10% dl-calycotomine [6,7-dimethoxy-1-OH-methyl-THIQ], as well as other alkaloids, including sparteine (White 1957).

C. scoparius seeds yielded 0.5-0.6% alkaloids, including lupanine as a major component, as well as hydroxylupanine and traces of sparteine (White 1957). Flowers have yielded 2% amines, such as L-*DOPA*, *dopamine*, *tyramine* and epinine; branches have yielded 0.5-1% alkaloids, c.60% of which was sparteine, as well as 17-oxo-sparteine and lupanine; the plant has also been shown to yield the tetrahydroisoquinoline salsolidine [6,7-dimethoxy-1-methyl-THIQ; MAOI (Bembenek et al. 1990)]. Terpenoids, and flavonoids such as chrysin [MAOI (Sloley et al. 2000); see **Passiflora**], genistein, quercetin and vitexin are also found, particularly in the flowers. Alkaloid concentration reaches a maximum in winter (Bruneton 1995; Harborne et al. ed. 1971; Henry 1939; International… 1994; Smith 1975; Watt & Breyer-Brandwijk 1962). Seed alkaloid content was found to be highest [over 1%] in March; the seeds are generally the most concentrated in alkaloids (Chopra et al. 1965).

G. linifolia seeds have yielded c.1% *cytisine*; pods yielded 0.08% *cytisine*. Stems and leaves yielded 1.2-1.3% alkaloids in Feb., 0.64% alkaloids in May, 0.99% in Jul.; stems and leaves separately [harv. May] yielded 0.81% and 1.24% alkaloids, respectively. This consisted of c.70% anagyrine (White 1944b).

S. junceum has been reported to contain sparteine in flowers [c.0.22%] and the rest of the plant [c.0.02%]. However, plants growing in New Zealand were found to contain no sparteine above the detection limit [0.02%] in tops, young shoots, petals, stamens, and seeds; instead, *cytisine* was found in stems and leaves [0.09%], petals [0.29%], other flower parts combined [0.36%], and seeds [1.24%]. This species is regarded as being more potent than C. scoparius; "serious poisoning" has been reported from an ingestion of as little as 6g dry plant material (White 1943a).

Cytisus canariensis is an erect, evergreen shrub 1-2(-3)m tall; stems erect, woody, ridged, softly hairy, usually one main stem with numerous branches. Leaves alternate, shortly stalked, trifoliate; leaflets entire, obovate, hairy on lower surface, less so on upper, middle leaflet 5-30mm long (can be to 40mm on young growth), the others shorter. Flowers bright yellow, pea-like, c.1.2cm long, shortly stalked, occurring singly or in clusters of up to 9 in leaf axils and terminally; calyx bilabiate; corolla lobes short, upper 2 free or slightly connate, lower 3 connate into a 3-lobed lip, standard ovate, wings oblong, keel petals oblong, slightly incurved, swollen at sides, claws of wings and keel petals usually adnate to the staminal tube; stamens 10, monadelphous; anthers alternately short and versatile, long and basifixed. Ovary sessile, 2-many-ovuled; style apex incurved; stigma capitate, terminal. Fruit a brown or black silky pod, linear-oblong, 2-valved, non-septate, 2.5 x 0.5cm, coiled after release of seeds; seeds 5-8, dark brown to black, rounded and flattened, 2mm diameter, smooth, shiny. Fl. late winter-spring, sometimes in late summer.

Native to Mediterranean region; a weed in west coast N. America, Hawaii, New Zealand, Australia, Chile and forests of S. Africa.

Hardy and drought-resistant, brooms may be cultivated by seed or cutting; seeds should be nicked and soaked until swollen before planting. Do not transplant until older; or, plant seeds where they are to grow. Grow in well-drained soil with full sun; often does not flower until 2 years old (Allen & Allen 1981; Parsons & Cuthbertson 1992). Should not be cultivated in many places due to its great invasive potential (pers. obs.).

For medicine, aerial parts are usually gathered before flowering; for psychotropic use, the flower buds are gathered.

DATURA

(Solanaceae)

Datura ceratocaula *Ortega* **(D. macrocaulis** *Roth.***; D. sinuata** *Sessé et Moc.***; Apemon crassecaule** *Raf.***)** – tlápatl, nexehuac, tornaloco, atlinan, 'sister of ololuiqui' [see **Turbina**]

Datura discolor *Bernh.*

Datura ferox *L.* **(Stramonium ferox** *Boccone***)** – fierce thornapple, long-spine thornapple

Datura inoxia *Miller* **(D. guayaquilensis** *H.B.K.***; D. lanosa** *Barcley ex Bye***; D. metel** *Dunal non L. (Sims non L.)***; D. meteloides** *DC ex Dunal***)** – downy thornapple, a'neglakya, toloache, tolohuaxihuatl, dekuba, wichuri, peyote, tikúwari, tokhu

Datura leichhardtii *F. Muell. ex Benth.* **(D. pruinosa** *Greenman***)** – native thornapple [Australia]

Datura metel *L.* **(D. alba** *Nees ex Eisenb.***; D. cornucopaea** *Hort. ex W.W.***; D. fastuosa** *L.***)** – tatorah, datora, jous-matehl, dhustura, unmata, dhatura, dutra, chocho wah, bhakli wah, chosen asago ['Korean morning beauty'], man t'o-lo, mehen-x-tokhu, mondzo

Datura quercifolia *H.B.K.* **(D. stramonium ssp. quercifolia** *(H.B.K.) Bye***; D. villosa** *Fernald***)**

Datura stramonium *L.* **(D. bertolonii** *Parl. ex Guss.***; D. inermis** *Jacq.***; D. laevis** *L. f.***; D. tatula** *L.***)** – common thornapple, jimsonweed, Jamestown weed, toloache, toloatzin, nacazul, wichuri, uchiri, dekuba, kieli-sa, chamico, hierba del diablo, miayu, miyaya, ?ama'y mushtak, mehen-x-tokhu, hexenkraut, hexenkümmel, sekle wah

Datura wrightii *Regel ex Bye* **(D. meteloides** *Dunal***)** – hairy thornapple

Datura spp. – thornapple, dhaturo

Few plants have acquired such a fearsome reputation as those grouped under the genus Datura, which bear a huge testimony of written lore. Given the enormity of the literature regarding this genus, the following can only be seen as a general summary. Overall, it could be said that Datura spp. are known largely for their reputed use in European witches potions and 'flying ointments' (Rudgley 1995; Schultes & Hofmann 1992).

The ancient Sao culture of Chad have been hypothesised to have smoked D. metel in pipes, though there is no conclusive evidence to support this (De Smet 1998). D. metel was recorded to have been used as a narcotic inebriant by the Arabs by c.1000AD; it was also acknowledged that the plant could be deadly in higher doses. In Morocco, D. stramonium is used as an inebriant alone, or as 6 flowers added to coffee [see **Coffea**]. Datura has long been commonly used in India and Nepal [generally as D. metel], where it is sacred to Shiva – as such, it is smoked by saddhus and others with **Cannabis** as a sacramental aphrodisiac and an aid to raising the kundalini-energy [see *Influencing Endogenous Chemistry*], particularly in tantric yoga. It has a long history of use in tantric sorcery, and has also been added to alcoholic beverages to make them more potent. It is sometimes used to fortify 'bhang' [see **Cannabis**]. Nepalese shamans use Datura spp. seeds for shamanic travel, and to treat insanity; for the latter, the Kirati prescribe 1 seed each of D. metel, D. stramonium and D. metel var. fastuosa, with the dose of each increased to 2-3 seeds for the next day or two. Its Sanskrit names, 'dhustura' or 'unmata', mean 'divine craziness'. The seeds have been used by Kali-devotees for criminal purposes, presumably homicidal poisoning. Others use the seeds to stupefy a victim in order to rob them or otherwise take advantage. D. stramonium has been used in Indian medicine to treat mental disorders, fevers, headache, rheumatism, epilepsy, asthma, diarrhoea, inflammation and opium poisoning [see **Papaver**] (Mehra 1979; Müller-Ebeling et al. 2002; Nadkarni 1976; Ott 1993; Rätsch 1990, 1992; Schultes & Hofmann 1980, 1992; Siklós 1993).

Although indigenous Australians have not been reported to use their native Datura spp. as drugs, some refer to D. leichhardtii as a 'cheeky bugger' [meaning that it has toxic properties], indicating some knowledge of its effects. In the 19th century, inhabitants of Norfolk Island were reported to eat D. stramonium seeds "to invoke temporary or permanent insanity" (Low 1990).

In China, flowers ['yang-jin-hua'] and seeds of D. metel have been taken internally to treat nervous disorders and colds, and externally for skin eruptions and infections. Combined with **Cannabis** in wine, D. metel was used as an anaesthetic for minor operations; the inebriating properties of the plant were also well-known (Li 1978). In Haiti and Jamaica, Datura spp. are known as 'concombre zombi' ['zombi cucumber'], and are used as an aphrodisiac and medicine by healers. In Haiti, the plant is sometimes an ingredient in the 'antidote' administered to new zombis when they are dug up from their fresh graves, and also afterwards to keep them enslaved [see *Methods of Ingestion*] (Davis 1988a; Rätsch 1992). This may explain why zombis are traditionally said to die when given salt, as sweating is reduced in Datura poisoning (theobromus pers. comm.).

Datura spp. leaves are smoked in gourd pipes in e. Africa to produce inebriation, and in tropical w. Africa the plants are used to strengthen native beers and palm wines [see *Methods of Ingestion*]. Leaves of D. metel are used for this purpose in Tanzania. Amongst the Fulani, a D. metel seed decoction is given to boys "to incite them in the Sharo contest or ordeal of manhood" (De Smet 1998). Datura spp. may also be used as sacred inebriants by Kunama women of north-east Africa. D. metel is known to be consumed in the final stages of female puberty initiation rites, by the Shagana-Tsonga of n. Transvaal, to induce contact with ancestral fertility spirits so that sexual fertility is ensured. In west and central Africa, D. metel is also used as an inebriant, and for divination on criminal matters. In some parts of Africa, schoolboys initiate one another with the administration of an inebriating dose of Datura sp. seeds ['langboontije'] (Johnston 1972; Watt & Breyer-Brandwijk 1932, 1962).

In S. America, the use of Datura spp. seems to be largely replaced by **Brugmansia** [once classified under the genus Datura], though D. stramonium has been claimed to be an ingredient of the mysterious 'cimora' potion based on **Trichocereus** pachanoi [see **Trichocereus** for further discussion] in Peru (Schultes 1967a). Even though 'cimora' may not actually exist as the name for such a beverage, rather being a term used for a variety of plants (Davis 1983), D. stramonium [as 'chamico'] might still be added to T. pachanoi brews in Peru (Rätsch 1998). Also, the Mapuche of Chile use D. stramonium and/or another Datura sp. as a 'narcotic', and administer the seeds to 'unruly children' (Plowman et al. 1971). D. stramonium has been reported as one of the 4 major visionary plants of the Mapuche [see also **Latua**, **Lobelia** and Ovidia pillopillo in *Endnotes*] (Rätsch 2001).

The Aztecs used Datura spp. as analgesics, and called D. ceratocaula 'tlapatl'. Species such as D. ceratocaula, D. inoxia, D. metel and D. stramonium are still used in Mexico as local analgesics and stupefacients. D. inoxia is also used in sorcery and as an anaphrodisiac, and is known in some areas of Mexico as 'peyote' [see **Lophophora**]. D. stramonium is also used in sorcery and as an anaphrodisiac, antiasthmatic, expectorant, antipyretic, and poultice for wounds and skin conditions. D. inoxia root has been used by Zuñi shamans of New Mexico to 'render the patient unconscious' for performing operations; they may also put the powdered root into their eyes or chew the root for shamanic purposes. The plant may be decocted and drunk, or made into an ointment and rubbed on the body. Datura spp. have long been used for divination and healing by Mexican shamans, and the Maya, Tarahumara and Mixe still practice their use. The Mixe administer 27 seeds for a man, and 21 for a woman, for divination at night. Mayan shamans in the Yucatan eat 10-30 Datura seeds and concentrate on a crystal to divine; they also smoke the flowers as an aphrodisiac, and offer them to the gods. Still, shamans prefer to use these plants only in difficult cases. Most Yucateo and Lacandon Maya will not handle the plants [usually D. stramonium or the introduced D. inoxia] unless necessary, and then only for medicinal use. Such use is external, except in the case of nightmares, where a leaf or root tea may be given. The Naja Lacandon know Datura spp. as 'ts'ak tsimin' ['medicine of the wind/thunder beasts']; they are regarded as only being used by 'evil' shamans, and many Maya say the plants emit the 'smell of death', referring to their noxious odour. On a more casual note, Datura spp. are sometimes added to the fermented maize drink 'tesguino' [see also 'chicha', in *Methods of Ingestion*], and to mezcal [see also 'pulqué', in *Methods of Ingestion*], to increase their potency (Bye 1979b; Diaz 1979; Furst 1976; Lipp 1990; Litzinger 1994; Ott 1993; Rätsch 1990, 1992, 1999a; Schultes 1937a, 1937b, 1979).

N. American natives north of Mexico have also made widespread use of the available Datura spp. The Luiseño and other tribal groups of southern California used the infused root of D. inoxia ['toloache'] in male puberty initiation rites; every male in their group must consume it once in his lifetime, to establish life-long bonds with the spirit-realms. The experience is known to last up to 3 nights, and has on occasion caused fatalities. The original inhabitants of Virginia also used a Datura sp. in boys initiation; root decoctions of it ['wysoccan'] were administered after a lengthy period of fasting and instruction from elders. The experience was said to last 18-20 days [probably due to a very high sub-lethal dose], and was intended to erase memory of youth, in order to begin manhood. To the Chumash, Datura is considered a powerful spirit teacher. Many tribes used it in a similar context, or as a ritual shamanic inebriant (Furst 1976; Ott 1993; Schultes 1979; Wellmann 1978).

In the US, D. stramonium acquired the name 'jimsonweed' as a corruption of 'Jamestown weed', referring to an incident in the 17th century, involving English soldiers on their way to stop a rebellion at Jamestown, Virginia. The soldiers picked, cooked and ate D. stramonium leaves, mistaking them for an edible plant, resulting in a mass delirious intoxication lasting several days (Furst 1976).

It is also noteworthy that hawk-moths of the genus Manduca, pollinators of D. wrightii [as D. meteloides], appear to experience intoxication when visiting the flowers of the plant (Grant & Grant 1983).

Occasionally, Datura spp. have caused accidental poisonings [as with the Jamestown incident mentioned above], which have sometimes been fatal, though full recovery usually occurs within several days. A child [3 years, 9 months of age] was taken to hospital after eating the seeds from 3 D. stramonium fruits, and although he suffered hallucinations and other characteristic effects, "twelve hours after his admission to hospital he was alert and rational, but his gait was still ataxic; after a further period of 12 hours he was normal in all respects, except for occasional episodes of head-rocking over the next two days" (Schumacher 1965).

Modern-day use of Datura spp. amongst non-traditional peoples has largely been conducted by young, ill-informed people in search of a free 'trip' – indeed, what are claimed by experimenters to have been 'Datura trips' are often in reality based on consumption of the closely related **Brugmansia**. It must be said, however, that these plants do have their adherents amongst responsible experimenters. Many of the consequent experiences are extremely frightening, disorienting, and sometimes life-threatening; few repeat the experience, it being notoriously difficult to work with. Smoking the leaves or seeds provides a relatively safer means of ingestion, as the dosage is easier to gauge, effects are usually less drastic, and the duration of the effects is shorter [see **Brugmansia** for more discussion on consumption and effects]. Some people do manage to ingest Datura-preparations and direct a useful experience. Such people usually accomplish this with the aid of ritual, 'magic', and experience; some just have a personal affinity with these plants and their effects, that is lacking in most other people. It is not an easy journey to extract positive results from if you are not a shaman already acquainted with it. Regular use is widely reputed, even amongst shamans, to cause insanity (Gowdy 1972;

Siegel 1976; Weil 1977a; pers. comms.; pers. obs.).

Use of D. stramonium in asthma preparations as an orally-consumed psychoactive drug occurred frequently when such preparations were still widely available. Such preparations were intended as smokable mixtures, consisting mainly of c. 50% D. stramonium and 25% potassium nitrate [to facilitate burning], as well as **Atropa** belladonna, a Grindelia sp. and a **Nicotiana** sp. to add bulk and adjust the average tropane alkaloid concentration to 0.3%, or 220µg *hyoscine* and 250µg *atropine* per cigarette. D. stramonium is also found in some brands of 'bidis', small hand-rolled cigarettes from India; one type was shown to contain 65µg *hyoscine* and 16µg *atropine* per cigarette (Gowdy 1972; Siegel 1976).

Datura spp. have been shown to contain predominantly anticholinergic tropane alkaloids, as well as an array of other tropines [including cuscohygrines; see **Erythroxylum**], and withanolides [see **Withania**]. The anticholinergic effects of these plants may be reversed by the administration of physostigmine [i.v.], an AChE-inhibitor. In one case, 6mg given in 2mg increments over 10min. was sufficient to counteract the majority of CNS effects, but not the pupil dilation (Orr 1975). Other treatments that have been used for Datura-poisoning include the administration of charcoal [slows absorption], magnesium citrate [speeds passage through intestines], and ipecac [as an emetic; see **Psychotria**] (Friedman & Levin 1989). The Mixe of s. Mexico say that 'bad effects' of Datura may be relieved by drinking "a broth of very hot chili peppers" [see **Capsicum**] (Lipp 1990).

D. discolor [cultivated in Mexico] aerial parts yielded 0.17% alkaloids, including *hyoscine* [0.08%], *hyoscyamine* [0.01%], apohyoscine, norhyoscine, meteloidine, tropine and ψ-tropine; roots yielded 0.31% alkaloids, including 0.02% *hyoscine*, norhyoscine, *atropine* [0.01%], littorine, meteloidine, tropine, ψ-tropine, 3α,6β-ditigloyloxytropane, 3α,6β-ditigloyloxytropan-7β-ol, and cuscohygrine [0.06%]. Both contained traces of tropanes which were not positively identified (Evans & Somanabandhu 1974).

D. ferox aerial parts yielded 0.06-0.4% *hyoscine*, 0.1% meteloidine, and an unknown alkaloid; roots yielded *hyoscine*, *hyoscyamine*, cuscohygrine, littorine, meteloidine, 3α-tigloyloxytropane, 3,6-ditigloyloxytropan-7-ol, and 3,6-ditigloyloxytropane; seeds [fresh] yielded 0.07% alkaloids, mostly *hyoscine*, with no meteloidine. Apoatropine is found predominantly in seedlings, later decreasing in proportion to *hyoscine*, and remaining at its highest level in leaves and pericarps (Evans & Partridge 1949; Evans et al. 1972c; Everist 1974; Saber et al. 1962b). The plant also contain withanolides called daturolactones (Veleiro et al. 1999).

D. inoxia leaves have yielded 0.3-1.8% alkaloids, mostly *hyoscine* [0.17-1.65%], as well as *hyoscyamine* [0.047-0.15%] and meteloidine [0.05%]; stems yielded 0.3-2.52% *hyoscine* and 0.54% *hyoscyamine*; seeds yielded 0.436% *hyoscine*; fruits yielded 0.668-0.77% *hyoscine*; green calyx yielded 1.12% *hyoscine*; whole roots yielded 0.055-0.394% *hyoscine*, 0.27% *hyoscyamine*, and 0.09% meteloidine; tap roots yielded 0.81-1.65% *hyoscine* and 0.05-0.1% *hyoscyamine*; and fine roots yielded 1.69% *hyoscine* and 0.34% *hyoscyamine* (Everist 1974; Gerlach 1948; James 1953; Shibata 1956). Roots have also been shown to contain norhyoscine, apoatropine, littorine, tigloidine, cuscohygrine, tropine, ψ-tropine, 3,6-ditigloyloxytropan-7-ol and 3,6-ditigloyloxytropane (Evans et al. 1972c). The leaves also yielded 0.00036% [w/w] *scopoletin* and aesculetin (Kala 1958).

D. leichhardtii leaves yielded 0.33% alkaloids, and stems yielded 0.07% alkaloids [combined aerial parts yielded 0.16% alkaloids], consisting mostly of *atropine* [0.06%], with lesser amounts of *hyoscine* [0.02%], apoatropine, noratropine, norhyoscine, apohyoscine, littorine, tigloidine, meteloidine, tropine, ψ-tropine and 3-α-tigloyloxytropane; roots yielded 0.31-0.46% alkaloids, consisting mostly of *atropine* [0.18%], with lesser amounts of *hyoscine* [0.01%], norhyoscyamine, littorine, tigloidine, meteloidine, tropine, ψ-tropine, cuscohygrine, 3-α-tigloyloxytropane, 3,6-ditigloyloxytropane and 3,6-ditigloyloxytropan-7-ol (Evans & Treagust 1973a; Evans et al. 1972c; Everist 1974).

D. metel combined aerial parts yielded 0.1% *hyoscine*, 0.02-0.04% *hyoscyamine* [disappears after flowering; none in seeds or root] and 0.01% norhyoscyamine; leaves yielded 0.264-0.52% alkaloids [0.113% *hyoscine*, 0.076% *hyoscyamine* in one test]; calyces yielded 1.08% alkaloids; stems yielded 0.3% alkaloids; roots yielded 0.39-0.66% alkaloids, mostly *atropine* or *hyoscyamine*, as well as 0.054% *hyoscine* and cuscohygrine; fruit yielded 0.2% [as D. fastuosa var. niger] to 0.77% alkaloids; capsules yielded 0.334% alkaloids; seeds yielded 0.23-0.5% alkaloids. Leaves also yielded the withanolides withametelin [0.0015-0.1%], withametelin B [0.00175%], 12-deoxy-withastramonolide [0.016%] and physalindicanol A [0.00375%]. Roots had highest alkaloid content [up to 0.77%] in cold and rainy seasons, and when flowering and fruiting; stems bear the highest content [up to 0.41%] when in flower and fruit; leaf is highest in alkaloids [up to 0.55%] when young and at the start of flowering; flowers are highest in content [up to 0.98%] near the end of flowering and fruiting; fruit has highest content [up to 0.089%] when ripe; and seeds also have highest content [up to 0.17%] when ripe. Plants grown at higher altitudes had higher alkaloid content in all parts than plants grown at lower altitudes. Tetraploid plants had higher alkaloid levels than haploid [lowest levels] and diploid plants (Afsharypuor et al. 1995; Gerlach 1948; Gupta, M. et al. 1991; Henry 1939; Karnick & Saxena 1970; Shibata 1956).

D. quercifolia leaves yielded 0.42% alkaloids, consisting of *hyoscine* and *hyoscyamine*; seeds yielded 0.29% alkaloids, of similar constituency (Henry 1939). The plant also contains withanolides called daturolactones (Veleiro et al. 1999).

D. stramonium aerial parts have yielded up to 0.54% alkaloids – 0.07-0.2% *hyoscine* [lower before flowering, higher after] and 0.04-0.15% *hyoscyamine* [lower before flowering, higher after]. Leaves have yielded 0.4% *hyoscyamine* and 0.01% *hyoscine*; stems yielded 0.2% *hyoscyamine* and 0.05% *hyoscine*; roots have yielded 0.1% *hyoscyamine*, 0.1% *hyoscine*, apoatropine, 0.01% 3,6-ditiglolyteloidine, cuscohygrine, littorine, meteloidine, tropine, ψ-tropine, 3,6-ditigloyloxytropan-7-ol, and 3,6-ditigloyloxytropane. Seeds yielded 0.2-0.48% alkaloids, mostly *hyoscyamine* [though one recent study (Friedman & Levin 1989) found *atropine* and *hyoscine* as the major alkaloids, with yields of 0.16-0.28% and 0.033-0.079%, respectively], as well as 0.017% *GABA*, 0.012% arginine, 0.008% histidine, and 0.16-0.56% tannins. Tetraploid plants had higher alkaloid content than haploid [lowest content] and diploid plants (Anon. 1916a; Evans et al. 1972c; Friedman & Levin 1989; Henry 1939; Karnick & Saxena 1970; Leete 1959). As D. tatula, leaves yielded 0.36% alkaloids [0.27% *hyoscyamine*, 0.09% *hyoscine*]; roots yielded up to 2.28% *hyoscyamine*, 0.012% *hyoscine* (Shibata 1956; Spurná et al. 1981) and the coumarin *scopoletin* [0.0002% w/w] (Kala 1958). Leaf tested positive for HCN (Watt & Breyer-Brandwijk 1962).

D. wrightii roots contain large quantities of *hyoscine* and *hyoscyamine*, whilst leaves contain only small quantities of *hyoscine* (Spurná et al. 1981). Root [as D. meteloides] has been shown to contain *hyoscine*, *hyoscyamine*, norhyoscine, norhyoscyamine, cuscohygrine, littorine, meteloidine, tropine, ψ-tropine, 3,6-dihydroxytropane, 3α-tigloyloxytropane, 3,6-ditigloyloxytropan-7-ol, and 3,6-ditigloyloxytropane (Evans et al. 1972c); leaves [as D. meteloides] from Australian plants yielded 0.18-0.45% alkaloids, mostly *hyoscine*, as well as *hyoscyamine* and norhyoscyamine; seeds yielded 0.17-0.47% alkaloids (Everist 1974). Whole plant [again, as D. meteloides] yielded 0.4% alkaloids, including 0.13% *hyoscine*, 0.03% *atropine* and 0.07% meteloidine (Henry 1939).

In tests on the Datura alkaloids in animals, very high doses [ie. too high to be of significance in human pharmacology] of *atropine*, *hyoscine* and total alkaloid mixture caused 9, 14.7 and 15.2% inhibition of MAO and 8, 9.3 and 8.9% inhibition of *5-hydroxytryptophan*-decarboxylase, respectively (Rastogi & Mehrotra ed. 1990-1993). D. stramonium inhibited human plasma AChE (Orgell 1963b).

Datura stramonium is a stout annual herb, glabrous or sparsely pubescent with non-glandular hairs; stems to 0.5-2m tall, purplish or green. Leaves 5-15(-36)cm long, rhomboid to angularly-ovate, deeply lobed, lobes few, usually coarsely toothed or sinuate. Flowers perfect, gamopetalous, solitary and pedicelled, erect; calyx 3-4(-5.5)cm long, tubular, 5-lobed, lobes 6-8mm long; corolla funnel-shaped, 5-lobed, lobes ending in a slender point c.10mm long, white or lavender, 6-10cm long, 3-4cm wide at apex; stamens 5, not exserted, alternating with corolla-lobes, attached to inner surface of tube near base; anthers 3-6mm long, purple in lavender-flowered types, white in white-flowered. Ovary superior, 2-celled at apex, often 4-celled below; style 4-6cm long, filiform; stigma below, level with or above anthers, 2-lobed. Capsule ovoid, to 4.5-5(-7)cm long, 3-5cm wide, erect, shiny green, spiny, spines c.100-200, slender, conical, sharp, variable in length, the longest less than ½ the length of capsule, dehiscing apically by (usually) 4 slits; persistent base of calyx to 10mm long; seeds many, 2.5-4.5mm long, black or grey when ripe.

Origin uncertain – widely naturalised around the world, also a weed of waste ground and disturbed areas (Haegi et al. ed.1982; Satina & Avery 1959; pers. obs.).

Sow seed in spring; freezing and subsequent thawing of the seed [notably in the case of D. inoxia] may aid in germination (Gerlach 1948).

Seeds of Datura spp. are a frequent contaminant of harvested soy beans, wheat, and other commercial grain crops, in one analysis comprising c.79% of organic contaminant material. As the alkaloids largely survive being baked in bread as a flour contaminant, there is an obvious risk of poisoning if post-harvest cleaning is insufficient (Friedman & Levin 1989).

DATURICARPA

(Apocynaceae)

Daturicarpa elliptica *Stapf.* **(Tabernanthe elliptica** *(Stapf.) Leeuwenb.***)**

This shrub from Zaïre [previously Belgian Congo] has no ethnobotanical uses to my knowledge, though it has yielded some indole alkaloids of great interest. The genus has been named in reference to the **Datura**-like appearance of the 'spiky' fruits.

D. elliptica root bark yielded 5.6% alkaloids, and stem bark yielded 2.4% alkaloids; in both samples, *ibogaine* was the major alkaloid [c.80% of total alkaloids], with lesser amounts of *iboxygaine*, *ibogaline*, (+)-ibophylli-

dine and *voacangine* (Bruneton et al. 1976).

Daturicarpa elliptica is a shrub or small tree; branches on previous year's growth closely striate-wrinkled and lenticellate-verrucose. Leaves opposite, broadly elliptic or elliptic-oblong, abruptly caudate-acuminate, acumine linear obtuse, 10-18cm long, 5.5-7cm wide, quite slender, upper side green or dark brown when dried, under side pallid, lateral nerves 6-7 on both sides; petiole 3-6mm long, bases opposite, laterally mostly sub-acutely angulate. Inflorescence a panicle, 3cm long including peduncle; peduncule c.5mm long; calyx very small, herbaceous, glandless within; sepals 5, imbricate, ovate-rotundate, obtuse or subobtuse; corolla hypocrateriform, 6-7mm long, 7-8mm diam., pale greenish-yellow, red-striate, tube widened at base, narrowing gradually from the middle to the apex, with a pilose line within for each anther, corolla lobes obtuse, contorted to the left, not inflexed in bud; stamens inserted at middle of corolla tube; anthers converging to a cone, included in tube. Disc indistinct; ovary adnate, 2-carpellate, slightly fleshy; ovules 3-5-seriate; style becoming abruptly filiform; stigma linear-sagittate, capitate, shortly apiculate-acuminate, not or scarcely adhering, base narrowly manicate, lightly 5-furrowed, subviscose. Mericarp peduncule 1-2cm long, mericarp spreading or erect, subtended, globose, to 3.5cm diam., indehiscent, ochre-reddish or orange, spines flexible and soft, 7-10mm long, closely scattered covering each other, outer layer 3mm thick; seeds to 20, 7-9mm long, ellipsoid.

Zaïre – Kwango District, Kikwit, Mondombe, Province Orientale, in virgin forest near Lubutu-Kirundu, Kasai District, Batempa, Kondue (Stapf 1921).

DAUCUS

(Umbelliferae/Apiaceae)

Daucus carota *L.* **(Carota sativa** *Rupr.***; Caucalis carota** *Crantz***; Cau. daucus** *Crantz***)** – wild carrot, Queen Anne's Lace, bird's nest, philtron, nanheshi, gajar

Daucus glochidiatus *(Labill.) Fischer et C.A. Meyer* – Australian carrot

Wild carrot [D. carota ssp. carota] is the original wild counterpart of the cultivated carrot [D. carota ssp. sativus], the root of which is fleshier, more colourful, more flavoursome and more nutritious. The wild plant is not without its virtues, however, as it is rich in medicinal compounds, some of which may be psychoactive.

There are only a few vague references to psychotropic usage of D. carota that I could find (Schultes & Hofmann 1980). A brief aside in the Bulletin on Narcotics (Phillips et al. 1968) stated that "It is reported that teenagers in the United States of America are smoking the leaves of Daucus carota [wild carrot], called the 'Queen Anne's Lace'." Another paper reported the 'dried tops' to "have been smoked with the intention of 'tripping'" (Krikorian 1968). The only other source I have located is an underground comic book (Sheridan 1969), where it is said that the herb of Queen Anne's lace may be smoked, with psychoactive effects alluded to. In neither case were any further details given. Rätsch (1998) reported that the aerial parts give **Cannabis**-like effects when smoked, with the wild variety giving best results, though the comparison to **Cannabis** seems dubious.

The root is sometimes ground into an edible flour, and has also been roasted and used as a coffee substitute [see **Coffea**] similar to dandelion or chicory. The root also lowers blood pressure, and acts as an antibacterial, anthelmintic, antacid, diuretic and ophthalmic. It has been used as a poultice for skin itches, though some people experience photosensitisation after contact with the foliage. The root may be useful in treating cancer. In TCM, the dried ripe seeds, known as 'nanheshi', are used as a galactogogue, emmenagogue, antispasmodic, and antiseptic, as well as to prevent formation of urinary stones. The herbage is used for similar reasons in Ayurvedic medicine, and in India the seeds are used as a stimulant, aphrodisiac and nervine tonic (Bremness 1994; Chiej 1984; Huang 1993; Mabey et al. ed. 1990; Nadkarni 1976; Polunin & Robbins 1992). The seeds have apparently also been used as a hangover remedy (Chevallier 1996). Wild D. carota has been suspected of causing mild intoxications in horses and cattle (Crosby & Aharonson 1967).

D. carota seed oil acts as a CNS-depressant and hypotensive in animals at higher doses; in smaller doses it is a stimulant, excitatant, vasodilator and a smooth muscle relaxant. The seeds also have a cholinergic action on GI smooth muscle (Chopra et al. 1965; Lawless 1995; Rastogi & Mehrotra ed. 1990-1993), and should probably be avoided in pregnancy, due to their potential abortifacient action (Chevallier 1996). An article I have been unable to locate suggests that D. carota may act as an MAOI (Gupta, L. et al. 1973. "Monoamine oxidase inhibiting activity of Daucus carota". Indian J. Exp. Biol. 11(4):342-3). Another elusive article (Vashist, M.G. et al. 1997. "Screwing a carrot out of the rectum." Indian J. Gastroenterology 16(3):120) suggests another use which the carrot may be put to!

D. carota seed has yielded 0.6-2.1% essential oil [from cultivated varieties], containing mostly carotol [(9-)65.85-67.2%; wild varieties contained almost none], as well as daucol [8.8-9.6%], β-bisabolene [5.6-6.2%], epoxydihydrocaryophyllene [2.5-20%], geranyl acetate [0-48%], geraniol, *asarone*, *elemicin*, α- and β-*pinene*, (+)-daucene, limonene, sabinene, dipentene, p-thymol, linalool, β-elemene, bergamotene, α-curcumene and farnesene; the fixed oil of the seed contains oleic acid, linoleic acid, linolenic acid and palmitic acid; the seed has also yielded *choline* (El Gendhi 1990a, 1990b; Rastogi & Mehrotra ed. 1990-1993; Stahl 1964). The leaf-wax has been found to contain *methylisoeugenol* (Berueter & Staedler 1971; Shulgin & Shulgin 1991) and the leaves contain compounds called porphyrins which stimulate release of sex hormones from pituitary gland (Chevallier 1996). Also, 0-0.023% *tyramine* been found in the plant (Lundstrom 1989). D. carota ssp. sativus root has yielded an essential oil containing β-caryophyllene, terpinolene, *pinene*, β-myrcene, γ-terpinene, p-cymene, α-humulene, and (E)-γ-bisabolene as major components, with lesser amounts of many other compounds, including traces of *myristicin*, *elemicin*, and *camphor* (Harborne et al. 1969; Kjeldsen et al. 2001); the root has also yielded carotatoxin [trans-1,10-heptadecadiene-5,7-diyn-3-ol], a compound which was neurotoxic in mice [LD50 100mg/kg] (Crosby & Aharonson 1967). Under some storage conditions, the roots have been shown to produce abnormal metabolites, such as the coumarins *scopoletin*, 6-MeO-mellein, and 6-OH-mellein, and the chromones eugenin and 5,7-dihydroxy-2-methylchromone (Coxon et al. 1973).

D. glochidiatus seed yielded *myristicin* (Harborne et al. 1969).

Daucus carota is a biennial pubescent herb with a stout taproot; stems 50-100cm tall, glabrous, scabrous, or commonly rough-hairy. Leaves pinnately decompound, oblong in general outline, the ultimate divisions linear, lanceolate or oblong. Inflorescence a terminal compound umbel, erect, long-peduncled, commonly 7-15cm wide, 20 rays or more, the lateral ones usually smaller; involucre of numerous large, pinnately dissected bracts; bracts divided into elongate filiform-attenuate segments 5-20mm long; umbellets several to many-flowered; bractlets linear or rarely pinnate; flowers white or rarely pinkish, the central one of each umbellet often purple; calyx greatly reduced; sepals minute or obsolete; petals 5, usually prolonged at tip to an inflexed appendage; stamens 5, inserted on disk; filaments elongate. Ovary inferior, 2-celled; 1 ovule in each cell; styles 2, usually swollen at base into stylopodium. Fruit 3-4mm long, oblong or ovoid, flattened dorsally, primary ribs low and inconspicuous, bearing a row of short inconspicuous bristles, the 4 secondary ribs prominently winged, divided into a row of flattened-subulate, hooked or straight spines; oil tubes 1 under each secondary wing, 2 on the commisure. Fl. Jun.-Sep. (northern hemisphere).

Native to Eurasia; established as a weed in fields, roadsides, waste ground and open woods throughout US, Canada and many other parts of the world (Gleason 1952), including Australia (Hnatiuk 1990).

DELOSPERMA

(Aizoaceae/Mesembryanthemaceae)

Delosperma acuminatum *L. Bolus*
Delosperma bosseranum *Marais*
Delosperma britteniae *L. Bolus*
Delosperma cooperi *(Hook.) L. Bolus* **(Mesembryanthemum cooperi** *Hook.***)**
Delosperma ecklonis *(Salm.) Schwant.* **(Mesembryanthemum ecklonis** *Salm.***)**
Delosperma esterhuyseniae *L. Bolus*
Delosperma hallii *L. Bolus*
Delosperma harasianum *(Delfers) Poppendieck et Ihlenf.*
Delosperma herbeum *N.E. Br.*
Delosperma hirtum *(N.E.Br.) Schwant*
Delosperma klinghardtianum *(Dtr.) Schwant* **(Mesembryanthemum klinghardtianum** *Dtr.***)**
Delosperma lebombense *(L. Bol.) Lavis*
Delosperma aff. litorale *(Kensit) L. Bolus*
Delosperma lydenbergense *L. Bolus*
Delosperma mahonii *(N.E. Br.) N.E. Br.* **(Mesembryanthemum mahonii** *N.E. Br.***)**
Delosperma minimum *Lavis*
Delosperma nubigenum *(Schltr.) L. Bolus*
Delosperma obtusum *L. Bol.*
Delosperma pageanum *(L. Bol.) L. Bolus*
Delosperma pergamentaceum *L. Bolus*
Delosperma pottsii *(L. Bol.) L. Bol.*
Delosperma pruinosum *(Thunb.) J. Ingram*
Delosperma rogersii *(Schoenl. et Berger) L. Bol.* **var. rogersii**
Delosperma tradescanthioides *(Berger) L. Bolus*
Delosperma and some related **spp.** – ice plants

Delosperma spp. are used for various purposes in parts of southern and eastern Africa. The Tswana consume a root decoction of D. herbeum to treat loss of male fertility. They also powder the plant and rub it into scarifications on the vertebral joints, to make one "strong and resist-

ant to witchcraft". The Bantu use the root of D. mahonii [which contains up to 3% oxalates] to brew an intoxicating beer or mead, often known as 'khadi', which is said to be poisonous when these plants are used in large amounts [see *Methods of Ingestion*]. The root has been shown to sometimes be infected by a Torula sp. yeast and the mould **Aspergillus** niger, as well as possibly A. oryzae and Mucor erectus, which are thought to possess fermenting properties. One of the moulds has been shown to form oxalic acid in sugar solution. Europeans have used the root for yeast in bread-making (Anon. 1916b; Steyn 1934; Watt & Breyer-Brandwijk 1962). D. cooperi leaves have also been used for khadi, and this species has been shown to host similar yeasts and moulds (Hargreaves 1999). Curiously, in his excellent discussion on khadi, Hargreaves did not refer to D. mahonii, unless he used a synonym not known to me. These symbiotic organisms may also possess psychotropic properties of their own, as some **Aspergillus** spp. have yielded psychoactive ergot-alkaloids, and Mucor heimalis has yielded the ergot-alkaloid [see **Claviceps**] ergosine (El-Refai et al. 1970), a *serotonin*-antagonist and uterotonic (Cerletti & Doepfner 1958).

D. bosseranum leaf has been obscurely used by some western psychoanuts in the same manner as **Sceletium** tortuosum and other **Sceletium** spp.; the effects are reportedly similar but more pleasant. The root reputedly has mild stimulant properties (t st tantra pers. comm. 2003).

Unidentified Delosperma spp. have been reported to contain *DMT* and *N-methyltryptamine* [*NMT*] (Smith 1977b); they have remained unidentified until recently, with independent researchers taking the initiative using thin-layer chromatography and colour-reaction tests. However, the results (in Heffter 1996; Trout ed. 1997a) should be considered tentative; it should also be noted that the tryptamines were often present in low amounts, if at all, and were usually accompanied by many unidentified compounds in larger amounts.

D. acuminatum contained *DMT*, *5-methoxy-DMT* [*5-MeO-DMT*] and *NMT*.

D. britteniae contained *5-MeO-DMT* [high in late autumn, absent in spring] and *NMT*.

D. cooperi contained *DMT* [more in autumn], *5-MeO-DMT* [more in late spring/summer] and *NMT* (Heffter 1996; Trout ed. 1997a). Earlier tests for alkaloid presence indicated a strong reaction (Jeffs 1981), and the alkaloidal material present was presumed to have been *mesembrine* (Steyn 1934). D. cooperi fo. cooperi has also been shown to contain small amounts of mesembrenone, 4'-O-demethylmesembranol [see **Sceletium**], and larger amounts [c. 8% of extract] of an unidentified, possibly indolic, compound (Smith, M.T. et al. 1998).

D. ecklonis was found to contain traces of alkaloids in an early assay (Jeffs 1981), presumed to be *mesembrine* (Steyn 1934); *DMT* was later tentatively detected (Trout ed. 1997a).

D. esterhuyseniae contained *DMT* in small amounts in autumn, as well as *NMT*.

D. hallii contained high amounts of *5-MeO-DMT* in autumn, as well as *NMT*.

D. harasianum contained *5-MeO-DMT* and *DMT* in small amounts in autumn, as well as *NMT*.

D. hirtum contained small amounts of *DMT* in late autumn/winter, as well as *NMT*.

D. klinghardtianum tested positive for other unidentified tryptamines (Heffter 1996; Trout ed. 1997a).

D. lebombense has been shown to contain small quantities of mesembrenone, as well as two unidentified peaks, believed to contain indole constituents (Smith, M.T. et al. 1998).

D. aff. litorale contained *5-MeO-DMT* in autumn, none in spring, as well as *NMT*.

D. lydenbergense contained *DMT* in autumn, none in spring.

D. nubigenum contained small amounts of *5-MeO-DMT* (Trout ed. 1997a).

D. obtusum has been shown to contain small quantities of 4'-O-demethylmesembrenol (Smith, M.T. et al. 1998).

D. pageanum contained *5-MeO-DMT* in larger amounts in late spring, as well as *DMT* and *NMT*.

D. pergamentaceum contained traces of *DMT* in autumn (Trout ed. 1997a).

D. pottsii has been shown to contain moderate quantities [c.39% of extract] of unidentified compounds, some of which appear to be indoles.

D. pruinosum has been shown to contain small amounts of *mesembrine*, mesembrenone and 4'-O-demethylmesembrenol, as well as unidentified compounds.

D. rogersii var. rogersii has been shown to contain small quantities of 4'-O-demethylmesembrenol, as well as at least two unidentified compounds which appear to be indoles (Smith, M.T. et al. 1998).

D. tradescanthioides contained small amounts of *DMT* in autumn, as well as *NMT*.

In general, no alkaloids were found in spring harvests of Delosperma spp.; late autumn and early winter harvests gave the highest alkaloid levels (Heffter 1996; Trout ed. 1997a).

D. lehmannii and D. subincanum have tested alkaloid-positive, the latter only in trace amounts (Jeffs 1981; Steyn 1934; Watt & Breyer-Brandwijk 1962). D. luteum contains humilixanthin (Buckingham et al. ed. 1994). Like Mesembryanthemum and other related plants [see **Sceletium**], most Delosperma spp. may be expected to contain considerable quantities of oxalates.

Delosperma cooperi is a small, soft, hairless perennial, with numerous small papillae; rootstock woody or tuberous; stems often prostrate, with distinct internodes. Leaves opposite, sessile, narrow, slightly connate, succulent, soft and fleshy, +- finely papillose, broadly triangular to cylindrical in cross-section, lowest up to 4cm x 5mm, most leaves much shorter and only c.2mm wide. Flowers axillary, singly or in small groups, shortly stalked, c.1.5cm diam., with leaf-like bracts; perianth-segments 5, the longer ones sometimes horn-shaped or caudate; longer calyx lobes long-tailed; sepals 5, long and narrow; petals magenta, narrow, numerous; staminodes in few series, +- linear; stamens whitish, sometimes hairy towards base. Ovary 5-locular, +- convex; glands separated, partly crenulated; placentas parietal; stigmas 5, acute, papillose. Fruit soft in texture, 5-locular, keels with membranous marginal wings; seeds suborbicular, pale brown.

In rock crevices; Sicanusa, Swaziland (Compton 1976; Launert et al. ed. 1978); common horticultural succulent.

DESFONTAINIA

(Desfontainiaceae/Loganiaceae)

Desfontainia spinosa *Ruiz et Pav.* **(D. acutangula** *Dunal***; D. chilensis** *Gay***; D. costaricensis** *Woodson***; D. fulgens** *D. Don***; D. hookeri** *Dunal***; D. ilicifolia** *Phil.***; D. novemdentata** *Gand.***; D. obovata** *Kraenzl.***; D. parvifolia** *D. Don***; D. pulchra** *Moldenke***; D. spinosa var. chilensis** *(Gay) Reiche***; D. spinosa var. hookeri** *(Dunal) Reiche***; D. spinosa var. parvifolia** *(D. Don.) Hook.***; D. splendens** *Bonpl.***; D. steyermarkii** *Moldenke***; Linkia peruviana** *Pers.***; L. splendens** *(Bonpl.) Poir.***)** – taique, borrachero de paramo, chapico, michai blanco, trau-trau, latué, latuy

Kamsa and Ingano shamans of the Sibundoy Valley area of Colombia are known to make a tea of D. spinosa leaves to diagnose illnesses and enter a visionary state; it is said to make them 'go crazy'. People with knowledge of the plant are reluctant to discuss it with outsiders. In Chile, leaves of D. spinosa are taken as a narcotic and stomachic. The local Mapuche use the plant to make a yellow fabric dye (Schultes 1977a), as well as using it obscurely "in a similar way" to **Latua** pubiflora (Rätsch 1998, 2001).

This species has screened negative for alkaloid content (Schultes 1977a), though D. spinosa leaves and stems have yielded the iridoids loganin [0.026%], loganetin [0.055%], loganic acid [0.06%] and 7-O-(p-coumaroyl)-loganin; the seco-iridoids sweroside, secoxyloganin and dimethyl secologanoside; the glucoside iridoid-triterpenoid congeners desfontainoside [in stems only] and desfontainic acid; the cytostatic triterpene 11-deoxycucurbitacin I [0.003%]; and the furofuran lignans (+)-syringaresinol, (+)-syringaresinol O-β-D-glucopyranoside and liriodendrin (Amonkar et al. 1985; Houghton & Ming 1985, 1986); nigaichigoside F1, hyptatic acid, 7α-OH-tormentic acid and 7α-23-dihydroxytormentic acid were also reported from the plant (Buckingham et al. ed. 1994).

Desfontainia spinosa is an evergreen shrub 1.5-3m tall, branched, with pale brownish shiny bark, the twigs greyish. Leaves opposite, simple, coriaceous, spiny, 2-4 x 1-2.3cm, elliptical to ovate or obovate, acute and pungent, cuneate at base, with 2-8 pairs of spiny, broadly triangular teeth, the spines 2-2.5mm; petiole 8-10mm; stipules absent. Peduncles 9-10mm, with 2 basal bracts c.6 x 1-1.2mm, +- linear; flowers solitary, terminal; sepals 5, united at base; calyx segments 7-8 x 3-3.5mm, elliptic-oblong, obtuse, ciliate, sparsely pubescent; corolla infundibuliform, shallowly 5-lobed, 4.5-6cm, with rotund lobes, the tube red, the lobes yellow-orange; stamens 5, inserted at base of corolla lobes. Ovary superior, (3-)5-celled; style 1; stigma subcapitate, included or slightly exserted; anthers subsessile. Fruit a many-seeded berry, 12-15 x 9-11mm, oblong-subglobose, greenish-purple; seeds 2-2.5 x 1-1.2mm, oblong-obovoid, smooth. Fl. Dec.-Feb.

Coastal forest, 0-30m; w. Argentina 42-40°S, Chile from 40°S, north along Andes to 25°S (Moore 1983).

DESMANTHUS

(Leguminosae/Mimosaceae)

Desmanthus cooleyi *(Eat.) Trel.* **(Acuan [Acuania] cooleyi** *(Eat.) Brit. et Rose***)** – bundleflower

Desmanthus illinoensis *(Michx.) MacM. ex Robinson et Fern.* **(D. brachylobus** *(Willd.) Benth.***; Acuan illinoensis** *(Michx.) Kuntze***; Mimosa illinoensis** *Michx.***)** – Illinois bundleflower, atikatsatsiks ['spider bean'], kitsitsaris ['bad plant'], pezhe gasatho ['rattle plant']

Desmanthus leptolobus *T. et G.* **(Acuan leptolobum** *(T. et G.) O. Ktze.***)** – prairie bundleflower, prairie mimosa, slenderlobed bundleflower, dragon's root

Desmanthus velutinus *Scheele.* **(Acuan velutinum** *(Scheele) Kuntze***)** – bundleflower

Children of the Omaha and Ponca use the dried pods of D. illinoensis [still containing seeds] as rattles, when imitating the ritual dances of the adults. Adults use the boiled leaves as a wash for itches. The Moapa Paiutes were said to have placed the [presumably ground] seeds in the eyes at night, washing them out the next morning, to relieve trachoma. D. illinoensis is now considered an important food crop for livestock animals, and is used in revegetation (Kindscher 1992).

Today, these Desmanthus spp. are of interest because the root bark of D. illinoensis has been used for around two decades as a *tryptamine*-component in ayahuasca analogues, mostly within the US. However, the plant is not an ideal source for these alkaloids, and many report dissapointingly low yields, requiring large amounts of plant material [c.60g for threshold effects]. More recently, D. leptolobus extracts have been bioassayed, both in the form of ayahuasca analogues, and vapourised freebase extracts. This plant seems preferable to D. illinoensis for practical use; some Texan users have dubbed it 'dragon's root' (DeKorne 1994, ed. 1996; Ott 1994; Van Heiden 1998; pers. comms.).

D. cooleyi has yielded c.0.07% *DMT* from roots (Appleseed 1993; Van Heiden 1998).

D. illinoensis aerial parts [flowering and fruiting] tested negative for alkaloids in a broad screening (Fong et al. 1972); root bark yielded 0.34% *DMT*, 0.11% *N-methyltryptamine* [*NMT*], and small amounts of *gramine*, indole-3-acetic acid, N-OH-N-methyl-1H-indole-3-ethanamine, 2-OH-*NMT* and tryptophol; root wood yielded only 0.01% *DMT* and 0.0016% *NMT* (Thompson et al. 1987). Rootbark of this species has sometimes been low or deficient in *DMT*; faulty identification could be responsible in some instances, chemical variation in others (pers. comms.). Seeds have been shown to contain djenkolic acid, N-acetyldjenkolic acid, dichrostachic acid, and smaller amounts of 4-OH-pipecolic acid, S-(β-carboxyisopropyl)-cysteine, and S-(β-carboxyethyl)-cysteine (Krauss & Reinbothe 1973).

D. leptolobus root bark has yielded 0.14% *DMT*, though it has often yielded larger quantities in practice; *gramine* and *NMT* may also be present.

D. velutinus yielded *DMT* in some root collections, but others contained none (Appleseed 1993; Van Heiden 1998).

Desmanthus illinoensis is a perennial shrub with a herbaceous stem, to 2m tall, several stems from the crown, strongly angled, glabrous to hirsute. Leaves bipinnate, 5-10cm long; pinnae 6-14 pairs, 2-4cm long with a small oblong or suborbicular gland between them or between the lower pair of pinnae only; leaflets 20-30 pairs, oblong, linear, acute, 2-5mm long, glabrous or often ciliate; stipules threadlike, 6-10mm long. Flowers perfect, white or whitish, in several-flowered heads; peduncles axillary, in fruit 2-7cm long, ascending; sepals 5, free to the top of the floral cup; calyx united, campanulate, 5-toothed; petals c.2mm long, 5, separate or slightly united at very base; stamens 5, separate to top of floral cup. Pods strongly curved or somewhat twisted together in a dense subglobose head, thin, flat, 1-2.5cm x 4-7mm; seeds 3-5mm long, nearly as wide. Fl. summer.

In moist or dry soil or clay soil in river banks, prairies, pastures, waste ground; from Minnesota across Colorado, south to Florida, Texas and New Mexico (Correll & Johnston 1970; Gleason 1952).

Seed should be soaked overnight before germination [after optional scarification]. Plant c.5-15cm apart, and cover with a sprinkling of soil; water well, but do not saturate. Germination may be staggered over a year or more. Enjoys full sun for part of the day; tolerates poor soil; drought-tolerant once established. Feed regularly, but do not saturate. Plants cultivated in rich soils seem to suffer a higher mortality rate than others. In areas with frosts, prune severely before winter. Root-bark growth can be encouraged by pruning back stems several times a year. Harvest roots late summer-autumn; witholding water at the end of summer, then watering heavily 4-6 weeks before harvest, is reputedly advantageous to alkaloid levels. Cleaned roots are processed more easily when still fresh; lightly beating with a hammer splits the bark, which can then be easily removed (Case 1995; see this and its updates for more in-depth discussion).

DESMODIUM

(Leguminosae/Fabaceae)

Desmodium adscendens *(Sw.) DC.* **(D. caespitosum** *(Poir.) DC.***; D. strangulatum** *Thw.***; Hedysarum adscendens** *Swartz.***; H. caespitosum** *Poir.***)** – beggar-lice, tick clover, margarita, amor seco ['dry love'], amores do campo, carrapichinho, acoumengate, pega-pega, lo a guo, tombolombo, koli-niki ['leopard's groundnut'], ndogbo-nikili ['bush groundnut'], hardstick, hard man, strong back

Desmodium caudatum *DC.* **(D. laburnifolium** *(Poir.) DC.***; Catenaria caudata** *(Thunb.) Schindl.***; C. laburnifolia** *(Poir.) Benth.***; Hedysarum caudatum** *Thunb.***; H. laburnifolium** *Poir.***)** – moh-t'sao, misonaoshi, qing jiu gang

Desmodium cephalotes *(Roxb.) Wall.* **(D. triangulare** *(Retz.) Merr.***; Hedysarum cephalotes** *(Roxb.) Wall. ex Wight et Arn.***; H. triangulare** *Retz.***; H. umbellatum** *Roxb.***)** – karabija

Desmodium gangeticum *DC.* **(D. maculatum** *(L.) DC.***; Aeschinomene gangetica** *(L.) Poir.***; A. maculata** *(L.) Poir.***; Hedysarum collinum** *Roxb.***; H. gangeticum** *L.***; H. maculatum** *L.***)** – saumya, amsúmat ['rich in soma juice'], shalaparni, salpani, salvan, sarivan, pullaadi, gitanaram, kolapanna

Desmodium gyrans *DC.* **(D. motorium** *(Houtt.) Merr.***; D. roylei** *Wight et Arn.***; Codariocalyx gyrans** *(L.f.) Hassk.***; C. motorius** *(Houtt.) Ohashi***; Hedysarum gyrans** *L.f.***; H. motorium** *Houtt.***)** – moving plant, telegraph plant, whirling plant, gyred cock's head, bhunakra, ote-atil

Desmodium lasiocarpum *(Beauv.) DC.* **(D. latifolium** *DC.***)** – anguchabadi, abashoka, chinanduri, chimbattai, damgere, ewe omo, kohemi koko, otokataka, simmathasura

Desmodium paniculatum *(L.) DC.* **(D. dillenii** *Darl.***; D. glabellum** *(Michx.) DC.***; D. perplexum** *Schub.***; Meibomia pubens** *(T. et G.) Rydb.***)** – panicled tick clover

Desmodium pulchellum *Benth. ex Baker* **(Dicerma pulchellum** *(L.) DC.***; Hedysarum pulchellum** *L.***; Phyllodium pulchellum** *(L.) Desv.***)** – birkapi, caliacay, jatasalpara, kadumuduru, krishnopornii, takamala, pai chien cao, p'ai-chien-t'sao ['string of coins']

Desmodium racemosum *(Thunb.) DC.* **(D. oxyphyllum** *DC.***)** – Chinese Desmodium, shan-ma-huang, nusubitonasi

Desmodium ramosissimum *G. Don.* **(D. mauritianum** *(Willd.) DC.***)**

Desmodium tiliifolium *(D. Don.) G. Don.* **(D. cinerascens** *Franch.***; D. elegans** *DC.***; D. esquirolii** *H. Lév.***; D. forrestii** *Schindl.***; D. franchetii** *Rehder***; D. glaucophyllum** *Pamp.***; D. rhabdocladum** *Franch.***; D. spicatum** *Rehder***; Hedysarum tiliifolium** *D. Don.***)**

Desmodium triflorum *(L.) DC.* **(Hedysarum triflorum** *L.***; Nicholsonia triflora** *(L.) Griseb.***)** – sweethearts, hinundupiya, jaharipana, jajaladbihir, kodalia, kolante, koli-niki, marlomin, muntamandu, outoupilli, pacpaclangao, pookarisa, ranmethi, sirupullady, trefle noir

Various Desmodium spp. have uses in folk medicine, particularly in Indian districts. Uses are generally to treat dysentery, liver diseases, catarrh, eye diseases and as a poultice for acne, abscesses and ulcers. Stems of some spp. are used to weave baskets and prawn traps, and flowers of some yield dyes. The leaves of D. oldhami are used as a tea in Japan (Allen & Allen 1981; Uphof 1968), and the Houma of N. America consume a root infusion of D. paniculatum as a stimulant. D. lasiocarpum is smoked by the Bontoc of the Philippines (Ott 1993), and the Bimin-Kuskusmin of Papua New Guinea use the leaves of a Desmodium sp. known as 'khaandisiim' as a wrapper for their ritual tobacco [see **Nicotiana**], smoked in the 7th stage of initiation (Poole 1987). In n. Thailand, the Mien use D. laxiflorum roots and leaves as a tonic and to treat high blood pressure; it has also been used to relieve unconsciousness. The Akha use D. longipes roots as a tonic, and to treat convulsions and epilepsy (Anderson 1993; Trout ed. 1997f). In Malaya, the roots of a Desmodium sp. ['kachang hantu'] are used in the manufacture of dart-poisons; the roots tested alkaloid-positive (Bisset & Woods 1966). The Asian D. cephalotes has been used as a CNS stimulant, as well as to treat bronchial spasms, coughs and dysentery (Ghosal & Mehta 1974).

In India, D. heterocarpon [D. polycarpum] has been used to relieve fainting and convulsions (Nadkarni 1976). In Ayurvedic medicine, D. gyrans leaves are considered to act as a tonic, aphrodisiac, diuretic and febrifuge; roots treat coughs and asthma, and are emollient, laxative and antidysenteric (Ghosal et al. 1972a). D. gangeticum aerial parts are used as an aphrodisiac and uterine stimulant; root extracts are used to treat diarrhoea, asthma and chronic fever. In Ayurvedic medicine, it has been used in compound medicines [with 10 or more other herbal drugs] to treat fever and a variety of other complaints, including "affections of the brain" and delirium in fever. The plant is known as 'saumya' or 'amsumat' ['rich in soma juice'], hinting at knowledge of its chemical properties (Ghosal & Bhattacharya 1972; Nadkarni 1976; Ott 1993). The Indian D. latifolium is used for its roots, to treat insanity, amongst other complaints. Leaves of D. triflorum are given as an anticonvulsant, galactagogue and diuretic (Nadkarni 1976). Also in Ayurveda, D. pulchellum bark is decocted to treat haemorrhage, poisoning, diarrhoea and eye diseases; flowers treat biliousness (Ghosal & Mukherjee 1964; Ghosal et al. 1972c; Nadkarni 1976). In TCM, the aerial parts of the same plant are used as an antipyretic and cold remedy (Huang 1993). In China, D. caudatum [as whole plant, which is collected in May] is used as an analgesic, antiseptic, antipyretic, detoxifier and insecticide. D. racemosum is also used there as a diaphoretic and respiratory stimulant (Perry & Metzger 1980; Trout ed. 1997f).

In central Africa, D. adscendens leaves are used to treat asthma, fever, pain, epilepsy (N'gouemo et al. 1996), convulsions and vertigo. The plant has been used magically when aid of some kind is needed. For this purpose, a 'heap' of leaves is mixed with earth and spread over the body; secretly, the person goes out into the sun. No other details were available (Trout ed. 1997f, citing Motte, E. 1980. Les Plantes Chez Les Pygmées Aka et Les Monzombo (Centrafrique), p.376). D. adscendens is considered to have 'magical powers' in the Amazon. The plant is taken as an infusion to treat nervousness, and is also believed to have the power to "reattract a mate whose affection has strayed" (Duke & Vasquez 1994). Mestizo shamans in Peru sometimes use it as a love charm. For this purpose, the roots from 5-6 plants are pulverised and dried to a powder, which is infused with perfume, dried again, and 'given strength' in an ayahuasca ceremony [see **Banisteriopsis**]. To be used, a small amount of the powder is "placed discretely on the body of a lady to make her fall in love with the owner of the preparation" (Luna & Amaringo 1991). The Cuna use D. intortum to prepare a love potion (Trout ed. 1997f). In Liberia, a leaf infusion of D. ramosissimum is used as a wash for children suffering convulsions (Watt 1967); in some parts of tropical Africa, the plant has been used as an excitant (Uphof 1968).

Fresh aerial parts of Desmodium spp. contained more than 3-5 times the amount of alkaloids than dried material, though little difference was noted with roots (Ghosal & Bhattacharya 1972; Ghosal et al. 1972a) – the alkaloids generally consisting of tryptamines, β-carbolines, phenethylamines, and tetrahydroisoquinolines [THIQs].

D. adscendens leaves contain indole-3-alkylamines, phenethylamines, THIQs and triterpenoid saponins [mostly dehydrosoyasaponin]. A plant extract acted as a CNS-depressant, hypothermic and analgesic, as well as inhibiting synthesis and release of *histamine*, prostaglandins and arachidonic acid (N'gouemo et al. 1996).

D. caudatum [harv. May, Japan] root has yielded 0.087% *DMT*, 0.03% *bufotenine* N-oxide, and the flavonoid desmodol; stems yielded 0.0035% *DMT*, 0.04% *bufotenine* [5-OH-DMT], 0.004% *bufotenine* N-oxide, and desmodol (Ueno et al. 1978); canavanine [see **Canavalia**] was also detected in the plant (Bell et al. 1978).

D. cephalotes stems and roots [combined] yielded 0.011% alkaloids – 0.00375% *hordenine*, 0.0027% *tyramine*, 0.00075% *phenethylamine*, 0.0014% candicine [4-OH-N,N,N-trimethyl-*phenethylamine*], 0.00088% salsolidine [6,7-dimethoxy-1-methyl-THIQ – see **Pachycereus**], 0.0018% *choline* and 0.0007% of an unidentified base; leaves yielded 0.0048% alkaloids, consisting mostly of *phenethylamine*, with smaller amounts of *tyramine* and traces of salsolidine (Ghosal & Mehta 1974).

D. gangeticum roots yielded 0.02% *DMT*, 0.0075% *DMT* N-oxide, *5-MeO-DMT* N-oxide, 0.0175% *phenethylamine*, 0.03% N-methyl-*tyramine*, 0.05% *hordenine*, 2-(N,N-dimethylamino)-*acetophenone*, candicine, *choline* and hypaphorine [see **Erythrina**]. Stems and leaves yielded 0.01-0.03% alkaloids [much higher in fresh samples]; the following yields are given as w/w – 0.041% *DMT*, 0.033% *DMT* N-oxide, 0.057% *5-MeO-DMT* [*5-methoxy-DMT*], 0.018% *5-MeO-DMT* N-oxide, 0.003% N-methyl-*tetrahydroharman*, leptocladine [1,2-dimethyl-THβC], 6-MeO-2-methyl-THβC [2-methyl-*pinoline*] and 0.004% 6-MeO-2-methyl-β-carbolinium salt [has AChEI activity]. In dry aerial parts, *5-MeO-DMT* is a dominant alkaloid. Seeds yielded 0.015% alkaloids – *DMT*, *DMT* N-oxide, 6-MeO-2-methyl-β-carbolinium salt and *norharman* (Banerjee & Ghosal 1969; Ghosal 1972; Ghosal & Banerjee 1969; Ghosal & Bhattacharya 1972; Ghosal et al. 1970b); the plant has also yielded 2-methyl-THβC, 2-methyl-β-carbolinium quaternary salt, 6-MeO-2-methyl-THβC quaternary salt, and 1,2-dimethyl-β-carbolinium salt [melinonine F] (Shulgin & Shulgin 1997). Alkaloids reached highest levels in red leaves from late autumn to winter (Trout pers. comm.). Alkaloids from aerial parts have CNS-stimulant, depressor, anticholinesterase and smooth muscle stimulant actions in animals (Ghosal & Bhattacharya 1972; Rastogi & Mehrotra ed. 1990-1993).

D. gyrans leaves from India have yielded 0.036% alkaloids [11.1% *DMT*, 25% *DMT* N-oxide, 5.55% *5-MeO-DMT*, traces *5-MeO-DMT* N-oxide, 8.3% *bufotenine*, 13.9% 5-MeO-*N-methyltryptamine* [5-MeO-*NMT*], 13.9% *phenethylamine*, 2.8% of an unidentified β-carboline, 13.9% *choline*, and uncharacterised indole-3-alkylamines]; roots yielded 0.33% alkaloids [3% a combination of *DMT*, *DMT* N-oxide and 2 unidentified indole-3-alkylamines, as well as 24.24% *choline*, 72.7% hypaphorine and traces of unidentified phenethylamines] (Ghosal et al. 1970b, 1972a). Canavanine has also been found in the plant (Bell et al. 1978).

D. pulchellum whole plant from India has yielded 0.3% alkaloids in one test [including, as % of plant, 0.2-0.25% *5-MeO-DMT*, and 0.0018% of combined *DMT*, *DMT* N-oxide and *bufotenine*] (Ghosal & Mukherjee 1964); another test also found 0.0004% *5-MeO-DMT* N-oxide, 5-MeO-*NMT* and *gramine* (Ghosal & Mukherjee 1966). The root of the young seedling has yielded c.0.27% *DMT*, 0.011% *DMT* N-oxide, 0.041% *DMT* N-methylcation, 0.022% N-methyl-*serotonin*, traces of 5-MeO-*NMT*, 0.026% *adrenoglomerulotropin* and traces of 6-MeO-N-methyl-β-carbolinium salt; root of mature plants yielded 0.067-0.451% *DMT*, 0.012-0.121% *DMT* N-oxide, 0.022-0.132% *5-MeO-DMT*, 0.013% N-methyl-*serotonin*, 0.0015% 3-alkylindole, 0.001% 5-OH-3-alkylindole, and traces of *bufotenine*, *bufotenine* N-oxide and 2-methyl-*pinoline*. Stem and leaf of mature plants yielded 0.294% *DMT*, 0.07% *DMT* N-oxide, 0.476% *5-MeO-DMT*, 0.154% *5-MeO-tryptamine*, 0.112% *bufotenine* and traces of *bufotenine* N-oxide. Green fruits and ripe seeds yielded 0.001% *DMT*, up to 0.007% *DMT* N-oxide and c.0.002% each of *5-MeO-DMT* and *5-MeO-tryptamine*; *harman*, *tetrahydroharman* and *pinoline* were also found in seeds, *harman* also in fruits (Ghosal 1972; Ghosal et al. 1972c). The plant has also yielded *hordenine*, *norharman*, 2-methyl-THβC, 2-methyl-β-carbolinium quaternary salt, 1,2-dimethyl-6-MeO-THβC, melinonine F, and canavanine. In dogs, the stem-leaf alkaloids [0.1mg/kg i.v.] caused initial respiratory stimulation, followed by hypotension and severe bronchoconstriction, which resulted in death in some cases; cardiac depression was also observed. Alkaloids of the green fruits and seeds inhibited cholinesterase (Bell et al. 1978; Ghosal 1972; Ghosal & Mukherjee 1966; Ghosal et al. 1970b, 1972c; Harborne et al. ed. 1971; Shulgin & Shulgin 1997).

D. racemosum was found to contain *5-MeO-DMT* in the whole plant (Hsu et al. 1986); canavanine has also been found (Bell et al. 1978).

D. tiliifolium root has yielded 0.00073% *tryptamine*, 0.0021% *tyramine*, 0.0006% *DMPEA*, 0.0022% N,N-dimethyl-*DMPEA*, 0.0012% *normacromerine*, 0.0005% *hordenine*, 0.0031% salsolidine, 0.0014% salsoline, 0.0036% *choline*, 0.0003% abrine [N-methyl-*tryptophan*], 0.0029% hypaphorine and 0.0003% betaine; homovanillylamine [3-MeO-*tyramine*] and N,N-dimethylhomovanillylamine have also been found in the plant. Alkaloid content is highest in roots, and lowest in leaves, with the stems being intermediate in concentration (Ghosal 1972; Ghosal & Srivastava 1973b; Lundstrom 1989).

D. triflorum from India yielded 0.01-0.015% alkaloids from the leaf [traces of *DMT* N-oxide, 17% *phenethylamine*, 12% indole-3-acetic acid, 9% *tyramine*, 8% hypaphorine, 5% N,N-dimethyltryptophan, 5% S-(+)-N,N-dimethyltryptophan methyl ester, 2% S-(-)-stachydrine, traces of trigonelline, *hordenine*, and hypaphorine methyl ester, and 39% *choline*, betaine and other bases]. Stems yielded 0.008% alkaloids [3% *DMT* N-oxide, 15% *phenethylamine*, 7% *tyramine*, 2% hypaphorine, 2% S-(+)-N,N-dimethyltryptophan methyl ester, traces of hypaphorine methyl es-

ter, N,N-dimethyltryptophan, *hordenine*, and indole-3-acetic acid, 3% S-(-)-stachydrine, 1% trigonelline, and 62% *choline*, betaine and other bases]. Stem and leaf have also yielded *tryptamine*. Roots yielded 0.01-0.018% alkaloids [4% *DMT* N-oxide, 5% hypaphorine, 2% hypaphorine methyl ester, traces of N,N-dimethyltryptophan, 3% S-(+)-N,N-dimethyltryptophan methyl ester, 11% *tyramine*, 6% *phenethylamine*, 3% *hordenine*, 3% 3,4-dihydroxyphenethyl-trimethylammonium cation, 2% S-(-)-stachydrine, 1% trigonelline, 58% combined betaine, *choline*, and other bases, traces of indole-3-acetic acid, and an unidentified *phenethylamine* with strong *nicotine*-like activity] (Ghosal 1972; Ghosal et al. 1971b, 1973); this species has also yielded coryneine [3,4-dimethoxy-N,N,N-trimethyl-*phenethylamine*] (Lundstrom 1989). The total alkaloids from the root [50mg/kg i.p.] "produced excitation, piloerection, tremors, salivation, and increased motor activity in albino rats and mice" (Ghosal et al. 1973).

D. brachypodum [leaf and stem] and D. uncinatum [whole plant] from Queensland [Australia] gave negative tests for the presence of alkaloids (CSIRO 1990). Others have found canavanine in D. uncinatum (Bell et al. 1978).

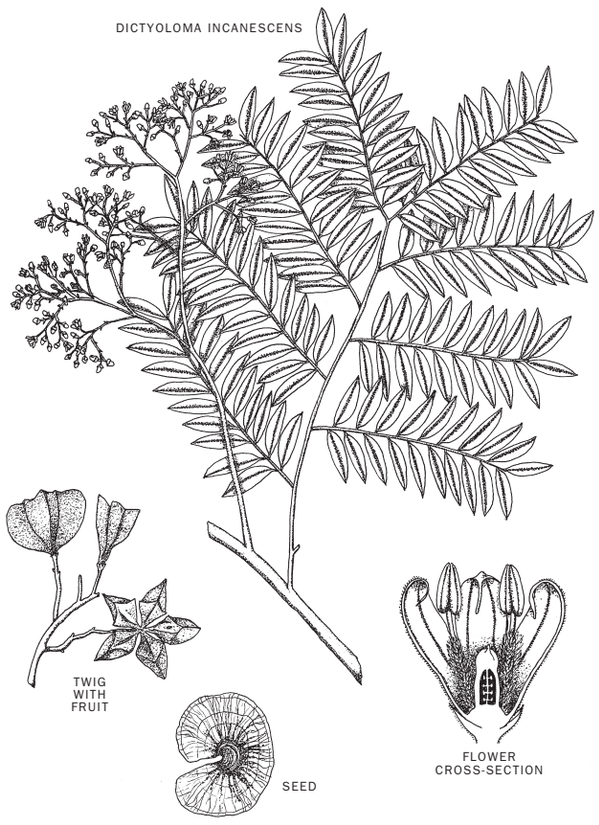
Desmodium gangeticum is a small shrub 0.6-1.2m tall; stems irregularly angled, glabrous; branches angled, covered with appressed white hairs. Leaves 1-foliate; petioles 1-2cm long; stipules dry, thin and membranous, 6-8mm long, linear subulate, striate at base; leaflets membranous, 9-12.5 x 3.5-6.3cm, ovate-oblong, acute or slightly acuminate, margins somewhat waved, glabrous and green above, paler and clothed with dense white appressed hairs beneath, reticulately veined, base rounded, truncate or subcordate; main nerves 8-12 pairs; petiolules 1.5mm long, hairy; stipels 3mm long, subulate. Flowers in copious ascending terminal and axillary racemes 15-30cm long, arranged in few-flowered clusters along a slender pubescent angular rachis; pedicels 4-6mm long, filiform, pubescent; bracts subulate, 1.5-3mm long; bracteoles minute; calyx 2mm long, hairy, teeth triangular, longer than the campanulate tube; corolla 4mm long, violet or white, standard 3mm broad, cuneate at base. Pods subfalcate, 12-20 x 2mm, deeply indented on the lower, slightly indented on the upper edge, joints 6-8, longer than broad, not opening, sparsely clothed with minute hooked hairs, lower edge rounded, upper edge straight.

Outer Himalaya up to 1530m, throughout India to Ceylon and Burma, Malay, China, Philippines and tropical Africa (Kirtikar & Basu 1980).

Plant in sandy loam, potting soil, or good garden dirt, not too rich; grows best in the ground, rather than potted; drought-tolerant, can handle full sun. Plants do not seem to produce *5-MeO-DMT* or *DMT* until 2-3 years old, at least in cultivated material (Trout ed. 1997f).

DICTYOLOMA

(Rutaceae)



Dictyoloma incanescens *DC.* **(D. vandellianum** *Adr. Juss.***)** – tinaqui

I have found no ethnobotanical information regarding this South American tree. D. peruviana [the only other member of the genus], known as 'shiksi huama', is used in Peru with **Ocimum** micranthum ['albahaca'] to reduce sexual desire in over-amorous women (Luna & Amaringo 1991).

D. incanescens is the plant from which *5-methoxy-DMT* was first isolated, in a yield of 0.04% from the bark, as the picrate salt (Pachter et al. 1959); stems have yielded the alkaloids casimiroine [see **Casimiroa**] and 4,7,8-trimethoxy-1-methyl-2-quinolone, as well as the limonoid deacetylspathelin [and its 21- and 23-γ-OH-butenolide derivatives]; fruits yielded the above limonoids, as well as triglycerides and sitosterol (Vieira et al. 1988). Although yields for the above stem components are given by Vieira et al., it is unclear whether the weight given in the data refers to the stems or the crude extract. The plant has also yielded 6-(3-methyl-2-butenyl)-allopteroxylin (Buckingham et al. ed. 1994).

D. peruviana stem bark has yielded 0.126% crude alkaloids, including dictyolomide A and dictyolomide B (Lavaud et al. 1995).

Dictyoloma incanescens is a tree 2-6m tall; branchlets 2-3mm thick, leafy, internodes 5-6cm long, branchlets terete, shortly and densely rusty-pilose. Leaves to 10-20cm long, erect-spreading, subcoriaceous, upper-side sparingly pilose, under-side very shortly tomentose and sericeous-pilose, 6-12-paired, petiole shortly rusty-pilose, internodes usually with alternate narrow wings; leaflets 3-5cm long, barely 1.5cm wide, oblique-oblong, unequal, obtuse, lateral nerves distinct on under-side, margin densely glandulose, revolute, base +- oblique, sessile, apex +- attenuate. Inflorescence a panicle to 33-66cm long, in upper axils, multi-branched, branchlets 10-15cm long, extremities cymose-corymbose, +- shortly rusty-tomentose; pedicels 2-3mm long; calyx laciniate, acute-ovate; sepals appressed sericeous-pilose, 1.5mm long, 1mm wide; corolla 6-lobed, petals 6 x 2mm, apex long, linear, inflexed; in females petals short, purplish, appendicule half equal, bifid, externally and internally glabrous, margin densely pallid-villose; anthers oblong-ovate, 1mm long, purplish; disc ashy-pilose, 2mm long. Ovary carpel 3mm long, laterally compressed, densely villose; style usually 2mm long, ashy-puberulous; stigma thick, deeply 5-lobed, lobes 0.5mm long, rotundate. Fruit a capsule, shortly rusty-pilose, up to 15 x 8mm; seed 2.5mm long, 2mm wide, wing 3.5mm wide, shiny, purplish, parenchyma lacking.

In Brazil (Fridericus & DeMartius ed. 1965-1975).

DICTYONEMA

(Dictyonemataceae)

DICTYONEMA SP.
'NENENDAPE' ON WOOD

Dictyonema sp. – nememdape, nenendape

The Waorani of eastern Ecuador used this lichenised tree fungus in the past, up until early last century. Their name for it is not specific, as they apply the same name to many other fungi. It was said to have been used by "bad shamans", who "ate it to send a curse to cause other Waorani to die". To place things into context, it is worth noting that the Waorani consider the use of psychoactive flora to be an "aggressive, anti-social act" practiced only by those who intend to project harm onto others. Any existing Waorani shamans obviously practice their craft in secret to avoid persecution from their fellow community members. The fungus was infused in water, along with an unidentified Bryophyte [the group containing mosses and liverworts] known as 'kigiwai' – when drunk, the infusion was said to cause severe headaches and confusion (Davis & Yost 1983). The Waorani also believe it to cause sterility, and may put it in children's drinks to cause future barrenness (Schultes & Raffauf 1990).

Chemistry of this rare Dictyonema sp. is unknown, though the related D. glabratum has yielded 3 galactosyldiacylglycerides [glycolipids] (Sassaki et al. 1999).

Dictyonema genus – basidiocarps sessile or resupinate, single or united in rosettes, soft or paper-like, small or up to 20cm or more diam. Upper surface glabrous, villous, hispid or radially fibrillose, sometimes sulcate or zonate, greyish or greenish, olivaceous or blue. Lower surface even, granulose, reticulate or with low concentrical bands of hymenophore. Hyphal system monomitic; generative hyphae thin- or thick-walled, with septa, with clamps or without, hyaline or yellowish, 3-11(-13)µm diam.; hymenium thickening, consisting of abundant basidioles and basidia, organised into a definite palisade layer; cystidia and gloeocystidia absent. Basidia in fascicles, clavate or subcylindrical, not constricted, 15-30 x 5-9µm, with 4 slightly curved slender sterigmata. Spores subcylindrical, narrowly ellipsoid or subnavicular, 6-10 x 2.8-5µm, thin-walled, hyaline, non-amyloid. Algal layer usually well-developed [algal component: Chroococcus or Scytonema] (Parmasto 1978).

The Waorani Dictyonema sp. has not yet been formally described, but it is known to possess a white hymenial layer, and a bright green-blue upper surface (Davis & Yost 1983).

DIMORPHANDRA

(Leguminosae/Caesalpiniaceae)

Dimorphandra mollis *Benth.* – faveira, faveiro-do-cerrado, fava-de-anta ['broadbean of the tapir'], farinha, jacaranda, barbatimão

Dimorphandra parviflora *Spruce ex Benth.* – holótipo, faveira, faveira-vermelha, sucupira amarela, fava-uim

According to the legendary ethnobotanist Richard Spruce, who collected D. parviflora in 1851 at Barra, Brazil, its seeds were used to manufacture an inebriating 'paricá' snuff [see **Anadenanthera** and **Virola**] (De Silva 1986; Ott 1993). It was not noted whether the seeds were mixed with these other snuff plants, or used alone – further studies are needed to verify this report. The related D. mollis is known to cause cattle intoxications in Brazil, with symptoms including intestinal disturbance, colic, blood in excrement, tremor, and cardiac depression. Later the animals lie down and moan until they die, if a fatal dose has been consumed [c.2.5kg/100kg] (Pott & Alfonso 2000).

D. mollis contains unidentified alkaloids [0.58% from bark, 0.7% from leaflets] and rutin (Murad & Gazinelli 1973) [c.8% in pods] (Mors & Rizzini 1966); the seeds contain protein compounds which inhibit the enzyme trypsin (Macedo et al. 2000).

D. parviflora has not been chemically studied to my knowledge.

Dimorphandra parviflora is a medium to large tree, 8-20(-23)m tall, 20-30(-60)cm thick; bark bitter; branches lenticellose; petioles, rachis and inflorescence rusty-puberulent. Leaves petiolate, with 8-12 pairs of primary opposing pinnae, subopposite or alternating, short-petiolate; petiole commonly subcylindric, deep and narrowly canaliculate, 3.5-5.5cm; primary petiole 3mm; secondary petiole thin, 1-1.5mm; pinnules oblique, ovate-elliptic, inequal, 1.25-1.5(-2)cm long, 6-9(-12)mm wide, subchartaceous, glabrous on upper side, finely puberulent beneath, base asymmetric, truncate on one side, the other cuneate, apex obtuse, margin entire, slightly revolute, primary nerves immersed in upper face, prominent beneath, secondary nerves immersed in both sides, or visible beneath under a hand lens. Inflorescence corymbose-paniculate, to 20cm, erect, consisting of densely flowered spikes, mostly reaching the same height as the upper leaves; peduncle thick, densely lenticellose; flowers foetid-creamy, 2-2.5mm; calyx glabrous, 1-1.5mm, 5-lobed at apex, lobes rounded, glabrous within and without; corolla with 5 petals double the size of the calyx, 2-3mm, glabrous; stamens 5, epipetalous, same size as petals; filaments glabrous; anthers rimose, introrse; staminodes 5, apex clavate-spatulate. Fruit a stipitate legume, thick, erect, 9-10 x 2-2.5cm, glabrous and wrinkled on the upper face.

In bush and capoeiras of firm land; Brazilian Amazonia (De Silva 1986).

DIOSCOREA

(Dioscoreaceae)

Dioscorea alata *L.* **(D. atropurpurea** *Roxb.***; D. colocasiifolia** *Pax***; D. globosa** *Roxb.***; D. purpurea** *Roxb.***; D. rubella** *Roxb.***; D. sapinii** *De Wildemann***; D. sativa** *Munro***)** – common yam, humped yam, winged yam, white yam, water yam, greater Asiatic yam, large leaf yam, chupri alu, pindalu

Dioscorea balcanica *Košanin*

Dioscorea batatas *Dcne.* – Chinese yam, cinnamon vine

Dioscorea deltoidea *Wall.* – kins, kniss, kildri, krit

Dioscorea dregeana *(Kunth) Dur. et Schinz* **(Helmia dregeana** *Kunth***)** – isidakwa

Dioscorea dumetorum *(Kunth) Pax.* **(D. buchholziana** *Engl.***; Helmia dumetorum** *Kunth***)**

Dioscorea hirsuta *M. Martens et Galeotti*

Dioscorea hispida *Dennstedt* **(D. daemona** *Roxb.***; D. mollissima** *Blume***)** – choo-ay-go, pashpoli ['strangle cake'], darakanda, kashalu, manda, tsiagri-nuren

Dioscorea mexicana *Scheidw.* **(D. deamii** *Matuda***; D. macrostachya var. sessiflora** *Uline***; D. tuerckheimii** *R. Knuth***)**

Dioscorea opposita *Thunb.* **(D. japonica** *Thunb.***)** – shan yao ['mountain medicine'], Chinese yam

Dioscorea villosa *L.* – China root, colic root, rheumatism root, devil's bones

Dioscorea spp. – wild yam, cabeza de negro

'Yams', Dioscorea spp., are much used today to yield precursors for manufacture of human steroid hormones, while some species exhibit narcotic and other medicinal properties. Yams are also cultivated for their edible tubers in tropical and subtropical zones of the world [though some are hardy in temperate regions]. The cultivation of enormous yam tubers is important in magical belief systems amongst many indigenous peoples of Papua New Guinea (Burkill 1985-1997; Paijmans ed. 1976).

Amongst some yam species cultivated or found wild in Africa, sever-

al are known to have tubers which may be narcotic or toxic in their fresh state. This toxicity is removed by a combination of cooking and leaching, the exact procedures differing in different areas. The fresh tuber of D. alata is considered narcotic, though some varieties are edible. The tuber of D. dregeana has narcotic and paralytic effects, and has been used to stun monkeys. It is sometimes used in S. African traditional medicine as a sedative anlgesic, and to treat epilepsy, hysteria, psychosis and insomnia. It is sometimes consumed with **Boophane** disticha for divination. The wild variety of D. dumetorum shows narcotic and convulsant properties, and has also been used to capture monkeys. D. sansibarensis is sometimes used as a homicidal poison. Tubers of D. diversifolia and D. dregeana are used by the Zulu as a remedy for 'hysteria', and an infusion of the latter is sometimes taken in 1 tsp doses as a soporific. Ingestion of these tubers, improperly cooked, causes paralysis of the lower limbs, and a 'drunken' state (Burkill 1985-1997; Van Wyk & Gericke 2000; Van Wyk et al. 1997; Watt 1967; Watt & Breyer-Brandwijk 1932).

These toxic properties of Dioscorea spp. are also known in Mexico, where they have been used obscurely in witchcraft (Heffern 1974). In Peru, a Dioscorea sp. known as 'papas-trueno' is said to enable one to control the rain if ingested (Luna & Amaringo 1991). In India, tubers of D. purpurea are used as an acrid aphrodisiac. In Burma, D. hispida tubers are eaten after slicing, repeated leaching, and steaming. Without this preparation, ingestion can cause "irritation in the mouth and throat, vomiting of blood, a sense of suffocation, drowsiness and exhaustion; and a piece of the tuber the size of an apple is sufficient to cause death in 6 hours". Though sometimes used as a poison, the tubers can be applied as a poultice to relieve swellings (Nadkarni 1976). Dioscorea spp. have also been used in Malaya, along with Antiaris spp. [curare-poison plants – see also **Strychnos**], to prepare arrow poisons for hunting (Bisset & Woods 1966).

In Arnhem Land, northern Australia, D. bulbifera [sometimes known as D. bulbifera var. rotunda] is eaten by local indigenous people. Considered 'cheeky' [referring to the undesirable bitterness] when fresh or improperly prepared, the tubers are usually baked and leached in running water overnight to render them edible; or, they are at least chopped and cooked (Smith et al. 1993; Webster et al. 1984). In some parts of Africa, D. bulbifera [D. latifolia] tuber is used as a suicidal poison and tubers of D. smilacifolia have been used as homicidal poisons. In Gabon, the tuber of D. latifolia var. sylvestris is sometimes used to strengthen palm wine [see *Methods of Ingestion*] (De Smet 1998).

The tuber of D. opposita is used in TCM – it is considered sweet, and has an affinity for the spleen and lungs. The dried, sliced tuber is used as a kidney, lung and stomach tonic, and applied as a poultice for abscesses, boils, bruises, carbuncles, swellings and other skin sores. It relieves diarrhoea, moistens skin and hair, strengthens kidneys, stimulates appetite, nourishes the semen, stimulates endocrine glands and tones the immune system. In decoction, it is usually given in doses of 10-30g (Bremness 1994; Hsu et al. 1986; Keys 1976; Reid 1995).

D. villosa tuber has been used to relieve muscle tension and spasm, leg and menstrual pains, inflamed colon, rheumatism and colic. It also dilates blood vessels and increases bile flow. In India, Dioscorea spp. are considered detergent, cardiotonic, expectorant, diaphoretic and antispasmodic (Kirtikar & Basu 1980; Polunin & Robbins 1992).

Until 1970, D. mexicana was the only yam species used as a commercial source of hormones for female contraceptive pills, made from the steroid sapogenin *diosgenin*, which can be transformed to a wide range of steroid hormones including cortisone and progesterone. *Diosgenin* had been isolated from other species earlier [such as from D. tokoro in 1936], but such species had not been put to much use. However, now many other species, particularly D. villosa [and also D. deltoidea and D. prazeri, in India], are used for these and other products (Abrol et al. 1963; Coppen 1980; Marker et al. 1940). A number of wild yam extracts are being sold in health supplement stores as 'pre-DHEA', containing precursors to *dehydroepiandrosterone*, which is difficult to obtain in Australia.

D. alata tuber contains c.88% carbohydrates, 7% protein, a saponin, alatanin 2, and the pyrrolidine alkaloid *dioscorine* [causes extreme excitation of CNS, and may paralyse it] (Buckingham et al. ed. 1994; Harborne & Baxter ed. 1993; Henry 1939; Watt 1967).

D. balcanica tuber has yielded up to c.2% *diosgenin* (Bisha & Pisha 1968).

D. batatas aerial tubers have yielded [w/w] 0.0103-0.0164% *diosgenin* (Edwards et al. 2002).

D. bulbifera tuber has reportedly yielded *dioscorine* (Willaman & Li 1970), and 0.08% *diosgenin* (Quigley 1978). However, more detailed analysis [using wild-harvested Australian varieties selected for their bitterness] could detect no *dioscorine* or other alkaloids, no *diosgenin*, and no saponins or cyanide. The presence of the furanoid nor-diterpene diosbulbin D [0.007%] was confirmed; diosbulbin D was determined to be the main compound responsible for the bitterness of the tubers. Bitter Japanese D. bulbifera tubers have yielded [w/w] up to 0.015% combined diosbulbins (Webster et al. 1984). Boiling, baking, and leaching were tested separately for their ability to remove bitterness from the Arnhem Land varieties, as measured by both taste and diosbulbin D content. Leaching was shown to be the only procedure that was effective alone; baking or boiling was thought to contribute to the process by softening tissue structure, allowing for greater leaching efficiency. However, an extract of the bitter yams was shown to be non-toxic in mice, at up to 4.5g/kg [the highest dose tested] (Webster et al. 1984).

D. burkilliana tuber has yielded 0.42-0.92% *diosgenin* (Quigley 1978).

D. deltoidea, from n.w. Himalayas, yielded [traces-]0.8-8% *diosgenin* from the tubers. Yields were highest when tubers were dormant in the winter (Abrol et al. 1963).

D. dregeana tubers have yielded 0.03% *dioscorine* and 0.02% crinamine [hypnotic sedative (Koorbanally et al. 2000); respiratory depressant and powerful transient hypotensive in dogs – LD50 10mg/kg (Buckingham et al. ed. 1994)], though the extraction was not exhaustive; sitosterol, stigmasterol, 3-(4'-OH,3'-MeO-phenyl)propenoate [0.024%], and 3,4',5-trihydroxybibenzyl [0.016%] were also isolated (Mulholland et al. 2002).

D. dumetorum tuber has yielded *dioscorine*, dihydro-*dioscorine* and dioscine (Watt 1967; Willaman & Li 1970).

D. hirsuta tuber has yielded *dioscorine* (Henry 1939).

D. hispida tuber has yielded [w/w] 0.017-0.12% *dioscorine*; no sapogenins, *diosgenin*, or cyanide have been found (Pinder 1953; Webster et al. 1984).

D. opposita tuber contains starch, mucilage, fat, sugar, the enzyme amylase, and the amino acids arginine, leucine and tyrosine (Reid 1994).

D. pentaphylla tuber has yielded *dioscorine* (Willaman & Li 1970).

D. prazeri rhizome tuber has yielded 2.1% *diosgenin* (Abrol et al. 1963).

D. sansibarensis tuber has yielded *dioscorine*, dihydro-*dioscorine* (Willaman & Li 1970), and 0.05% *diosgenin* (Quigley 1978).

D. villosa tubers have yielded [w/w] 0.00022-0.0519% *diosgenin* (Edwards et al. 2002; Marker et al. 1940).

Dioscorea dregeana is a climber; stems stout, very twining, pubescent. Leaves alternate; fully developed petiole 7.6-10.2cm long; leaf blade digitately trifoliate; leaflets 7.6-20.3cm long, thin but firm in texture, green, pubescent beneath, the end one obovate-cuspidate, triplinerved from base to apex, the side ones obliquely ovate, much-produced on the lower side. Male flowers in ample panicles, in sessile globose clusters spaced out on the slender, spreading pubescent branches; perianth campanulate, 16mm long, with short tube and 6 subequal spreading lobes; segments ovate; bracts ovate, very hairy, about as long as clusters; fertile stamens 6; filaments short, incurved; anthers small, oblong or globose; style rudimentary. Female flowers in ample panicles, with spreading spicate branches; perianth segments 6, free, very small, ovate; staminodes minute, 0-6; ovary inferior, linear-oblong, acutely triquetrous, 3-celled, densely pubescent; ovules 2 in each cell, laterally attached near apex; styles 3, short; stigmas 3, terminal, bifid or entire, reflexed above style. Capsule oblong, deflexed, 3.8-5.1cm long, loculicidal; seeds compressed, with semiorbicular apical wing about the breadth of the nucleus.

Eastern S. Africa and Cape region (Harvey & Sonder 1984; Kirtikar & Basu 1980).

DIPLOPTERYS

(Malpighiaceae)

Diplopterys cabrerana *(Cuatrecasas) B. Gates* **(Banisteriopsis cabrerana** *Cuatr.***; B. rusbyana** *sensu non (Niedenzu) Morton***)** – oco-yajé, yajé-oko, yajé oco, cajé uco, yaji, chagropanga, pucuhuasca, chalipanga, ka-hee-ko, mene kahi ma, nyoko-buku guda hubea ma

Diplopterys involuta *(Turcz.) Niedenzu* **(Mezia includens** *(Benth.) Cuatr.***)** – ayahuasca negro, ee'-taw-gaw

D. cabrerana, closely related to the yajé vine itself [see **Banisteriopsis**], is a common additive to ayahuasca potions in parts of the Amazon. It is documented to have been used by the Shuar, Kofan, Mocoa, Siona, Secoya, Taiwano, Tukano, Inga, and possibly the Barasana and Karapana. The common name 'oco-yajé' means 'water yajé', as the wild form grows near river banks, and its fruits are well-suited to water-dispersal. It is often cultivated inland by shamans, grown from cuttings, and it rarely flowers. Leaves and young shoots are the parts added to ayahuasca (Bennett 1992; Bristol 1966; Der Marderosian et al. 1968; Gates 1982; Pinkley 1969; Schultes 1957, 1969c; Schultes & Raffauf 1990; Uscategui 1959). Some shamans consider it unfit for human consumption, and seem to fear it at the same time as deriding it (McKenna 1990) – this might be due to the exceptionally high *DMT* content of some specimens [and possibly also due to any *5-methoxy-DMT* and *bufotenine* present].

D. involuta is not known to have use as an ayahuasca additive, but its colloquial name gives the impression that it may have once been used in such a capacity (Ott 1994). The Makuna use the bark as a diuretic, and the leaves as an emetic. D. martiusii was once used by the Kubeo of Colombia, who burned the leaves and added the ash to their coca [see **Erythroxylum**] (Schultes 1950; Schultes & Raffauf 1990).

D. cabrerana leaf has yielded 0.17-1.75% *DMT*, as well as traces of *N*-

methyltryptamine, *5-methoxy-DMT* [5-MeO-DMT], *bufotenine* and 2-methyl-THβC. Stems yielded 0.177% alkaloids, consisting of 94% *DMT*, 2% *5-MeO-DMT* and 2% 2-methyl-THβC (Agurell et al. 1968a, 1968b; Der Marderosian et al. 1968; McKenna et al. 1984a). It should be noted that the higher range of *DMT* content in leaves was an estimated quantity, which was not actually isolated (Trout pers. comm.).

Diplopterys cabrerana is a liana, young branches golden-appressed-sericeous; old branches glabrate, sometimes appearing flattish; stipules minute, triangular, sparsely sericeous, often joined by an interpetiolar line. Petiole (4-)8-15(-22)mm long, appressed-sericeous to glabrate, channeled adaxially, apex biglandular, glands convex then prominent. Leaf coriaceous, falcate, (8.5-)10-21(-25.9) x (2.9-)4.1-9cm, elliptic to broadly elliptic, base truncate, apex long-acuminate, acumen up to 3cm long, margin with minute glands, plane to slightly revolute, upper side glabrous, underside sparsely appressed-sericeous, the hairs with trabecula 0.2-0.3(-0.6)mm, reticulation prominulous to prominent adaxially and 6-8(-10) pairs of lateral veins prominent on underside. Inflorescence axillary, of 4-flowered umbels, borne singly or in short racemes or condensed panicles, appressed-sericeous; bracts and bracteoles (1.5-)2-3mm long, ligulate, sparsely sericeous abaxially, glabrous adaxially, spreading, persistent; pedicels sessile, 5-12 x 0.4-0.5mm, up to 1mm diam. in fruit, sparsely appressed-sericeous to glabrate; sepals 1.5-2.2mm long, anterior sepal 0.7-0.8mm wide, narrowly elliptic, eglandular (rarely 1-glanded), 4 lateral sepals up to 1.4mm wide at base, 0.7-0.8mm at apex, deltate, inpressed, apex reflexed, biglandular, projecting 1-1.3mm beyond glands, glands 1-1.8 x 0.5-1mm; petals yellow, sparsely sericeous in middle of limb externally, long-fimbriate, eglandular, 4 lateral petals reflexed between sepals, antero-lateral petals with claw 1-1.5mm long, limb 7-8mm long and wide, concave, postero-lateral petals with claw 0.5-1mm long, limb 5-7mm long, 4-5.5mm wide, broadly elliptic, plane, posterior petal with claw erect, 2.5-3.5mm long, up to 0.6mm wide, apex constricted, limb 4.5-5.5 x 3-4.5mm, obovate; stamens glabrous, with filaments connate at base for 0.4-1mm, those opposite sepals 2-2.8mm long, those opposite petals 1.6-1.8mm long; anthers with locules 0.8-1mm long, sparsely hairy to glabrate. Ovary densely hairy, 1mm tall; styles 1.4-1.6mm long, posterior styles slightly longer than anterior style, with stiff straight hairs at base; stigmas strongly capitate. Fruit of 3 mericarps, without carpophore, nut orbicular, up to 15mm long and wide, bearing crest-like dorsal wing 1-5mm high, usually 4 ridges or winglets on each side 1-10mm high, irregular or dissected along margin, interconnected with ridges so that the surface of the nut between winglets is irregularly foveolate, surface of nut between areole and proximal winglet smooth, appressed-sericeous throughout, hairs and trabecula 0.1-0.2mm long. Fl. Sep.; fr. Oct.-Dec. (fruit once found in April).

Often on river margins; Colombia, Ecuador, Brazil, Peru, Venezuela. Due to having often been incorrectly referred to as **Banisteriopsis** rusbyana [a name that is now regarded as synonymous with B. longialata] by ethnobotanists, it is unclear whether some reports of use of B. rusbyana actually refer to B. longialata or D. cabrerana, though the uses of the latter are confirmed (Gates 1982).

DODONAEA

(Sapindaceae)

Dodonaea viscosa *Jacq.* **ssp. viscosa** – hops bush, giant hops bush, wild hops, wase, watchupga, kirni, tecan

Dodonaea viscosa ssp. angustifolia *(L. f.) J.G. West* **(D. angustifolia** *L. f.***; D. salicifolia** *DC.***; D. viscosa var. angustifolia** *(L. f.) Benth.***; D. viscosa var. linearis** *(Harv. et Sond.) Sherff***)**

Dodonaea viscosa ssp. angustissima *(DC.) J.G. West* **(D. angustissima** *DC.***; D. attenuata** *A. Cunn.***; D. denticulata** *F. Muell.***)** – slender hop bush, narrow-leaf hop bush

Dodonaea viscosa ssp. burmanniana *(DC.) J.G. West* **(D. burmanniana** *DC.***)**

Dodonaea viscosa ssp. cuneata *(Sm.) J.G. West* **(D. cuneata** *Sm.***)** – wedge-leaf hop bush

Dodonaea viscosa ssp. mucronata *J.G. West*

Dodonaea viscosa ssp. spatulata *(Sm.) J.G. West* **(D. asplenifolia** *Rudge***; D. spatulata** *Sm.***; D. viscosa var. spatulata** *(Sm.) Benth.***)** – sticky hop bush

Dodonaea spp. – wild hops, hop bush

Leaves of D. viscosa [possibly D. viscosa ssp. angustifolia?] are sometimes chewed as a stimulating 'coca' substitute [see **Erythroxylum**] in Peru, or used to adulterate real coca. The bitterness of Dodonaea spp., combined with the superficial resemblance of the fruits to true 'hops' [see **Humulus**], meant that some Australian species [especially D. viscosa ssp. angustissima] gained use as hops substitutes for brewing beer [see *Methods of Ingestion*] in Australia's early white pioneer days. D. viscosa was used by some indigenous Australians as a painkiller. The leaves were chewed without swallowing the juice to treat toothache; the chewed leaves and juice also treated stonefish and stingray [see **Urolophus**] wounds. A root decoction or root juice of D. viscosa is also used for toothache, and is externally applied for healing cuts and open wounds (Cribb & Cribb 1981; Lassak & McCarthy 1990). D. viscosa is also used in Baliem, Papua New Guinea in rituals concerning the dead, and is burned as an incense in funeral pyres (Paijmans ed. 1976). In the Ashburton region of Western Australia, leaves of D. lanceolata are boiled and mashed; this mixture is applied externally as an analgesic, or diluted to drink (Reid & Betts 1979).

D. viscosa leaves contain up to 18% tannin, pinocembrin [anaesthetic, antiseptic, fungicidal, antileukaemic], quebrachitol, aliarin, barringtogenol, viscosol, eriodictyol, *chlorogenic acid*, caffeic acid, isorhamnetin, 5,7-dihydroxy-3'-(4-OH-3-methylbutyl)-3,4',6-trimethoxyflavone, 5-OH-3,4',6,7-tetramethoxyflavone, 15,16-epoxy-13(16),14-labdadiene-3,8-diol and hautriwaic acid; they are slightly cyanogenic. Bark has yielded shikimic acid, *chlorogenic acid*, glucose and a leucocyanidin. Seeds have yielded dodonic acid, dodonin, dodonosides A and B, β-sitosterol and stigmasterol (Brooker et al. 1987; Buckingham et al. ed. 1994; Cambie & Ash 1994; Duke 1998; Lassak & McCarthy 1990; Sachdeu & Kulshreshtha 1984; Watt & Breyer-Brandwijk 1962). Leaf from Queensland tested weakly positive for alkaloids (Webb 1949).

Dodonaea viscosa is a spreading or erect shrub or tree to 5(-8)m tall, often resinous; branchlets angled to flattened, usually slightly ribbed, puberulent to glabrous. Leaves alternate, simple, linear to obovate or spatulate, 1-15.5cm x 1-25(-40)mm, apex obtuse to acuminate, sometimes rounded and mucronate, base attenuate to cuneate, glabrous, viscid, sessile or petiolate; petiole to 18mm long. Inflorescence a cymose terminal panicle; pedicels 3-9mm long; sepals 3-4, lanceolate to ovate, 1.3-3mm long, free, not persistent, viscid; petals absent; stamens (6-)8-10(-16), usually longer than sepals, in female flowers absent or rudimentary. Disc small; ovary 2-6-carpellate, glabrous to pubescent. Fruit a capsule, usually prominently 3-4-winged, 8.5-28 x 11-28mm, glabrous, membranous or leathery, sometimes coriaceous, dehiscence usually by valves breaking away from septa, wings 2-10mm wide; seed lenticular, 2-3.1mm long, black, dull, aril mostly absent, testa covered with hyaline membrane. Fl. (mostly) spring-summer.

Mainly in open forests, woodlands, mallee scrub; all states of Australia, pantropics, extending to S. Africa, Pacific Islands, s.e. Asia and the Americas.

The subspecies may be distinguished by these differences -

D. viscosa ssp. angustifolia grows to 5m; leaves linear-lanceolate, mostly 6-13cm x 5-10mm, apex narrow-acute to acuminate, base narrowly-attenuate; petiole (2-)6.5-18mm. In dry sclerophyll forest and woodland.

D. viscosa ssp. angustissima grows to 4m; leaves sessile, linear to narrow-oblong, rarely oblanceolate, 3-9.5cm x 1-6mm, apex acute to obtuse, margins irregularly sinuate or toothed. In woodland, mostly in arid or semi-arid regions.

D. viscosa ssp. burmanniana grows to 6m; leaves lanceolate to narrowly-elliptic, mostly 7-12cm x 14-23mm, apex acute; petiole 6-18mm; capsule 8.5-20(-28)mm long, 11-22(-28)mm wide, wings 3-6(-10)mm wide. In wet sclerophyll forest, sometimes on rocky slopes, coastal areas.

D. viscosa ssp. cuneata grows to 3m; leaves cuneate to angular- or narrow-obovate, margins entire to irregularly sinuate, apex truncate or obtuse, shortly apiculate or occasionally irregularly 2-3-toothed, rarely emarginate, (0.8-)1.2-3(-3.8)cm x 4-9mm; sessile or petiole short. In sandy loams in open forest, and mallee scrub in semi-arid regions.

D. viscosa ssp. mucronata grows to 4m; leaves obovate to spatulate, 2.5-6cm x 10-25mm, apex mucronate, base broad-attenuate, margins entire to irregularly sinuate; petiole 3.5-20mm. On rocky hills and ranges, sometimes near creeks in arid regions.

D. viscosa ssp. spatulata grows 1.5-4m; leaves obovate to spatulate or oblanceolate, 2.3-7.5(-9)cm x 6-16(-18)mm, apex broad-acute to obtuse, sometimes short-apiculate, margins entire to toothed or irregularly sinuate, leaf morphology highly variable; petiole 0-10mm. Open forest and mallee shrubland in high-rainfall regions.

D. viscosa ssp. viscosa – grows to 2m; leaves elliptic, 7-13cm x 20-40mm, apex broad-acute to obtuse; petiole 2.5-6mm; capsule 15-23mm long, 20-25mm wide, 2(-3)-winged, wings 4-4.5mm wide. In sandy coastal areas.

Many of the subspecies are known to intergrade in the wild, and some [such as D. viscosa ssp. spatulata] can also be very variable in appearance. There is also a horticultural variety, D. viscosa 'purpurea', which is becoming more widespread due to escaping cultivation. It has attractive deep-purplish foliage (Albrecht et al. 1999; Harden ed. 1990-1993).

DUBOISIA

(Solanaceae)

DUBOISIA HOPWOODII

Duboisia hopwoodii *(F. Muell.) F. Muell.* **(Anthocercis hopwoodii** *F. Muell.***)** – pituri, pitcheri, pitchiri, pitjiri, bedgery, pedgery, petcherie, murulunga, mononga, mo-da, ne-em-pa, ta-rem-bo-la, ti-rum-bo-la, tjilla, undakora, ungulpa, unkulpa, walgul, walgulba, walkal, emu plant, camel poison, poison bush, spinifex poison, narrow leaf

Duboisia leichhardtii *(F. Muell.) F. Muell.* **(Anthocercis leichhardtii** *F. Muell.***)** – Leichhardt corkwood, corkwood

Duboisia myoporoides *R. Br.* **(Entrecasteauxia elliptica** *Montr.***)** – corkwood, cork tree, elm, eye plant, ngmoo, onungunabie, orungurabie

'Pituri' [the prepared terminal leaves and stems of D. hopwoodii] was once widely used as a 'narcotic' by the indigenous inhabitants of parts of central Australia; it was said by Wills [of Burke and Wills fame] to have "a highly intoxicating effect when chewed, even in small quantities". The term pituri [and its variants] has been applied by both 'black' and 'white' men to other plants used as tobacco substitutes, many of which are actual **Nicotiana** spp. Earlier, the name had only been used by a small group of indigenous clans [such as the Ulaolinya], living in arid s.w. Queensland, near the Northern Territory border, but the use of the term appears to have spread primarily from white people. Today, use of the drug is uncommon, and may have even died out. One indigenous healer from s.w. Queensland, George Quartpot, reported to Tim Low (1990) that it was once chewed by all older people, but that the practice was stamped out by local police.

Pituri was often only used by the older men of the tribe, who reserved it for themselves, though sometimes it was used by all males, for social or ceremonial purposes, or to relieve physical stress. The leaves have also reportedly been burned, to provide an anaesthetic smoke "for such crude operations as they performed." The drug has also been alleged [by A.S. Vogan] to "enable old men to act as seers, and thus obtain power and perquisites." Amongst pituri-clans, the correct methods of preparation were only revealed to men when their beards had turned grey. Although younger men and women were allowed to come close to the collection and preparation area, they were not allowed to witness the process, instead remaining to prepare the bags to hold the pituri, and to collect food for the older men. The elders would build a fire near the plants, and let it die down, before harvesting branch-tips up to 30cm long. The remains of the fire were raked out to form a pit, in which the fresh pituri was placed, and covered with sand for 2hrs or more. The exact length of 'steaming' is a matter of expertise. When ready, the sand was raked away, and the pituri left to cool and dry out, after which it was broken up with the edge of a boomerang, and large twigs removed. This pituri was now ready for storage in specially made string bags [made from a type of **Verbena** or a broom species (see **Cytisus**)]. For use, a tablespoon or more of the dried, semi-pulverised herb is powdered, moistened, rolled with plant-derived alkaline ashes [the preferred donor being **Acacia** salicina, high in calcium sulphate] to aid in alkaloid release, and sometimes mixed with fibrous matter such as kangaroo hair or native flax [Psoralea spp.]. This is rolled into a quid c.6cm long and 1.5cm thick, ready for chewing [as with **Areca** and other drugs taken as a quid, this is more accurately described as sucking]. The quid may be passed from person to person, or enjoyed by one's self. It is stored in or behind the ear when not being used; this also allows passage of the alkaloids through the skin in those places. Pituri has occasionally been observed to be smoked, though this is believed to be a 'post-contact' phenomenon (Aiston 1937; Cox 1880; Cribb & Cribb 1981; Johnston & Cleland 1933; Lassak & McCarthy 1990; Low 1990; Peterson 1979; Thomson 1939; Watson et al. 1983; Webb 1948). The taste of the fresh leaves has been described as burning and 'chilli-like' [see **Capsicum**] (Letnic 2000).

Intricate trade-routes called 'pituri roads' network through parts of Australia's arid interior, and were once more widely used in inter-tribal pituri trading. This was necessitated because the highly-prized plant does not grow in many regions, and even where it does, it is not always recognised by locals; today there are reported to be very few indigenous people who still know what the plant looks like. Also, it is said that only strains from a select few localities are suitable for use, particlularly those of the Mulligan-Georgina Rivers [south-west Qld]. This may have been due to chemical differences, or may have even been a simple but effective rumour, spread to maintain the monopoly over pituri preparation. Some people would travel great distances to this area to obtain it, and there was use of "message sticks requesting the sending of pituri". In much of central Australia, the local plants have only been used to trap emus or other animals, by placing a maceration of the herbage in waterholes, to stun the prey and make them easier to catch. D. myoporoides branches have similarly been used to stun eels, though such use for this species is not widespread. Around 1860, it was reported that indigenous people in the areas near Illawarra, Kurrajong and Shoalhaven, made a practice of cutting a hole in the trunk of D. myoporoides, putting water in the hole to soak overnight, and drinking the potently stupefying beverage the next day (Aiston 1937; Bailey 1880; Johnston & Cleland 1933; Letnic 2000; Low 1990). This latter report remains unconfirmed, though it may well have been an accurate observation.

Intoxications have reportedly occurred even from D. myoporoides branches hung in a closed room! An extract of the leaves and fruits has been used medicinally to produce pupil dilation for eye examination, as well as to treat 'maniacal delirium' [a condition that this plant could cause in large enough doses], goitre, night sweats, painful tenesmus caused by urethra and bladder inflammation, and as a sedative for an inflamed cornea. Along with D. leichhardtii, it was used in WWII as a source of *hyoscine* [scopolamine] and *atropine* derived from *hyoscyamine*, to treat motion sickness and shock. They are still used as sources for these chemicals. D. myoporoides is also used in New Caledonia to treat ciguatera fish poisoning (Cribb & Cribb 1981; Lassak & McCarthy 1990; Low 1990; Morton 1977; Peterson 1979; Watson et al. 1983; Webb 1948).

In Australia, D. myoporoides, D. leichhardtii, and hybrids between these two species are cultivated commercially for their alkaloid content. In the course of harvesting and processing the material, it has been inevitable that unintended intoxications have occurred. This is primarily due to contact with small leaf fragments and 'dust' from the harvested plant, or from extensive handling during harvest. The tropane alkaloids contained in these plants are potent, and easily absorbed through the skin or mucous membranes. It would seem, due to the lack of precautions taken, that the people involved in the Duboisia industry were unaware of this. The initial symptoms of low-level intoxication have been dubbed 'cork-eye' by those involved in the trade – this includes strong pupil dilation and reddish eyes. Mid-level exposure also causes flushing of the face and dry throat. Someone suffering from strong intoxication is referred to as being 'corked up', and symptoms are consistent with *hyoscine* and *hyoscyamine* inebriation. One worker who had been sieving and baling D. myoporoides leaves in a shed was observed to become inebriated after 3hrs [probably to the amusement of his friends] – "he became withdrawn and quiet, and wandered away from the shed. He was found making a crank-handle from thin case-wire, which he then used irrationally and inappropriately to try to start a large diesel tractor" (Pearn 1981).

The only instance of recreational use coming to mainstream media attention, that I am aware of, occurred in Queensland in 1974. "Four male teenagers prepared an intoxicant by boiling leaves of Duboisia sp. with coffee granules [see **Coffea**], which they subsequently imbibed. Thirty minutes after they had drunk the coffee and corkwood infusant, hallucinations and drunken behaviour ensued, and disturbed neighbours called the police. One teenager was found unconscious and naked, and another was lying in eight centimetres of water in the bath, claiming he could see butterflies. Early symptoms had included drowsiness, a feeling of weightlessness, and difficulty focussing on objects in the room. All four patients were admitted to hospital but were discharged 48 hours later without specific treatment" (Pearn 1981). One person reported being unable to walk properly and experiencing strong drying of the mouth after smoking 'a couple of the leaves' of D. myoporoides. There is also one human death on record, of a Wollongong man who ate some D. myoporoides leaves and suffered a cardiac arrest. However, this is not a characteristic effect of this plant, and it was suspected that the unfortunate deceased already had heart problems (Low 1990).

Aiston (1937) observed the effects of pituri on some indigenous people at Mungeranie – "[it] had very little apparent effect on the old people who had been in the habit of using it for years, but it gave the young peo-

ple a swollen bestial look; one young woman I remember at Mungeranie had the appearance of being heavily drugged with opium; her eyes were swollen, her mouth loose and sloppy and she spoke as if in a drunken daze. The effect wore off and the next morning she was apparently normal."

In 1995 I conducted a bioassay using a small handful of whole, dried leaves from an unidentified Duboisia sp. These were given to me by a friend who had wild-harvested them, believing them to be 'pituri' [ie. D. hopwoodii]. Although I did not, unfortunately, attempt to identify them properly at the time, memory allows that the leaves were most likely from D. myoporoides x leichhardtii, due to their morphology and the high possibility that my friend had inadvertently encountered the outskirts of a commercial plantation, or escaped plants from one. The leaves were chewed, several at a time, over c.2hrs. The saliva was swallowed; leaves were chewed and sucked until leached of flavour, at which time they were spat out and replaced with new leaves. Initially, only a mild stimulation was noted. However, after 2hrs of chewing, sudden waves of nausea were felt, accompanied by dry mouth and throat ['cottonmouth'], 'gagging' sensation in the throat, dizziness, sedation, and impaired concentration. I was compelled to lie on my bed, looking up at the sky-light in the ceiling, and had a repeated hallucination of the sky-light swinging down as though hinged on one side. When I would look again directly at it, however, the sky-light would appear as normal. This strange but simple scenario continued for c.20min., after which the symptoms subsided enough for me to sleep. There was no interference with sleep – on the contrary, sleep seemed to be improved (pers. exp.).

D. hopwoodii may generally yield 1-2% alkaloids from the aerial parts, though up to 5% has been reported; this is mostly *nicotine* or *nornicotine* [plants from west Qld and WA seem to be *nicotine*-dominant; plants from SA and central Australia seem to be *nornicotine*-dominant], as well as 0.1% ursolic acid. Plants from the Mulligan-Georgina Rivers area yielded 0.5% *nicotine*, 0.2% metanicotine, and traces of *nornicotine*, N-formylnornicotine, anatabine, cotinine and bipyridyl in the aerial parts. Plants from Alice Springs contained *nornicotine* [major alkaloid; 0.5% in root, 0.3% in stem wood, 0.5% in stem bark, 1.6% in young leaf, 2.4% in middle leaf, 2.2% in old leaf], *nicotine* [0.2% in young leaf, none found in other parts by Kennedy (1971)], N-formylnornicotine, N-acetylnornicotine, *anabasine* [none found by Kennedy (1971)], anatabine, anatalline, hygrine [0.1-0.2% in roots, 0.1% in stems, 0.2% in young leaf, 0.1% in middle and old leaf], isopelletierine [0.2% in medium root, 0.1% in young and old leaf, none in other parts], myosmine and bipyridyl in leaves; roots and stems also contained cuscohygrine [0.2-0.3% in root only], *hyoscyamine* [0.8% in roots, 0.4% in stems] and *hyoscine* [0.1% in coarse root, 0.8% in medium root, 0.1% in stem wood, 0.6% in stem bark]. Plants from WA contained *nicotine* [major alkaloid], *nornicotine* [major alkaloid at 1.8%, in Kalgoorlie plants studied by Kennedy (1971)], hygrine [0.2%], isopelletierine [0.2%], metanicotine and *hyoscyamine* [0.1%] in leaves; roots contained *nornicotine* [0.6%], N-formylnicotine, N-acetylnicotine, *hyoscine* [0.2%], *hyoscyamine* [0.4%], cuscohygrine [0.1%], cotinine and myosmine. Plants from Kimba, SA, yielded *nornicotine* [3.2% in middle leaf, 0.3-0.4% in roots], *nicotine* [0.2% in middle leaf, 0.1% in roots], *anabasine* [0.1% in roots], cuscohygrine [0.1-0.2% in roots], hygrine [0.1% in medium root only], isopelletierine [0.1% in roots], *hyoscine* [0.1% in middle leaf, 0.1-0.2% in roots] and *hyoscyamine* [0.5% in medium root, 0.3% in coarse root, none in leaf]. Pituri prepared from the plant contains lower levels of *nicotine* than the material it is made from (Cribb & Cribb 1981; Evans 1979; James 1950; Kennedy 1971; Lassak & McCarthy 1990; Peterson 1979; Watson et al. 1983). Young regrowth may generally contain higher alkaloid levels than mature shrubs (Webb 1948).

D. leichhardtii leaves have yielded up to 5% alkaloids, and are very variable in content – the alkaloids may consist of 10-80% *hyoscyamine*, 6-46% *hyoscine*, 3-42% norhyoscyamine, apoatropine, apohyoscine, *atropine*, noratropine, tigloidine, isobutyroyl tropine, and traces of calystegines B1, B2, C1 & C2 [see **Convolvulus**]. Atroscine, scopadonnine, tetramethylputrescine and valtropine have also been found in the plant (Buckingham et al. ed. 1994; Kato et al. 1997; Lassak & McCarthy 1990; Morton 1977).

D. myoporoides is also very variable, and may exist in different chemical races. Leaves may yield up to 3% alkaloids. In cooler areas, *hyoscyamine* and norhyoscyamine are dominant; hotter regions may produce *hyoscine*-dominant plants [eg. north of Gosford, NSW]. Plants around Yarraman, Qld, were dominant in norhyoscyamine. However, tests on a plant cultivated in Nambour, Qld, showed 3% *hyoscine* in April, but 2% *hyoscyamine* in October [as the dominant alkaloid in each case]. Plants on the **Acacia** Plateau [near Killarney, Qld] are dominant in *anabasine*; New Guinea plants are *nicotine*-dominant. Sometimes, plants cultivated in different locations will continue the alkaloid patterns usual to their place of origin, but sometimes the chemistry will be altered. The leaves also yield *nornicotine* [in seedlings], *atropine*, 6-methyldotriacontane, hentriacontanyltetratriacontanoate, 3-OH-dotricontan-28-one and 4-pentatriacontanone. Fresh roots of plants from Beenleigh, Qld, were assayed – young root wood yielded 0.0049% tropine, 0.0038% *hyoscyamine*, 0.0012% valtropine, and traces of valeroidine; old root wood yielded 0.0068% *hyoscyamine*, 0.0031% *hyoscine*, 0.0023% apohyoscine, 0.0021% tropine, and 0.0005% tetramethylputrescine; young root bark yielded 0.13% *atropine*, 0.025% *hyoscine*, 0.02% tropine, and 0.007% apohyoscine; old root bark yielded 0.031% *hyoscyamine*, 0.027% tetramethylputrescine, 0.018% tropine, 0.017% *hyoscine*, 0.007% valtropine and 0.006% apohyoscine. The plant has also yielded neonicotine, pelletierine, isoporoidine, poroidine, and tigloidine (Buckingham et al. ed. 1994; Coulsen & Griffin 1968; Evans 1979; James 1950; Lassak & McCarthy 1990; Morton 1977; Rastogi & Mehrotra ed. 1990-1993). Leaf alkaloids have been observed to vary greatly over the course of a day. The best yields were obtained in the morning (Lee & Chiu 1989). Seedlings have yielded c.1% *hyoscine*, with *hyoscyamine* not appearing until plants are 5-6 months old; alkaloid levels similar to those from adult plants are reached at about 9 months of age. Alkaloid levels decline in stems as the plant matures (Hills & Rodwell 1947).

A Loranthus sp. 'mistletoe' [see *Endnotes*] growing on D. myoporoides yielded c.0.4% alkaloids, 80% of which was *hyoscine* (Bock unpubl.; Trautner 1952).

All of the above Duboisia spp. may yield up to c.1-2% ursolic acid from their dry leaves (Trautner & Neufeld 1947).

Experiments with a hybrid strain between D. leichhardtii and D. myoporoides showed an accumulation in the lower leaves. Alkaloids increased over the morning to reach a peak at midday, tapering off to a low in the afternoon. *Hyoscine* and *hyoscyamine* were in a roughly equal proportion in the early months after planting, until *hyoscine* became dominant in late spring, and decreased to a minimum in late autumn. Treatment with a weak dilution of Maxicrop™ fertiliser boosted alkaloid levels dramatically; greater amounts of K increased *hyoscine*; increased N actually decreased *hyoscine* and *hyoscyamine* content (Luanratana & Griffin 1980a, 1980b).

Duboisia hopwoodii is a rounded shrub to 4m tall, 3m wide. Leaves alternate, narrowly elliptic or ovate-elliptic to linear, sessile (rarely with petiole to 3mm long), 2-12cm x 1-13mm, concolorous. Inflorescence narrow, panicle-like, terminal, leafy; flowers bisexual, slightly zygomorphic, subtended by pairs of opposite bracts 0.5-4mm long; pedicels 1.5-5mm long; calyx campanulate, 1.5-4.5mm long, 5-lobed, the lobes usually about 1/3 as long as tube; corolla campanulate, white with purple striations in throat, 7-15mm long, tube funnel-shaped to campanulate, 4.5-8mm diam. at apex, limb 5-lobed, the lobes 2.5-5.5mm long, volutive in bud; stamens 4, 3-8mm long, inserted at base of corolla tube; anthers unilocular, dehiscing by a terminal, semicircular slit. Ovary bilocular; stigma capitate, very shortly bilobed; style 3.5-6.5mm long, equal to or shorter than upper stamens. Succulent berry usually globose or subglobose, rarely ellipsoid, 2-5mm diam., purple-black; fruiting pedicels 3-5mm long; seeds 2-2.5mm long.

Widespread, in red or yellow sand or sandy loam, on plains, low dunes or rises; arid regions of Western Australia, s. Northern Territory, South Australia, to c.w. Queensland and w. New South Wales.

May hybridise with **Grammosolen** dixonii (Haegi et al. 1982).

DUTAILLYEA

(Rutaceae)

Dutaillyea drupacea *(Baillon) Hartley*
Dutaillyea oreophila *(Baillon) Sevenet-Pusset*

These two New Caledonian plants seem to have very elusive descriptions, and I can find no reference to them outside of their chemical analysis. They both contain a number of alkaloids, including indoles of interest.

D. drupacea leaves yielded 0.04% alkaloids, of which 98% was *5-methoxy-DMT*. Stem bark yielded 0.2% alkaloids, of which 30% was evolitrine [7-MeO-dictamnine], 25% pteleine [6-MeO-dictamnine], 15% (-)-edulinine, 10% dictamnine [4-MeO-furo-[2,3-b]quinoline; shows antibacterial, antifungal, strong smooth muscle contracting and DNA-binding effects], 10% kokusaginine [6,7-dimethoxydictamnine; enhances *norepinephrine* and *dopamine* levels in mouse brain, 5-HT2 receptor agonist] and 2% dutadrupine (Baudouin et al. 1981; Cheng et al. 1994; Harborne & Baxter ed. 1993).

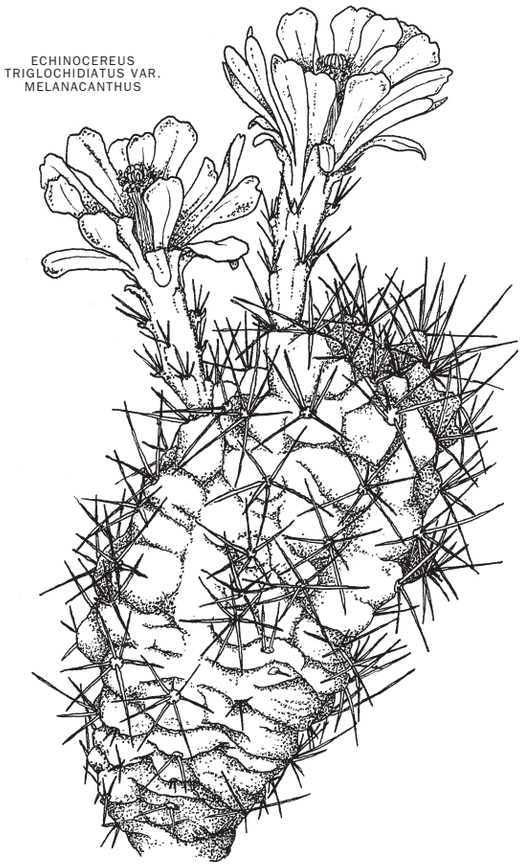
D. oreophila leaves yielded 0.05% alkaloids, of which 40% was *5-methoxy-DMT*, 25% kokusaginine, 25% *hordenine* and 10% 2-methyl-*pinoline*. Stem bark yielded 0.03% alkaloids, of which 40% was dictamnine, 20% kokusaginine, 20% pteleine and 20% evolitrine (Baudouin et al. 1981).

Dutaillyea spp. are shrubs or bushes. Leaves large, digitately trifoliolate, opposite; leaflets entire, petiolulate. Flowers mostly hermaphroditic, in axillary composite-cymose racemes; receptacle shortly conical; sepals 4, free, moderately thick, at first mildly decussate, becoming subvalvate; petals longer than calyx, imbricate or tortuose, rarely alternately imbricate; stamens 4, alternating with petals; filaments free, subulate, germ in disc glandulose near base, obscurely lobed, thickened, inserted; anthers oblong, 2-locular, filament somewhat longer, introrsely 2-rimose. Ovary su-

perior, conoid, 4-locular, locules opposite petals; ovules 2 in each locule, descending; micropyle above, extrorse; style apically erect, slender, entire, apex simple; stigma not at all thickened (Baillon 1871-1873).

ECHINOCEREUS

(Cactaceae)



ECHINOCEREUS TRIGLOCHIDIATUS VAR. MELANACANTHUS

Echinocereus berlandieri *(Engelmann) Hort. F.A. Haage* **(E. blanckii** *(Pos.) Palmer* [misapplied]**)**
Echinocereus cinerascens *(DC.) Lemaire*
Echinocereus merkeri *Hildmann ex Schumann* **(E. dubius** *(Engelm.) Rümpler***; E. enneacanthus** *Engelm.* **ssp. enneacanthus; E. sarissophorus** *Britton et Rose***; E. uspenskii** *Hort. A. Blanc ex Haage***)**
Echinocereus salm-dyckianus *Scheer* – hikuri, peyotl, wichuri, pitallita
Echinocereus triglochidiatus *Engelm.* **(E. gonacanthus** *(Engelm. et Bigelow) Lemaire***)** – hikuri, peyotl, wichuri, pitallita
Echinocereus triglochidiatus var. neomexicanus *(Stand.) Stand. ex W.T. Marshall* – hikuli, pitallito
Echinocereus triglochidiatus var. paucispinus *Engelm. ex W.T. Marshall*
Echinocereus spp. – hedgehog cactus, pitaya, tjeenayookisih

The Tarahumara of n. Mexico consider E. salm-dyckianus and E. triglochidiatus to have similar properties to **Coryphantha** compacta, but less effective, and collect them from mountainous areas (Bye 1979b; Diaz 1979; Schultes & Hofmann 1980). The Navajo eat Echinocereus spp. as cardiac stimulants; they know them as 'twisted heart plant' or 'tjeenayookisih'. The Isleta roast the stems and apply them as a poultice to reduce swelling (Winter 1998). E. cinerascens has been used for its edible fruit, and the dry plant used as fuel (Bruhn & Sánchez-Mejorada 1977).

E. berlandieri has yielded [w/w] 0.0013% *DMPEA* and 0.0033% N,N-dimethyl-*histamine* (Wagner & Grevel 1982).

E. cinerascens has yielded [w/w] 0.014% alkaloids, most of which was N,N-dimethyl-*DMPEA*, with lesser amounts of N-methyl-*DMPEA* (Bruhn & Sánchez-Mejorada 1977).

E. merkeri has yielded 0.016% alkaloids, of which 20% was N-methyl-*DMPEA*, and 60% N,N-dimethyl-*DMPEA*, as well as *DMPEA*, 3-MeO-*tyramine*, *hordenine* and salsoline [6-OH-7-MeO-1-methyl-THIQ] (Agurell et al. 1969b).

E. salm-dyckianus is rumoured to contain entheogenic tryptamines; this appears to be without foundation.

E. triglochidiatus has long been thought to contain *5-methoxy-DMT* (Bye 1979b; Schultes & Hofmann 1980), but this is now known to have been in error, stemming from tentative preliminary data which showed the possible presence of this alkaloid. However, it seems that this species does contain small amounts of indole compounds which researchers have not succeeded in isolating. This cactus, represented as two of its varieties [var. neomexicanus and var. paucispinus], has yielded N,N-dimethyl-*histamine*, detected chromatographically in the former variety, and isolated in 0.11% yield from the latter (Ferrigni et al. 1982). Based on the assumption that *5-MeO-DMT* was present in useful amounts, one person performed an acid-base extraction on E. triglochidiatus and obtained a good yield of crystalline material. This material was vapourised and inhaled, and the psychonaut perceived some kind of vague effect which was not described further. This material was probably mostly, or entirely, N,N-dimethyl-*histamine* (Trout pers. comm.), which has hypotensive activity in animals (Rizvi et al. 1985). The human pharmacology of this alkaloid is unknown, and caution is advised in experimentation due to possible toxicity in doses larger than were bioassayed by the subject just mentioned (Trout pers. comm.).

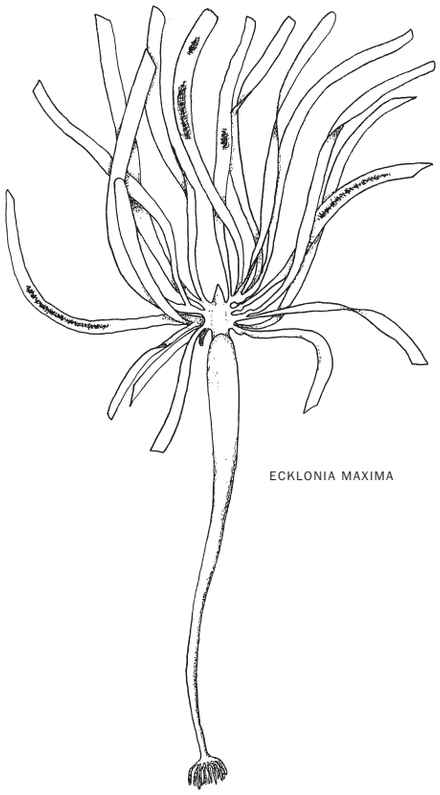
Echinocereus triglochidiatus is a caespitose cactus, with few or many simple stems (5-)20-40(-60)cm long, (2.5-)5-8(-15)cm diam., branching from base, erect or spreading, frequently forming dense mounds to 30cm high and 30-120cm across, deep green, larger terminal joints green or bluish-green, cylindroid to ovoid-cylindroid; 5-8(-12) ribbed, slightly tuberculate; areoles nearly circular, 3-4.5mm diam., usually 6-12mm apart, areoles of mature parts of stems with white felt or cobwebby hairs; spines from sparse to dense on joint, (2-)3-8(-16) per areole, variable amongst varieties, nearly terete to strongly angled, when young reddish/pinkish to yellow, grey in age, usually spreading, often all radial, 3cm long or less. Flowers scarlet, (2.5-)5-7cm long, 2.5-5(-6.4)cm diam.; perianth segments with greenish midribs, red entire margins, oblong to narrowly elliptic, obtuse to rounded apically, mucronulate, (1.5-)3cm long, 6-9mm across; petals red or red and yellow, largest broadly cuneate-obovate, 2-2.5cm x 6-12mm, apex rounded, outer petals slightly mucronulate, entire; areoles on flower tube and ovary few, white-felted, subtending scales small and red; spines on ovary and flower tube few, red and white; filaments white or pale green, 9-12mm long; anthers pale yellow, c.0.5-0.75mm long, up to 1-1.5mm diam.; style greenish, 12-20 x 1-2mm; stigmas c.10, 3-4.5mm long, slender; ovary in anthesis 9-12mm diam. Fruit at first spiny, in age smooth, bright red, 12-25 x 10-15mm, obovoid to cylindroid; seeds 1.5-2mm long, 1.2-1.5mm broad, 0.8-1mm thick, strongly papillate. Flowers do not close at night, and remain open for 2-3 days.

Very variable in habit and number and kind of spines; has at least 8 varieties.

W. Texas, New Mexico, Colorado (Benson 1982; Britton & Rose 1963), Arizona, Missouri.

ECKLONIA

(Alariaceae)



Ecklonia maxima *Osbeck* **(E. buccinalis** *L.***)** – brown algae, kelp

This marine plant is marketed in the form of a seaweed extract [Kelpak™] to promote rooting of cuttings in the horticultural industry (Crouch et al. 1992). It is related to Ecklonia kurome, a popular edible seaweed known as 'kun bu', which is used in TCM interchangeably with Laminaria japonica ['hai dai'] to lower blood pressure, and correct thyroid function and iodine deficiency. L. japonica is a natural source of monosodium glutamate [MSG] (Huang 1993).

Recently, the aforementioned extract of E. maxima was found to contain various indoles, such as *DMT*, indole-3-acetic acid, indole-3-carboxylic acid, indole-3-aldehyde and isoindole-1,3-dione [N-OH-ethylphthalimide] (Crouch et al. 1992; thanks to Michael Bock for this reference); the kelp itself has yielded 35-38% alginic acid, a variety of phenols called phlorotannins (Glombitza & Vogels 1985), and a high level of iodine [0.25% w/w] (Chapman & Chapman 1980) – hence, caution should be exercised by those with acute tuberculosis or chronic bronchitis, as their symptoms may be exacerbated (Huang 1993). Other studies have failed to identify *DMT*, suggesting great variation in chemical content of wild harvested kelp.

Ecklonia maxima has three basic parts – the blades, the stipe and the holdfast with which it keeps its grip on the ocean floor. Thalli brown, coriaceous, to 10m or more long. Blade flat, multiple divided frond, branching off bilaterally into flat, linear marginal portions. Stipe hollow, becoming inflated towards apex. Holdfast composed of dichotomously branched robust rhizoids. Cannot survive over 25°C. Usually carries the 'red alga' Suhria vittata as an epiphyte on its stipes.

On intertidal and subtidal rocks to depth of 8m; 0-4m deep, it makes up ⅔ of total kelp biomass, falling to ½ from 4-8m deep. Off west coast of S. Africa; prominent kelp in the cool Benguela upwelling region on the west coast of S. Africa, occurring from Swakopmund, Namibia, to Aasfontein, 15km west of Cape Agulhas (Chapman & Chapman 1980; Luning 1990; Tseng ed. 1983).

ELAEAGNUS [Eleagnus]

(Elaeagnaceae)

Elaeagnus angustifolia *L.* **(E. hortensis** *M.B.***; E. orientalis** *L.***)** – Russian olive, Trebizond date
Elaeagnus commutata *Bernh. ex Rydb.* – silverberry, wolf willow
Elaeagnus pungens *T.* – hu tin yie
Elaeagnus spinosa *L.*
Elaeagnus triflora *Roxb.* **(E. latifolia** *L.***)** – millaa vaine, millaa millaa, malay malay

The Gimi of the New Guinea highlands sometimes smoke the leaves of an unidentified Elaeagnus sp. with tobacco [see **Nicotiana**] and an Amaracarpus sp. [see *Endnotes*] to enter trance for divination (Glick 1967). This may be E. triflora, which is the only Elaeagnus sp. recorded in New Guinea (Bock unpubl.). E. angustifolia is used in India for lung problems and malignant fevers; the seed oil is also taken in syrup to treat catarrh and bronchial problems. In Spain, its flower juice is used as a cure for malignant fevers (Kirtikar & Basu 1980). In TCM, E. pungens leaf has been used as an antitussive (Huang 1993). The fruits of some Elaeagnus spp. are eaten as food – such as E. argentea ['silver berry'] in N. America, E. triflora in Nepal and Hindustan and E. multiflora ['cherry Elaeagnus', 'goumi'] in Japan, where they are also made into an alcoholic beverage (Usher 1974). In parts of India, the mealy covering of E. angustifolia fruits has been used as a binding adulterant in 'hashish' manufacture [see **Cannabis**] (Clarke 1998).

Some species contain β-carboline alkaloids of interest. Leaf extract, bark and seeds from E. angustifolia have been smoked for the effects of these alkaloids, and simply handling the herb seems to result in some absorption through the skin (Gerbil pers. comm.).

E. angustifolia aerial parts were shown to contain *tetrahydroharman* [eleagnine] and traces of *harman* (Lutomski & Nowicka 1969; Lutomski et al. 1968b; Men'shikov et al. 1951); root bark and bark from aerial parts was richest in *harman*; *harmol* and *tetrahydroharman* were also detected in these organs. As the plant matures, *harman* levels increase, and *tetrahydroharman* levels decrease (Gill & Raszeja 1971; Massagetov 1947; Nikolaeva et al. 1971a, 1971b). Stem bark has also yielded *tetrahydroharmol* and N-methyl-*tetrahydroharmol* (Platonova et al. 1957). *Harmalan* [dihydro-*harman*] and 2-methyl-THβC have also been isolated from the plant (Nikolaeva 1971). The presence of *harmine* has been reported (Shulgin & Shulgin 1997), but this may be a mis-reading of Gill & Raszeja (1971), which referred to the presence of *harmine* in **Peganum** harmala, in an ambiguous passage. Bark also yielded (+)-catechin, (-)-epicatechin, and 2 other catechin-derivatives; leaf has yielded *chlorogenic acid*s, neo-*chlorogenic acid*s, caffeic acids (Nikolaeva et al. 1971c), quebrachitol, kaempferol-7-p-coumaryl-3-D-glucoside, isorhamnetin-3-D-gluco-D-galactoside, isorhamnetin-3-D-gluco-D-feruloylgalactoside and isorhamnetin-3-rhamno-glucorhamnoside (Plouvier 1951; Rastogi & Mehrotra ed. 1990-1993). An aqueous extract of the fruit had analgesic and antiinflammatory effects in rats, and contained flavonoids, terpenoids and cardioactive glycosides (Ahmadiania et al. 2000).

E. commutata root bark has yielded 1-isobutyl-THβC (Slywka & Locock 1969); the plant inhibits human plasma AChE (Orgell 1963b).

E. pungens leaf has yielded *harman* and *tetrahydroharman* (Huang 1993). Quebrachitol has been found in leaves of E. pungens var. simonii and E. pungens var. reflexa (Smith 1975).

E. spinosa bark has yielded *tetrahydroharman* and another alkaloid which was not identified (Massagetov 1946).

E. triflora [as E. latifolius] leaf from Innisfail, Queensland [Australia], harvested in June, tested positive for alkaloids (Webb 1949).

Unspecified members of the genus Elaeagnus were also reported to have yielded *leptaflorine* [tetrahydroharmine] and 2-methyl-*tetrahydroharmol* (Shulgin & Shulgin 1997). Quebrachitol has also been found in the leaves of E. argentea, E. macrophylla [0.15%], E. multiflora and E. umbellata (Plouvier 1951), the latter of which also contains *serotonin* in the leaf, stem bark and cotyledons (Regula 1973b), as well as *eugenol* and many other compounds in the flower essential oil (Potter 1995).

Elaeagnus angustifolia is a shrub or small tree, of somewhat scraggly habit, to 3-9m tall; the older bark grey and shreddy; branches often thorny, dark brown. Leaves deciduous, alternate, simple, 2.5-8cm long, obtuse, lanceolate or oblong-lanceolate, bright green on upper surface, densely silvery-lepidote beneath, nerves faint; petiole 6mm. Flowers small, yellow, perfect or polyamodioecious, very fragrant, apetalous, solitary or in axillary clusters; perianth 4-6mm long, silvery, campanulate above, teeth triangular-ovate; calyx 4-lobed, pale yellow; stamens 4-8, on mouth of perianth; hypanthium closely surrounding but not uniting with the ovary; filaments short. Ovary 1-celled, superior; stigma lateral. Fruit ovoid, drupe-like, mealy, red or yellow, silvery-lepidote, 1-2cm long, enclosed in persistent accrescent berried or rarely dry perianth base, endocarp thick, bony, pericarp thinly membranaceous; seed with hard, shining testa. Fl. May-Jun.

W. Himalaya, Baluchistan, west to Spain, west and central Asia to China, often between 1220-3200m; introduced to US, where it is frequently cultivated, and a frequent roadside escape; New Mexico chiefly along streams, valleys and roadsides, usually in waste ground, widespread (Kirtikar & Basu 1980; Martin & Hutchins 1980).

ELAEOPHORBIA

(Euphorbiaceae)

Elaeophorbia drupifera *(Thonn.) Stapf.* **(E. grandifolia** *(Haw.) Croizat***; E. leonensis** *N.E. Br.***; E. neriifolia** *A. Chevalier***; Euphorbia drupifera** *(Thonn.) Stapf.***)** – kankan, ayang beyem, mbisa, ongitsimbi, getsimbi, mbego, amataisongo, dolo, douo, turo, toro, dodo, do, baga, tene

The latex of this w. African tree has gained interesting uses in its natural range. The crushed leaves and fruit are used as a fish poison, and a decoction of these parts is used in some areas as an ordeal poison (Usher 1974). The latex has also been applied to the eyes as an ordeal poison, with ocular damage signifying guilt (De Smet 1998). The latex was reportedly once applied to the eyes of slaves and prisoners to make them easier to deal with (De Smet 1998). The latex is used to treat ringworm, warts, scorpion stings, and as a purgative. It has sometimes been used as an additive to preparations made from 'iboga' [see **Tabernanthe**] and/or 'niando' [see **Alchornea**] root barks, to enhance their effects. The Byeri Fang of Gabon reportedly used the latex, mixed with vegetable and animal oils, by dipping a feather into the mixture ['ibama'] and brushing it across the eyes of initiates. Other groups carefully pour drops of it into the eyes. The highly caustic latex may normally cause blindness if brought into contact with the eyes, but diluted with oil it is said to produce brilliantly coloured visions; others say it causes 'odd visual states' and a 'general sensation of dulling' (De Smet 1998; Emboden 1979a; Samorini 1996c, 1997a).

The latex of E. drupifera has yielded the proteases euphorbain d1 [11%] and euphorbain d2 [7%] (Lynn & Clevette-Radford 1985), and the diterpene ingenol [0.47%]. The latex is highly irritating (Kinghorn & Evans 1974) and can act as a co-carcinogen (De Smet 1998). A crude extract of the leaves appears to stimulate muscarinic *acetylcholine* receptors (Eno & Itam 1998).

Elaeophorbia drupifera is a tree with a woody stem and fleshy, angular branches containing abundant caustic white latex; branchlets fleshy, armed with pairs of broad-based prickles c.5mm long; branched low down in open situations but with a clear bole in forest, 3-15m or more tall. Leaves oblanceolate to obovate, sometimes widely emarginate at apex, up to 25 x 9cm, fleshy, entire. Peduncles forked, with a sessile involucre in the fork, sometimes with lateral branches forked again; common peduncles 2.5-4.5cm long, axillary in threes, lateral branches of inflorescence 1-2cm long; involucre with 5 transversely oblong, denticulate lobes and 5 fleshy similar shaped glands; male flowers numerous, male and female flowers much reduced and enclosed in the same involucre as the stamens or in a separate involucre, the latter cupular or 4-angled; stamens 1. Fruits indehiscent drupes, thick and fleshy, ellipsoid, yellow when ripe, with very short stipe, usually c.2-3 x 1.5-1.8cm.

Common in forests and coastal plains; Guinea, Sierra Leone (Hutchinson & Dalziel 1954-1972), Gabon.

ELEUTHEROCOCCUS [including Acanthopanax]

(Araliaceae)

Eleutherococcus senticosus *(Rupr. et Maxim.) Maxim.* **(Acanthopanax senticosus** *(Rupr. et Maxim.) Harms***)** – shigoka, Siberian ginseng, ci wu jia, chi wu cha, wu jia pia, north wu pie pi, wa cha seng, touch-me-not, devil's bush, eleutherococc

Acanthopanax gracilistylus *W.W. Smith* – wu jia pi, south wu jia pi

Acanthopanax japonicus *Franch et Savart* **(A. nipponicus** *Makino***)**

Acanthopanax sciadophylloides *Franch. et Sav.* - gonzetsunoki, gonzetsu, koshiabura

Acanthopanax sessiliflorus *Seem.* – short stem wu jia

Acanthopanax sieboldianum *Makino* - ukogi, himeukogi

E. senticosus, a common plant of east Russia, is valued today as a potent tonic, which may rival even the 'true ginseng' [see **Panax**] in its efficacy – it is often used today as a cheaper, effective ginseng substitute. Its virtues were only revealed to the west last century [1958] after testing of the adaptogenic properties of Russian Araliaceae, by the Soviet scientist Itskovity Brekhman. Leaves and roots of E. senticosus share the major effects of **Panax** ginseng, but are less heating; the stimulant and tonic actions, during periods of high-intensity work, are stronger and longer-lasting than from ginseng. Extracts have been shown to increase stamina, improve immune function, improve alertness and clear mental functioning, reduce reaction-time, antagonise narcosis, increase visual and auditory acuity, increase weight and RNA-content of seminal vesicles and prostate glands, lessen X-ray toxicity, and act as an adaptogen and hypoglycaemic, as well as showing some antitumour properties. After the Chernobyl disaster in 1986, E. senticosus was given to treat radiation sickness. In Russia, extracts of the plant are commonly used by factory workers, Olympic athletes, soldiers and astronauts. The root and rhizome have been much longer used in TCM as a ginseng-substitute, male sexual tonic, and digestive. However, due both to confusion in ancient herbals with similar plants, and to a decrease in its use over history [probably partly in turn due to confusion with Periplocea sepium ('xiang jian pi'; see *Endnotes*), which is quite toxic], this historic useage was only rediscovered relatively recently by herbal scholars. On at least one occasion, P. sepium has been sold as E. senticosus (Fugh-Berman 2000). The closely related E. sieboldianus is used as a hedging plant in horticulture, but has not been tested for medicinal properties (Brekhman & Dardymov 1969a, 1969b; Bremness 1994; Farnsworth & Cordell 1976; Fulder 1993; Halstead & Hood 1984; Hikino et al. 1986; Huang 1993).

Plants from the closely related genus Acanthopanax have been used in similar ways in China. In TCM, A. gracilistylus and A. sessiliflorus roots are used as a ginseng-like tonic and aphrodisiac, the latter also with analgesic and antiinflammatory effects (Halstead & Hood 1984; Huang 1993). Extracts of leaves and roots from the Japanese A. japonicus are used as a tonic health supplement in Korea (Park et al. 2002). In rural Japan, A. sciadophylloides and A. sieboldianum leaves are used as an energising tonic tea; the roots treat rheumatism and stomach complaints. All parts of the latter species also treat hypotension (Brussell 2004).

E. senticosus contains predominantly the glycans eleutherans A-G (Hikino et al. 1986) and the eleutherosides [a diverse array of compounds, many of which are triterpenoid saponins], as well as lignans, sterols and coumarins. Some of these are known by previous synonyms, such as eleutheroside A [daucosterol], eleutheroside B [syringin], eleutheroside B1 [β-calychanthoside; isofraxidin-7-O-α-L-glucoside], eleutheroside B4 [(-)-sesamin], eleutheroside C [methyl-α-D-galactoside], eleutheroside D [(-)-syringaresinol-ol-di-O-β-D-glucoside], eleutheroside E [acanthoside D], eleutheroside I [mussenin B], eleutheroside K [β-hederin] and eleutheroside M [hederasaponin B]. Eleutheroside H is a mixture of I & K. The triterpenes known as senticosides, which are also found, may be identical to some of the eleutherosides. Also found are sinapyl alcohol glycoside, polysaccharides, sucrose, glucose, vitamin A, vitamin C, vitamin E, and an essential oil (Brekhman & Dardymov 1969a, 1969b; Bruneton 1995; Farnsworth & Cordell 1976; Halstead & Hood 1984; Segiet-Kujawa & Kaloga 1991). Roots yielded eleutherosides B4, C, D and E; leaves yielded eleutherosides I, K, L and M (Halstead & Hood 1984; Huang 1993). Eleutheroside B was found mainly in stem bark and root bark, whilst eleutherosides A, C, D and E were found mainly in stem bark and stem pulp (Lapchik & Ovodov 1971).

The herb should not be taken with digoxin, as it can increase the levels of that compound (Fugh-Berman 2000). The bark is tasteless, which may aid in detection of substitutes (pers. obs.). A synergy between the actions of E. senticosus and **Schisandra** has been noted (Halstead & Hood 1984). The herb is very non-toxic, with an oral LD50 of the root [using a 33% ethanolic extract] being 14.5g/kg (Huang 1993). Its effects are best realised with daily consumption as a tonic (Halstead & Hood 1984).

A. japonicus leaves yielded triterpene glycosides named acanjaposides (Park et al. 2002).

A. sessiliflorus root has yielded acanthosides A-D, 1-savinin, and 1-sesamen (Huang 1993).

Eleutherococcus senticosus is a shrub to 2(-5)m tall, with light-grey bark; shoots light brown, usually densely covered with thin brittle prickles curved below, sometimes prickles wanting. Leaves palmately compound of 5 leaflets; leaflets obovate-oval to elliptic, base cuneate, apex short-acuminate or tapering to +- long mucro, thin, adult leaves glabrous or +- densely covered with short bristly hairs, with rufous hairs below along nerves, upper leaflets larger than lower ones, 7-12.5 x 3-7cm, margins acutely bidentate; petioles to 10cm, glabrous or with sparse rufous hairs, with or without solitary prickles; petiolules 1-2cm, covered with dense rufous hairs. Umbels on long stalks, single, terminal but usually 3-4, the distal commonly solitary, fertile, larger and more multiflorous; peduncles to 8cm; pedicels (6-)10-20mm, glabrous or hairy only at base, not jointed, thin; flowers polygamous-dioecious; calyx of (4-)5(-6) small teeth; corolla of (4-)5(-6) petals, valvate in bud, soon deciduous, yellowish in pistillate flowers, light violet in bisexual and staminate flowers; stamens 5. Ovary (3-)5(-7)-locular; styles (3-)5(-7), adnate to tube for entire length, connate; stigmas 5, free, short. Fruit a subglobular berry-like double-drupe, black, pentapartite, strongly flattened, 7-10cm long. Fl. Jul.-Aug.

In mixed and coniferous mountain forests forming small undergrowths or groups in thickets and edges – a common undergrowth component – rarely in oak groves at the foot of cliffs and ravines, more rarely in high-forest riparian woodland; far-east Russia, Manchuria, n. China, Korea, Japan (Shishkin ed. 1986a).

Seed can be tricky to germinate. Harvest root in autumn (Chevallier 1996).

EPHEDRA

(Ephedraceae/Gnetaceae)

Ephedra americana *Humb. et Bonpl. ex Willd.* **(E. andina** *Poepp.***)**

Ephedra californica *S. Watson* – California joint fir
Ephedra distachya *L.* – shrubby horsetail, ma huang ['yellow hemp']
Ephedra equisetina *Bunge* **(E. shennungiana** *Tang***)** – mu-ts'è ma huang ['horsetail ephedra'], shan ma huang ['mountain ephedra'], mu ma huang ['wood ephedra'], ma huang, codati-mao
Ephedra fragilis *Desf.* – encarnaillo, carnaillo, canutillo, apalain fino
Ephedra gerardiana *Wall. ex C.A. Mey.* **(E. vulgaris** *Rich.***)** – amsania, butshur, chewa, tse, tseh, tseput, teapat, trano, rachi, khanda, huma, somalata, sang kaba
Ephedra intermedia *Schrenk ex C.A. Mey.* **(E. ferganensis** *Nikitin***; E. glauca** *Regel***; E. microsperma** *Nikitin***; E. pachyclada** *Boiss.***; E. persica** *(Stapf.) Nikitin***; E. tesquorum** *Nikitin***; E. valida** *Nikitin***)** – chung ma huang, ma huang
Ephedra intermedia var. tibetica *Stapf.* **(E. tibetica** *(Stapf.) Nikitin***)** – hum
Ephedra major *Host* **(E. nebrodensis** *Tineo.***)**
Ephedra monosperma *C.A. Mey.* **(E. minima** *K.S. Hao***)**
Ephedra nevadensis *S. Watson* **(E. antisyphilitica** *S. Watson***)** – Nevada joint fir, Mormon tea, desert tea
Ephedra sinica *Stapf.* **(E. flava** *Smith***; E. ma-huang** *Liu***)** – tien ma huang ['field ephedra'], ts'ao ma huang, chuan ma huang, ma huang
Ephedra viridis *Coville* **(E. nevadensis subvar. pluribracteata** *Palmer ex Stapf.***; E. nevadensis var. viridis** *(Coville) M.E. Jones***)** – mountain joint fir, squaw tea
Ephedra spp. – joint fir, tepopote

As 'ma huang' ['yellow hemp'], several species of Ephedra [E. distachya, E. equisetina, E. intermedia, E. sinica] have been used for at least 5,000 years by the Chinese in the form of the dried stems and scale-leaves to treat asthma, bronchitis, fluid retention, chills, fever, allergies and excessive appetite (Hu 1969; Huang 1993; Liu et al. 1993; Morton 1977; Reid 1995). The roots, as 'ma huang gen' [China] or 'mao kon' [Japan], are used in doses of 6-9g to relieve night-sweats associated with ch'i-deficiency or yin-deficiency (Hikino et al. 1984; Hsu et al. 1986). From c.2000-1700BC, for some 2,000 years, the Qäwrighul of far-west China buried their mummies with bundles of Ephedra twigs tied into their shrouds (Mallory & Mair 2000).

Ephedra spp. were thought to have been used ritually by the Neanderthals of Shanidar 60,000 years ago (Rätsch 1992); however, this claim was based merely on the finding of high concentrations of pollen from an Ephedra sp. [closely related to E. distachya, E. fragilis, and E. altissima], as well as pollen from 28 other species of medicinal plants, at the Shanidar cave burial site [in what is today n. Iraq/Kurdistan]. One theory was that the dead had been buried with medicinal flowers by their colleagues. However, bones of rodents [mostly of the 'Persian jird', Meriones persicus] also found at the site, once thought to have been attracted to the cave by the human carcasses, offer a different explanation, as the Persian jird is known to collect and hoard many of the same flowers (Leroi-Gourhan 1975, 1999; Sommer 1999).

In India, E. vulgaris has been used as a 'soma' substitute [see **Amanita**], and [as well as E. intermedia and E. pachyclada] has even been proposed by some to have been the original soma (Flattery & Schwartz 1989; Nadkarni 1976; Ott 1993, 1998b; Tyler 1966). In Nepal, E. gerardiana is "only used as an incense by powerful shamans and high lamas for burial ceremonies" (Müller-Ebeling et al. 2002). Some findings in the Kara Kum Desert [in what is now Turkmenistan] indicate that Ephedra spp. may have been important as an ingredient of the related [or perhaps synonymous] 'haoma' [see also **Peganum**], if haoma was a composite drug rather than a single-plant preparation. Ritual vessels from the temple of the fire-religion at s. Gonur [c.2000BC] were shown to contain traces of Ephedra and **Cannabis**; traces of Ephedra and poppy pollen [see **Papaver**] were found in bowls from the shrine at Togolok 21, and bone tubes with faces engraved on the side contained high concentrations of poppy pollen [to c.1750BC]. The Ephedra may have served as a stimulant to counteract the sedative effects of **Cannabis** and/or **Papaver** (Sarianidi 1993, 1994; theobromus pers. comm.). Modern-day Iranian Zoroastrians use Ephedra spp., with 'pomegranate' [Punica granatum – see *Endnotes*] and milk, as a haoma substitute (Flattery & Schwartz 1989).

E. gerardiana, E. intermedia, and E. distachya, amongst others, are used medicinally in India to treat rheumatism, and digestive and respiratory disorders (Chopra et al. 1958; Nadkarni 1976). In Ladakh, India, fruits of E. gerardiana are dried and powdered with tobacco [see **Nicotiana**], to make a kind of 'chewing tobacco' preparation [called 'tsotuck']; for use, a pinch of the powder is placed under the tongue (Bhattacharyya 1991). The Turkis of the Gobi Desert grind an Ephedra sp. with tobacco and lime in a mortar, to prepare a mixture known as 'naz', which "they chew with the most evident enjoyment" (Cable & French 1942). Zen monks are said to have used Ephedra spp. to "promote calm concentration during meditation" (Chevallier 1996).

The ancient Greeks, Romans and Egyptians knew of the properties of E. distachya and E. fragilis, which were considered to be 'foods of Saturn', and were ritually consumed in wines during Saturnalian rites, along with other intoxicating plants. E. americana was used by the Aztecs, and is today smoked with tobacco by some indigenous Mexicans to treat headache. Some native N. American groups use E. californica as a stimulant to prepare for their vision quests. The early Mormons drank a beverage made from E. nevadensis (Emboden 1979a; Heffern 1974; Rätsch 1992), which filled the gap left by their non-consumption of caffeinated products. E. fragilis is used in Spain decocted with water and honey, to treat coughs and colds (Martinez-Lirola et al. 1996).

Ephedra spp. contain *phenethylamine*-related alkaloids based on *ephedrine*; these give the herbage its CNS-stimulant, astringent, bronchodilating, vasoconstricting, diuretic, antispasmodic [for bronchi], hypertensive, appetite-suppressant and antiallergenic effects (Bruneton 1995; Chopra et al. 1965; Morton 1977). Ephedroxane, which is found in some Ephedra spp., has antiinflammatory activity (Bruneton 1995) and is structurally related to aminorex and 4-methylaminorex ['ice', 'euphoria'], synthetic CNS-stimulants. Like *ephedrine* and *amphetamines*, aminorex has been shown to stimulate release of *norepinephrine* and *dopamine* (Rothman et al. 2001). In *ephedrine*-containing Ephedra spp., *ephedrine* is almost always the major alkaloid, followed by pseudoephedrine, which is less potent than *ephedrine* as a CNS-stimulant by c.10-50 times. European Ephedra spp., like E. distachya, are generally low in alkaloids, and American species generally do not contain appreciable levels of *ephedrine*. The thin, green stems are the most potent parts; the roots are the least potent, and may contain the hypotensive imidazole alkaloid feruloylhistamine. Alkaloid content decreases with greater rainfall over the year. Alkaloids are most abundant when the plants are blooming in autumn. Exposure to heat or humidity whilst drying decreases the alkaloid levels, though once dry, they are very stable (Bruneton 1995; Chopra et al. 1965; Hikino et al. 1984; Huang 1993; Liu et al. 1993; Morton 1977; Nadkarni 1976).

The herbage can be prepared dry or fresh. Either way, the chopped and/or shredded herb may be decocted in dosages of 10-30g or more for stimulant effects [some use only a heaped tablespoon or less; I find I need a little more], though wide variation in alkaloid content should be expected, depending on species, strain and ecological conditions. At higher does, side-effects may occur, such as dry mouth and throat, heart palpitations, sweating, dizziness, headache, nausea, flushed skin and numbed extremities. It should not be consumed by persons with cardiovascular problems, or those taking an MAOI (pers. obs.; pers. comms). Ephedra has been reported to intensify the effects of psychedelics such as **Psilocybe** mushrooms (pers. comms.). In recent years, Ephedra spp. and extracts thereof have been banned in some countries, following adverse cardiovascular reactions in some consumers, many of whom probably had existing heart conditions and had been taking the drugs for an extended period. It does not seem unreasonable to suspect that a hidden agenda for this banning is related to the use of Ephedra spp. and its alkaloids in *methamphetamine* manufacture.

E. americana contains *ephedrine*.

E. californica contains *ephedrine* and pseudoephedrine (Lundstrom 1989).

E. compacta [from Mexico] tested positive for alkaloids (Fong et al. 1972).

E. distachya has yielded *ephedrine*, pseudoephedrine, norephedrine, and *norpseudoephedrine* [cathine] (Lundstrom 1989), as well as the flavonoid vicenin 2 (Porter & Wallace 1988).

E. equisetina has yielded 0.61-2.2% alkaloids, of which 85-90% was *ephedrine*, and 10-15% pseudoephedrine (Bruneton 1995; Henry 1939; Liu et al. 1993; Morton 1977), as well as the flavonoids vitexin, vicenin-1, vicenin-2 and vicenin-3 (Porter & Wallace 1988).

E. fragilis has yielded *ephedrine* and pseudoephedrine (Lundstrom 1989); E. fragilis ssp. campylopoda also yielded the flavonoids violanthin and vicenin-3 (Porter & Wallace 1988).

E. gerardiana has yielded 0.28-2.79% alkaloids, of which 50-90% was *ephedrine*, with lesser amounts of pseudoephedrine (Chopra et al. 1958; Henry 1939; Liu et al. 1993). E. vulgaris var. helvetica has yielded 0.018-0.305% *ephedrine* from Chinese plants; European plants seem to contain predominantly pseudoephedrine instead (Chen & Hao 1926; Masucci & Suto 1926).

E. intermedia yielded 0.42-2.33% alkaloids, of which 4.1-53.3% was *ephedrine*, 30-78% pseudoephedrine, 0.8-5% methylephedrine, 0.7-4.3% methylpseudoephedrine, 0.5-4.3% norephedrine and 1.4-15.1% *norpseusoephedrine*, as well as ephedroxane (Buckingham et al. ed. 1994; Chopra et al. 1958; Henry 1939; Liu et al. 1993; Lundstrom 1989); the flavonoids vicenin-1 and vicenin-3 are also found in the species (Porter & Wallace 1988).

E. intermedia var. tibetica has yielded 0.2-1% alkaloids, mostly pseudoephedrine, as well as *ephedrine* [0.025-0.056%] (Chopra et al. 1958).

E. major has yielded 1.31-2.56% alkaloids, 62-75% being *ephedrine* (Chopra et al. 1958; Henry 1939; Morton 1977), as well as the flavonoids violanthin, vicenin-1, vicenin-2 and vicenin-3 (Porter & Wallace 1988).

E. monosperma has yielded 2.8% alkaloids (Bruneton 1995).

E. nevadensis contains predominantly *norpseudoephedrine* (Emboden 1979a), though others have found no alkaloids, only large amounts of gallotannic acid (Terry 1927); the flavonoids vicenin-2 and lucenin-2 are also found (Porter & Wallace 1988).

E. sinica has yielded 0.44-2.31% alkaloids, of which 18-85% was *ephedrine*, 7.6-35% pseudoephedrine, 2.6-20.4% methylephedrine, 0.26-2% methylpseudoephedrine, 0.9-5.9% norephedrine and 1.2-9.9% *norpseudoephedrine* (Henry 1939; Liu et al. 1993).

E. tweediana [from Uruguay] tested positive for alkaloids (Fong et al. 1972).

Ephedra spp. roots, as used in TCM [usually from E. equisetina or E. sinica; see above], have yielded ephedradines A-D [spermidine alkaloids with hypotensive activity], feruloyl-*histamine*, and maokonine [betaine] (Hikino et al. 1983; Hsu et al. 1986).

Other chemicals have been reported from the genus – benzylamine, ephedralone, ephedrannin A, 5-phenyloxazolidines, nilcitin, sexangularetin, lucenin, mahuannins A-D, proanthocyanidin A5, herbacetin 7-(6-quinoylglucoside), 5,11,14,17-eicosatetranoic acid, and catechins (Bruneton 1995; Buckingham et al. ed. 1994).

Ephedra sinica is an erect, irregularly shaped perennial shrub 6-45cm high, monoecious or rarely dioecious; woody stem creeping in soil; aerial stems erect; braches irregular, radical, 1.5mm diameter, slender, stiff, articulate, furrowed, cylindrical, slightly flattened, slightly fibrous, pith form elliptical to circular; internodes slender, 2.5-5cm x 1-1.5mm, broken surface showing brownish-red pith. Non-functional scale-leaves sheath-like, in whorls around the nodes, 2 per whorl, basal ones half connate, surrounding nodes, apical ones half divided, free portion triangular, apex acuminate, with 2 nerves in middle, all generally acute-triangular, membranous, 2-4mm long, subulate, connate and reddish at base, apex recurved, base united into a cylindrical form. Inflorescences cone-like spikes; male cones broad-ovoid, 4-5mm long, terminal or axillary, 3-5 together, rarely solitary, individual cone consisting of 3-5 pairs of bracts; bracts connate, coriaceous with membranous margin, each subtending 1 male flower with a hyaline obovate scale and 6-8 exserted stamens; perianth 2-lobed; anthers exserted, stalked, rectangular or ovoid, crowded, dehiscent by apical slit; filaments connate, separated near anthers; female inflorescences usually solitary, terminal, ovoid spikes, consisting of 4-5 bracts; bracts green, coriaceous, connate, with narrow hyaline margin, upper 2 each subtending 1 female flower with shell-like perianth below ovule; apical end of integument extending, forming an erect tube 1-1.5mm long. Fruit a small, globular fleshy red cone; seeds 1-2, usually oblong to ovoid, plano-convex, 4.5-5.5 x 4mm. Fl. May; fr. Jul.

At c.1515m; n. China from Sinkian to Hopeh Province, north to outer Mongolia (Borrell 1996; Hu 1969; Liu et al. 1993; Morton 1977).

These plants may be cultivated from seed, layers, or dividing the rootstock in spring. Seed should be sown where they are to grow in early spring, spaced at least 75cm apart, and 1.25cm deep. Seedlings should be watered regularly in the first year, but will later tolerate much dryness and full sun, preferring less than 50cm of rainfall a year. Prefers loose, rocky, loamy soil. Harvest after 4 years old (Chopra et al. 1958; Grubber 1973; Morton 1977).

Ephedra spp. are more closely related to conifers than to true flowering plants.

EPIPHYLLUM

(Cactaceae)

Epiphyllum sp. – pokere, pukara, wama panako

Epiphyllum oxypetalum *(DC.) Haw.* **(E. acuminatum** *Schumann***; E. grande** *Br. et R.***; E. latifrons** *(Link) Zucc.***; Cereus latifrons** *Pfeiffer***; C. oxypetalus** *DC.***; Phyllocactus acuminatus** *Schumann***; P. grandis** *Lemaire***; P. guyanensis** *Brongnart***; P. latifrons** *Link***; P. oxypetalus** *Link***; P. purpusii** *Weingart***)** – flor de baile, belle de nuit, queen of the night, Dutchman's pipe, strap cactus, orchid cactus, night-blooming cereus, tarn hua

The Sharanahua and Culina of Amazonian Peru use an unidentified Epiphyllum sp. as an ayahuasca additive [see **Banisteriopsis**]. They either add only one 'leaf' to the brew, or drink its unboiled juice with the ayahuasca (McKenna et al. 1995; Pinkley 1969; Rivier & Lindgren 1972; Schultes 1972). It is not reported how the plant contributes to the effects of ayahuasca. E. oxypetalum has been claimed to cause "hallucinations" when taken in high doses (Trout ed. 1998; Trout & Friends 1999), but this may be a confusion with Selenicereus grandiflorus [see below], which has had similar claims made for it. E. oxypetalum is popular in horticulture for its large, fragrant, nocturnal flowers. Two of its common names, 'queen of the night' and 'night-blooming cereus', usually refer instead to the [equally popular] cactus species Selenicereus grandiflorus [see *Endnotes*].

E. oxypetalum is reportedly used in Malaya for longevity (http://squid2.laughingsquid.net/hosts/herbweb.com/). The flowers [as 'tarn hua'] are claimed to be used in Chinese medicine to "replenish the vital essence" and "strengthen the lungs". To prepare a medicine for this effect, a dose of 8 flowers is collected at night, and gently decocted for 30min., before being cooled, strained and consumed (http://www.massherb.com/Merchant/herbs/commonherb40.htm). However, this might also be a confusion with S. grandiflorus or another plant. I have not been able to find further reference to either of these American plants being adopted into TCM, and the internet reference quoted above gave no supporting reference for the claim.

The Javanese goddess Ratu Kidul was said to have stolen the 'night flower' wijayakusuma from Arjuna, in order to gain immortality. This flower has tenuously been proposed to be represented by a number of different plants, including E. oxypetalum (Jordaan 1997), which would seem unlikely, because of its disparate geographical origin [see below].

I conducted an experiment with an Epiphyllum sp. which had been labelled as E. oxypetalum [confirmation of species identity pending]. Branches were harvested shortly after midday from a greenhouse in Sydney, Australia, in early August. They were washed with cold water to remove possible contaminants, and due to necessity of circumstance, they were stored in a cool position for 20 days. A branch which had undergone minimum water-loss was selected for the experiment [44cm long, up to 9.5cm wide; c.22g]. This was rinsed again, then crushed in water with a pestle, before being frozen in the same water, in a sealed container. Two days later, the mixture was thawed and homogenised in an electric kitchen blender, then strained through fine cloth. The procedure resulted in c.200mls dark, brownish water with a smell of chlorophyll. The brew was consumed in several mouthfuls, and tasted quite tolerable. I did not expect much, if anything, to happen. After 1 hour, no obvious 'hallucinogenic' symptoms had been noted, though some vague alteration of consciousness seemed to be occurring. My head and body felt as though 'tightly packed', and a slightly altered sense of my surrounding space was felt; these effects were quite mild, and not unpleasant, and persisted for several hours. This may have been a 'placebo effect', a product of my imagination, but the experiment demonstrated a lack of toxicity, and further experiments at higher doses may be warranted.

E. angulifer contains traces of kaempferol [MAOI (Sloley et al. 2000)] and several organic acids.

E. truncatum [Zygocactus truncata] contains betacyanins, betaxanthins and caffeic acid (Schultes & Raffauf 1990), as well as unidentified alkaloids (Wheaton & Stewart 1970). Unidentified alkaloids have also been observed in E. ackermannii and E. phyllanthus (Trout & Friends 1999).

Epiphyllum oxypetalum is a stout epiphytic plant, up to 3m long or more, much branched, main stems terete and woody; branches flat, thin, leaf-like, to 10-12cm wide, long-acuminate, deeply crenate or 'feather-like'; areoles small, on margins of flattened branches. Flowers fragrant, tube 13-15cm long, c.1cm thick, stout, +- curved, red, bearing distant narrow scales c.10mm long; outer perianth segments narrow, acute, reddish to amber, 8-10cm long, inner perianth segments oblong-lanceolate, white, c.9.5cm long; stamens numerous, white; ovary green, slightly angular; style thick, 20cm long, white; stigma-lobes numerous, entire, cream-coloured. Flowers open in the evening; after anthesis, they are drooping and limp.

Mexico, Guatemala, Venezuela, Brazil; widely cultivated in tropics (Borg 1951; Britton & Rose 1963).

Sow from seed in spring or summer; treat as for typical cactus-seed germination. Propagate from cuttings by taking stem cuttings 15-20cm long, in the spring; allow to callus over, then plant in pots of sand or very sandy soil, in a gentle light situation. Only water when fairly dry. Once established, drench with water, and let the top 1/3 dry out before watering again. Feed monthly with a low-N fertiliser, except in winter; keep only slightly moist in winter. Prefers good air circulation, but dislikes strong winds; prefers c.50% humidity. Min. temp. 10°C, prefers warmer. Frost-sensitive (pers. comms.).

EPITHELANTHA

(Cactaceae)

Epithelantha bokei *L. Benson* **(E. micromeris var. bokei** *(L. Benson) Glass et Foster***)** – hikuli rosapari?

Epithelantha micromeris *(Engelmann) Weber* **(E. micromeris ssp. micromeris; Mammillaria micromeris** *Engelm.***)** – hikuli mulato, button cactus

Epithelantha micromeris var. greggii *(Engelm.) Borg.* **(E. micromeris ssp. greggii** *(Engelm.) Taylor***; E. densispina** *Bravo***; E. greggii** *(Engelm.) Orcutt***; E. rufispina** *Bravo***; Mammillaria micromeris var. greggii** *Engelm.***)** – hikuli rosapari?

Epithelantha micromeris ssp. pachyrhiza *(W.T. Marshall) Taylor* **(E. pachyrhiza** *(W.T. Marsh.) Backeberg***)**

Epithelantha micromeris ssp. polycephala *(Backbg.) Glass* **(E. polycephala** *Backbg.***)**

Epithelantha micromeris ssp. unguispina *(Bödeker) Taylor*

The Tarahumara of Mexico know E. micromeris as a type of peyote [see **Lophophora**], 'híkuli mulato'. It was reported early last century, by Carl Lumholtz, to "make the eyes large and clear to see sorcerers, to prolong life and to give speed to the runners." The fruits were also claimed to

be used, but to be less potent. 'Hikuli rosapari' or 'rosapara' was said to refer to older specimens [according to some botanists a distinct and different species, possibly **Mammillaria** senilis], which are believed to cause insanity in 'bad people' and cause them to throw themselves from cliffs (Bravo 1937; Bye 1979b; Schultes 1967a). E. micromeris fruits are edible, and are known as 'chilitos' (Bravo 1937; Britton & Rose 1963).

A bioassay of a single de-spined specimen of E. micromeris [c.2.5cm diam.] was conducted by one psychonaut. Approximately 30min. after eating the plant, the subject "entered a pleasant state of lucid mind. There was a distinct enhancement of perceptions and my energy level was incredibly high all day. That night I fell easily to sleep and experienced lots of hypnagogic imagery in my dreams. There were no noticeable negative side-effects". Smoking the plant "seems to produce some central nervous system stimulation and mild perceptual change for several hours" (Anon. 1998).

E. micromeris has yielded [w/w] 0.006% 3-MeO-*tyramine*, 0.0042% *DMPEA*, 0.001% N-methyl-*DMPEA*, 0.0003% *tyramine*, 0.0004% N-methyl-*tyramine* and 0.0026% *hordenine*; as well as triterpenes – 0.00008% epithelanthic acid, 0.004% methylepithelanthate, 0.0003% methylmachaerinate, methyloleanolate, 0.58% oleanolic acid, and 0.0002% of an unidentified triterpene lactone; and 0.001% β-sitosterol (Štarha 1994; Štarha 1995b; West & McLaughlin 1977; West et al. 1978).

Epithelantha micromeris is solitary, or offsetting and mat-forming, clumps to 6cm high, 15cm across; +- globose, 1.5-4(-12.5)cm high, 2.5-6(-7.5)cm diam., green, completely covered with chalk-white spines, slightly depressed at apex; tubercles small, barely 1mm or more high, conic-cylindroid, close-set in spirals (20-35 rows); areoles c.1mm diam., usually c.2mm apart; spines white, numerous and very dense, obscuring stem, arranged in 2-3 series, 20-30 per areole, with wooly hairs, 2-6mm long, c.0.1mm diam. at base, acicular, with numerous forward-directed minute barbs; spines of upper areoles (before disarticulating) c.twice as long as in lower areoles at flowering. Flowers funnel-shaped, from apical areoles, usually obscured by spines, c.3-4.5mm diam., 6mm long, whitish to rose-red; perianth segments 3-5, with pink midribs and pale pink margins, the larger elongate-semicircular, 1mm long and wide, apex rounded, irregularly denticulate; petals pale pink, largest approaching obdeltoid, upper sides somewhat curving, 1mm long and wide, acute, entire; stamens c.10-15; filaments tinged with red, c.0.5-0.7mm long; anthers white or pale yellow, 0.25mm long and wide; style yellowish, c.4.5 x 0.25mm; stigmas 3, 0.5mm long and wide; ovary in anthesis c.1mm long. Fruit club-shaped, red, sometimes colourless, fleshy at maturity, clavate, the lower portion not producing seed, 3-12 x 1.5-6mm; seeds (1-)4-11, large, 1mm long or more, rather cap-shaped, with recessed-elongate basal hilum, seedcoat red-brown or black, verrucose.

Limestone or igneous soils of rocky hills and ridges in desert and grassland, 1020-1500m; w. Texas, Arizona, New Mexico, to n. Mexico (Benson 1982; Haustein 1991).

'Híkuli rosapari' may represent a different species or subspecies. Lumholtz noted that compared to 'híkuli mulato', "it looks quite different, being white and spiny" (Schultes 1967a). Some consider this plant to be represented by **Mammillaria** senilis (Bye 1979b). This might also fit the description of E. bokei, which is often regarded as a subspecies or variant of E. micromeris, and has far more dense spination, making the plant appear white. Intermediate in appearance is E. micromeris var. greggii, which grows to a larger size, and has larger spines. It does not appear to be as white as E. bokei (Benson 1982; Innes & Glass 1991).

EREMOPHILA

(Myoporaceae)

Eremophila alternifolia *R. Br.* – taritjanpa, irmangka-irmangka, narrow-leaved fuchsia bush, magenta emu bush

Eremophila bignoniiflora *(Benth.) F. Muell.* – bignonia emu bush, fuchsia bush, dogwood, eurah

Eremophila longifolia *(R. Br.) F. Muell.* – amuna, utnirringa, tulypurpa, otenerrenge, julpur, berrigan, emu bush, weeping emu bush, long-leaf emu bush, native plum tree

These shrubs, the fruits of which emus are quite fond, have an esteemed position in the pharmacopoeia of aboriginal cultures in north and central Australia. Many Eremophila spp. are used medicinally. The Walbirri of the Northern Territory drink the flower nectar of E. freelingii and E. latrobei as a delicacy. E. freelingii leaves are also infused as a tonic and tea substitute [see **Camellia**]. E. gilesii and E. neglecta are also used as tonics. E. alternifolia is considered by many tribal elders to be 'number 1 medicine', and it was one of the few herbs to be actually dried and carried around, so that a supply was always at hand. The foliage is sun-dried, stripped from the twigs, broken up, and wrapped in a soft piece of bark for storage. A small handful is generally used for a medicinal dose, infused or decocted in water. It acts as a decongestant, expectorant, and analgesic, and is said to promote a feeling of well-being. For internal pains, a drink of it is both consumed and rubbed on the body, and the essential-oil vapours may be inhaled to relieve congestion. The plant is also used to treat insomnia or fitful sleep, colds, flu, headache, fever and septic wounds. E. longifolia is one of the most sacred of plants to central Australians. It is smouldered to 'smoke' new-born babies [to strengthen the child, and stop the mother's bleeding], as well as in other sacred ceremonies. Leaves and branches may be placed in head- and arm-bands during circumcision rites; the leaves are also used to brush men and sacred objects during some rituals. The branches are used to shroud dead bodies and line their graves. Some groups say preparations of E. longifolia are only safe for external use, and are not to be brought into contact with the eyes. However, some tribes are reported as applying a wash of it to sore eyes, as well as drinking a decoction for colds. A decoction of it is usually used as a wash for sores, wounds, pain and fever; a leaf infusion is also used for insomnia (Aboriginal Communities 1988; O'Connell et al. 1983; Richmond & Ghisalberti 1994). A decoction of E. bignoniiflora leaves is also reputed to be an excellent insomnia remedy, analgesic, and general medicinal tonic. George Quartpot, an indigenous healer in s.w. Queensland, stated that "When a haunted place is annoying you, you can't sleep, or dream bad thoughts, this will fix you right up" (Low 1990).

E. alternifolia leaves yielded 3.6-4% essential oil, of which 44% was fenchone, 15% limonene, 0.4% *camphor*, and lesser amounts of other compounds (Aboriginal Communities 1988).

E. longifolia seems to be quite variable in chemical makeup. One study found the leaves to yield 5.8% essential oil, which contained 37-93% *safrole* and 6-63% *eugenol* (Della & Jefferies 1961). An un-vouchered specimen of leaves, thought to belong to E. longifolia, gave only 0.025% essential oil, of which 55% was α-*pinene*, with no interesting phenylpropenes at all (Aboriginal Communities 1988). Furthermore, it has been documented that in different areas, this species has been deficient in oil glands (Della & Jefferies 1961).

Eremophila longifolia is a root-suckering shrub or small tree to 8m tall; branches drooping, +- tuberculate, grey, pubescent, hairs appressed or spreading, usually non-glandular, or rarely with glandular ones or a mixture of both; bark dark grey, rough. Leaves alternate, linear to linear-lanceolate, apex acuminate or attenuate, (3-)6-14(-20)cm x 2-7(-14)mm, margins entire, sparsely to densely pubescent or tomentose, often glabrescent. Flowers axillary, 1-3(-5) per axil; pedicels pubescent, 4-10.5mm long; sepals 5, green, valvate or imbricate, triangular or +- ovate, 2-8mm long, 1.5-2.5mm wide, apex acute to attenuate, pubescent; corolla zygomorphic, 5-lobed, unequal, 2-3cm long, lobes obtuse, pubescent externally, pinkish to reddish-brown, spotted inside; stamens 4, exserted; anthers reniform, rarely sagittate when dehisced, dehiscing by slits. Ovary superior, with nectariferous base, of 2 fused carpels, 2-locular or 4-locular with intruding septa; ovules 1-3(-4) per locule; style slender. Fruit a drupe, ovoid-oblong to subglobose, 5-12mm diam., dry, fleshy, indehiscent, endocarp woody, glabrous or rarely with scattered hairs. Fl. most of the year.

On deep sand or rocky plains and gravelly watercourses, in NT, otherwise adapted to a wide variety of plant communities and soil types; inland in all mainland states of Australia (Aboriginal Communities 1988; Harden ed. 1990-1993).

ERIOGONUM

(Polygonaceae)

Eriogonum annuum *Nutt.*

Eriogonum campanulatum *Nutt.* **(E. brevicaule ssp. campanulatum** *(Nutt.) S. Stokes***)**

Eriogonum inflatum *Torr. et Frém.* – desert trumpet

Eriogonum jamesii *Benth.* – James buckwheat, big snake's tobacco, horned worm's tobacco, antelope sage, yellow flower, bil nat'oh, bilatah lico, ta'loo

Eriogonum ovalifolium *Nutt.* **(E. nivale** *Canby***; E. ochroleucum** *Small***; E. roseiflorum** *Gandg.***; E. rubidum** *Gandg.***; E. vineum** *Small***)**

Eriogonum umbellatum *Torr.* **(E. ellipticum** *Nutt.***; E. hausknechtii** *Dammer***; E. polyanthum** *Benth.***; E. stellatum** *Benth.***; E. subalpinum** *Greene***; E. tolmieanum** *Hook.***; E. torreyanum** *Gray***)** – mountain tobacco

Eriogonum spp. – umbrella plants, wild buckwheat

This large genus of herbs is widespread in North America; many species are used medicinally or as food by native Americans. The medicine pipe used by the Shoshone is filled with a mixture of tobacco [see **Nicotiana**] and E. inflatum. The young stems of this species are also eaten raw as food, harvested before flowering. The Navajo use all parts of E. jamesii medicinally, applying it to wounds, as well as to ease the pains of childbirth. E. umbellatum, 'mountain tobacco', is used with other herbs as a ritual fumigant and emetic. The Navajo smoke the leaves of Eriogonum spp., such as E. jamesii and E. umbellatum, mixed with other herbs to relieve 'disturbing dreams' [see *Endnotes*] (Siegel et al. 1977; Usher 1974; Winter 1998).

E. alatum roots have yielded *hordenine*.

E. annuum [whole plant] has yielded *hordenine* and N-methyl-4-MeO-*phenethylamine*.

E. campanulatum yielded these compounds from the aerial parts, but only contained *hordenine* in the roots.

E. inflatum [whole plant] yielded *hordenine* (Schroeder & Stermitz 1984).

Unidentified Eriogonum spp. have been reported to yield *DMT* (Ott 1994, quoting Schroeder 1986), but this was a misreading of Schroeder (1986), who discussed the finding of *hordenine* and N,O-dimethyl-*tyramine* [N-methyl-4-MeO-*phenethylamine*] in four species, most likely those reported above.

E. ovalifolium tested positive for the presence of *DMT* in small amounts, by TLC; another unidentified compound was observed under UV light, in higher concentrations. An unidentified Rocky Mountain Eriogonum sp. with narrow leaves also contained traces of *DMT* (Trout pers. comm., citing Appleseed unpublished work).

The subgenus Flava does not seem to contain alkaloids (Schroeder & Stermitz 1984).

Eriogonum ovalifolium is a caespitose perennial herb, forming mats up to 30-40cm across; with closely branched, woody caudices thickly beset with leaves; densely white-tomentose; flowering stems scapose, slender, tomentose, (1-)3-20(-30)cm tall. Leaves basal, roundish to elliptic or oblanceolate, 5-20(-30)mm long x 3-15mm wide, from greenish on upper surface and tomentose, to nearly white on both sides and pannose-lanate, spatulate to slenderly petiolate; petioles 1-3 times as long as blades. Inflorescence a capitate cluster of several involucres, 1-2.5(-3.5)cm diam., +- umbellate, subtended by 3 or more linear-lanceolate bracts, very rarely with 1 foliaceous bract; involucres several, white-wooly, mostly (2.5-)4-5(-6)mm long, narrowly campanulate-turbinate to nearly cylindric, with 5 lanceolate, erect [rarely recurved] teeth 0.5-1.5mm long, rarely short-pedunculate; perianth cream-white to ochraceous, often tinged yellow, or pinkish to purplish in age, glabrous externally, (2.5-)3-4(-5)mm long, not stipitate, segments free almost to the swollen base, outer ones oblong-obovate to elliptic, often slightly cordate at base, inner ones narrower, oblong-spatulate, exserted; filaments basally pilose; stamens 9, inserted near base of perianth. Pistil 3-carpellary; ovary glabrous, 1-celled; ovule 1; styles 3; stigmas mostly capitate. Achenes glabrous, 2-2.5mm long, 3-angled. Fl. May-Aug.

Dry slopes and flats, sagebrush scrub [see **Artemisia**], alpine ridges, **Juniperus** or ponderosa pine woodland, mostly between 1600-2400m; from British Colombia [Canada] s. through Cascades and Olympic Mts. [Washington], w. Oregon, n. California, to mts. of s. California, to east slope of Sierra Nevada, n. and e. to Alta., Rocky Mountains.

Varies greatly under different ecological conditions. Plants at higher altitudes tend to be smaller. Intermediate forms between the similar E. ovalifolium and E. strictum have been observed. The two species are usually differentiated by the latter having a foliate-bracteate inflorescence, and/or pedunculate involucres (Hitchcock et al. 1959; Munz et al. 1968).

ERYTHRINA

(Leguminosae/Fabaceae)

Erythrina americana *Miller*

Erythrina berteroana *Urb.* **(E. neglecta** *Krukoff et Moldenke***)** – pito, coral bean, coralilla, tzinte, mata caiman

Erythrina coralloides *DC.* **(Corallodendron coralloides** *(DC.) Kuntze***)** – colorín, coral bean

Erythrina flabelliformis *Kearney* **(E. purpusii** *Brandegee***)** – coral bean, coralina, chilicote, kaposi, aposi, aposhi

Erythrina fusca *Lour.* **(E. atrosanguinea** *Ridl.***; E. caffra** *Blanco***; E. glauca** *Willd.***; E. moelebei** *Vieill. ex Guill. et Beauv.***; E. ovalifolia** *Roxb.***; E. patens** *DC.***; E. picta** *Blanco***; Corallodendron fuscum** *(Lour.) Kuntze***; C. glaucum** *(Willd.) Kuntze***; C. patens** *(Moc. et Sessé ex DC.) Kuntze***; Duchassaingia glauca** *Walp.***; D. ovalifolia** *Walp.***; Gelala aquatica** *Rumph.***)** – amasisa, assacú-rana, gachico, moté manso, moté bravo

Erythrina indica *Lamk.* **(E. indica** *Zoll.***; E. variegata var. orientalis** *(L.) Merr.***)** – Indian coral tree, parijataka, parijata, pangra, mandar, palita-madar, moochy wood tree

Erythrina mulungu *Mart. ex Benth.* **(E. corallodendron** *L.***; E. crista-galli** *L.***; E. verna** *Vell.***; Corallodendron crista-galli** *(L.) Kuntze***; C. mulungu** *(Mart. ex Benth.) Kuntze***)** – cockspur coral tree, mulungú, murungú, murungo, muchoc, flor-de-coral, pau imortal, suina-suina

Erythrina poeppigiana *(Walp.) O.F. Cook* – amaciza, amasisa, oropel, mulungú

Erythrina vespertilio *Benth.* **(E. biloba** *F. Muell.***; Corallodendron vespertilio** *(Benth.) Kuntze***)** – grey corkwood, cork tree, bat's wing coral tree, heilaman tree, goomurrie, aranyi

Erythrina spp. – coral tree, colorín, colorines, moté, patol, sompantle, zumpantle, xoyo, chakmol-che, parencsuni, te'batai

These plants, particularly their seeds and bark, have medicinal, magical and psychoactive uses. E. coralloides may have been the 'tzompanquahuitl' of the Aztecs, a tree associated with sacrificial death. Figurines of Aztec gods were carved from its wood; such amulets are still carved today, and are used to protect the home from evil. Its seeds are said to cause 'madness and impotence'. The stem and bark have been claimed to represent another kind of 'sinicuichi' [see **Heimia**]. Guatemalan shamans from the Ixil and Mam groups use seeds of E. flabelliformis in divination [not consumed], as well as for calendar markers. The Tarahumara say that these seeds induce erotic dreams, though they generally only use them with caution to treat toothache and intestinal disorders. The Maya of Yucatan attribute magical medicinal powers to a local Erythrina sp. Modern Lacandon Maya women wear the seeds beaded onto strings for ornamentation, and they may have once been used as a female aphrodisiac (Bye 1979b; Diaz 1979; Malone & Rother 1994; Rätsch 1992; Schultes & Hofmann 1980, 1992); it has been reputed that after eating only 2-3 seeds, a woman would turn into a raging nymphomaniac (Rätsch 1990)! 'Accidental poisonings' have been reported from such necklaces (García-Mateos et al. 2001), presumably from prolonged skin contact, or perhaps from absent-mindedly chewing or sucking on the seeds.

E. berteroana is used as a soporific in C. America. For this, the flowers are picked before the corolla has opened and turned red, though if they have opened, only the calyx is used. Other parts of the plant, ie. young leaves and twigs may be used, but are less prized. They are taken either cooked with food or made into a tea, as a sedative, nerve tonic and soporific, said to bring deep, relaxed sleep in 30 minutes. In Guatemala, E. fusca flowers are taken in a similar way. Crushed branches of Erythrina spp. have been used to stun fish (Hastings 1990; Morton 1994). Flowers of E. americana and E. flabelliformis are also a popular food in Mexico, and unripe green flowers of E. americana are infused or decocted for insomnia by the Huastec Maya (García-Mateos et al. 2001; Hastings 1990; Ott 1993). The seeds, bark and leaves of E. americana have also been reported to act as sedatives. The wood of this and other species is too soft for use in construction, and is rarely used as firewood, though it is widely used in the manufacture of carved figurines, and sometimes masks for religious ceremonies. E. americana, E. fusca and other species are commonly grown as shade trees for coffee [see **Coffea**] and cacao [see **Theobroma**] plantations, as well as for living fences and green manure (García-Mateos et al. 2001). E. fusca and E. poeppigiana are sometimes used as ayahuasca-additives in Iquitos [see **Banisteriopsis**] (Luna 1984; McKenna et al. 1995). E. poeppigiana wood is used for the floors of houses of worship in Candomblé (Voeks 1997).

E. mulungu is used in Brazil as a hypnotic sedative and nerve-tonic; it also treats asthma, bronchitis, constipation, hepatitis, water retention, skin diseases and intermittent fevers. The bark, leaves and/or flowers may be used, though it is most often the bark (Anon. 1881a; http://www.rain-tree.com). 'Mulungú' is used in the form of bark scrapings as a strong soporific in small amounts [several tsp.], and it is very effective, promoting a deep, uninterrupted sleep without fogginess upon waking (pers. obs.). However, as E. mulungu shares the common name 'mulungú' with E. poeppigiana, there may be some confusion regarding the specific origin of bark obtained commercially under this name.

Australian aboriginal peoples of some regions make shields from E. vespertilio. A leaf decoction is sometimes used as a sedative. A water maceration of the bark is applied externally for headache and sore eyes (Lassak & McCarthy 1990; Usher 1974). In India, E. indica [bark, juice and leaves] is said to "act on the central nervous system so as to diminish or abolish its functions" (Nadkarni 1976); the leaves are sometimes eaten as a soporific, and as well as the seeds, are considered narcotic (Perry & Metzger 1980). This species is usually regarded as being 'parijata', a 'celestial wishing tree', which in myth was created from the churning of the milky ocean, along with the divine intoxicants 'soma' and 'amrit' [see **Amanita**], Sri Lakshmi [goddess of luck and beauty], and Varuni [also called Amrtsvari – 'lady of amrit'; goddess of wine]. Varuni also wears the flowers of parijata in her hair (Liebert 1976).

Hypaphorine [N,N,N-trimethyl-*tryptophan*] is often encountered in this genus. It is a convulsive poison in frogs, but also a potential precursor to *tryptamine*s such as *DMT*. Although such a synthesis returns a low yield, some species contain very high levels of hypaphorine in the seeds [eg. 5.8% in E. acanthocarpa, 6.7% in E. pallida] which may make the process more practical. Many of the isoquinoline alkaloids found in this genus, eg. α- and β-erythroidine, are neuromuscular blocking agents and peripheral paralytics with some curare-like actions. β-Erythroidine is also a hypnotic, hypotensive and respiratory depressant [LD50 in rats – 27mg/kg]; dihydro-β-erythroidine binds as an antagonist at nicotinic *acetylcholine*-receptors, and is more potent than β-erythroidine, with similar effects [LD50 in rats – 6.55mg/kg]. Their activity as neuromuscular-blockers is antagonised by AChEI's. The erythroidines also synergise with some anaesthetics and hypnotics. Many of the other 'Erythrina alkaloids' have also shown CNS-depressant, neuromuscular blocking, and/or convulsant effects in animal studies (Boekelhede 1960; García-Mateos et al. 2001; Harborne & Baxter ed. 1993; Henry 1939; Marion 1952b; Sloan et al. 1988; Trout ed. 1997c).

Eating ¼-½ a seed of an Erythrina sp. has been claimed to result in a stuporous inebriation (Gottlieb 1992). Seeds of Erythrina spp. are generally believed to be highly toxic (García-Mateos et al. 2001). However, I know of several cases where they have been ground and taken internally, in doses ranging up to 6 seeds, with no apparent effects other than sedation, and occasionally nausea, with some reporting no effects at all (pers. comms.). Although it would seem from this that the toxic activity of hypaphorine injected into frogs does not tranfer to oral consumption by mammals, caution should still be exercised (pers. obs.) as other alkaloids in the seeds [such as β-erythroidine] are known to be orally active. 'Detoxified' seed flour is sometimes used as a stock feed fairly rich in proteins and lipids (García-Mateos et al. 2001).

E. americana seeds have yielded hypaphorine, erythrine, erysodine, erysopine, erysovine [erysocine; isolated as a complex with erysodine], erysothiovine, α-erythroidine, β-erythroidine, erythrocoraloidine, erythratine, erythraline, erythramine, erysothiopine, coraloidine and hexadecanoic, octadecanoic and tetradecanoic acids; lectins and trypsin inhibitors have also been reported from the seeds, as toxic constituents. Flowers have yielded α- and β-erythroidine, erythristemine N-oxide and erythrartine N-oxide (García-Mateos et al. 2001; Hastings 1990; International... 1994; Marion 1952b). In final stages of seed maturation, protein amino acid content increases and free amino acid content decreases (García-Mateos et al. 2001). Alkaloid extracts from the seeds diminished agressive behaviour in rats, proposed to be due to interaction with *acetylcholine* and *GABA* neurotransmission (Garín-Aguilara et al. 2000).

E. berteroana seeds contain erysodine, erysopine, erysothiopine, erysothiovine, erysovine, α- and β-erythroidine and hypaphorine; leaves contain erythroidine and 8-oxo-erythidine. Wood contains α- and β-erythroidine. The plant has also yielded erysoline, erysonine, 8-oxo-α-erythroidine, its β- counterpart, 11-OH-erythratidine, 11-OH-erysosalvine and 11-OH-erysotine (Hastings 1990; Jackson & Chawla 1983; Morton 1994).

E. coralloides seeds have yielded erythraline, erysonine and erysotramidine (García-Mateos et al. 2001).

E. flabelliformis seeds contain hypaphorine, erysodine, erysopine, (+)-erysotrine, erysoline, erysovine, erysothiovine and erysothiopine. Flowers contain callistephin, cyanidin-3-sophoroside and pelargonidin-3-sophoroside (Hastings 1990; International... 1994; Marion 1952b).

E. fusca contains hypaphorine, erysodine, erysovine, erythraline, erythramine and erythratine (Hastings 1990; Marion 1952b).

E. indica seeds contain hypaphorine and erythraline; leaves, stems, roots and fruit produce HCN (Perry & Metzger 1980).

E. mulungu seeds have yielded 1.25-1.87% hypaphorine, 0.04% erythraline, 0.00036% erythramine, 0.012% erythratine, 0.124% erysodine, 0.34% erysopine and 0.0074% erysovine (Deulofeu et al. 1939, 1947; Gentile & Labriola 1942). Leaves, trunks, and roots of the 'Maruba Deiko' cultivar were examined – leaves yielded erythraline, erybidine and N-nororientaline [a benzyltetrahydroisoquinoline]; bark, heartwood, and roots yielded erythraline, erythratine, and erythrinine (Ito et al. 1973). Leaves have also yielded [w/w] 0.0037% *tyramine* (Wheaton & Stewart 1970). Flowers yielded 1.91% erythrinine, 0.11% erythraline, 0.64% 11-β-MeO-erythraline, 0.2% 8-oxo-erythrinine, 0.09% erysopine, 0.05% 11-β-MeO-erythraline-N-oxide, 0.04% 11-MeO-erythratine, hypaphorine, betaine and *choline* (Chawla et al. 1987). An extract of the bark showed sedative properties (Anon. 1881a).

E. poeppigiana leaf has yielded erythroidine, dehydro-α-erythroidine, erythratidine, 11-OH-erythratidine, erysodine, erysopine, erysovine, erybidine, erythratidinone, erysothiovine and isoboldine (Jackson & Chawla 1983; Marion 1952b).

E. vespertilio leaf and stem [plants from Queensland, Australia] yielded 0.025% alkaloids (CSIRO 1990).

Hypaphorine and N,N-dimethyltryptophan are also found in seeds of E. arborescens, E. lithosperma [as well as N,N-dimethyltryptophan methyl ester] and E. variegata (Ghosal 1972; Ghosal et al. 1970b).

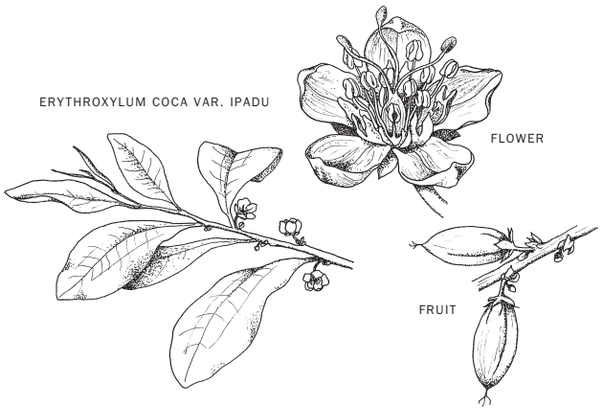
Erythrina flabelliformis is a shrub or small tree to 8m tall, armed with short spines 2-10mm long on branches and petioles; petioles 5-24cm long, tomentulose with fine hairs when young, eventually glabrate. Leaves pinnately trifoliolate; leaflets broadly ovate to suborbicular-deltoid, 3.5-11cm wide, 2.5-7.5cm long, obtuse, rounded or shallowly retuse at apex, base truncate to broadly cuneate, pubescent when young, finally glabrous or nearly so, pinnately-veined; stipules large, stipels of conical glands only. Flowers large and showy, in axillary or terminal racemes to 35cm long; calyx tube nearly truncate, slightly 2-lipped, c.1cm long, reddish, sparsely puberulent to subglabrate; banner red, 4-7cm long, to 18mm wide, much larger than other petals; wings 9-16mm long; keel petals slightly shorter than wings; stamens diadelphous, tube usually longer than free filaments. Ovary short-stipitate or sessile, densely strigose-pubescent, several-ovuled. Pods large, torulose, dehiscent, subwoody, 10-35 x 1.5-2.5cm, constricted between seeds, 1-several-seeded. Seeds 12-18mm long, 2/3 as broad, dark red, with a black line near hilum. Fl. Mar.-May.

Hillsides, along arroyos and rocky canyons; Sonoran Desert, Arizona, n. Mexico (Shreeve & Wiggins 1964).

Propagate from seeds, which must be nicked and soaked first in warm water to enhance germination; or from wood cuttings 0.6-10cm in diameter. Frost-sensitive. Likes well-drained soil, full sun and frequent-watering, though it is said to be drought-resistant (García-Mateos et al. 2001; Grubber 1973). Seedlings, however, require regular water when becoming established, to prevent death from dehydration, which can occur fairly rapidly (pers. obs.).

ERYTHROXYLUM [Erythroxylon]

(Erythroxylaceae)



Erythroxylum acuminatum *Ruiz et Pav.* – coca de mono
Erythroxylum cataractarum *Spruce ex Peyr.* **(E. zuluense** *Schoenland***)** – coca de pescado, ajicito
Erythroxylum catuaba *Martius* – catuaba, tatuaba, caramuru, chuchuhuasha, piratancara, pau de reposta
Erythroxylum coca var. coca *Lam.* **(E. bolivianum** *Burck***; E. chilpei** *E. Machado***; E. peruvianum** *Mitchell et Pascal., ex Steud.***)** – Bolivian coca, mamox-coca
Erythroxylum coca *Lam.* **var. ipadu** *Plowman* – Amazonian coca, ipadu, ipatu, huangana-coca, pato, pa-too, ka-hee, iga-tua
Erythroxylum fimbriatum *Peyr.* – coca brava
Erythroxylum gracilipes *Peyr.* **(E. cuatrecasasii** *W.A. Gentner***; E. novogranatense var. macrophyllum** *O.E. Schulz***; E. recurrens** *Huber***)**
Erythroxylum macrophyllum *Cav.* **(E. costaricense** *Donn. Sm.***; E. filipes** *Huber***; E. floribundum** *Mart.***; E. laurinum** *Planch. et Lind. ex Triana et Planch.***; E. lucidum** *Kunth***; E. multiflorum** *Lundell***; E. skutchii** *Standl.***; E. tabascense** *Britton***)** – coca brava
Erythroxylum novogranatense var. novogranatense *(Morris) Hieron.* **(E. coca var. novogranatense** *Morris***)** – Colombian coca, hayo
Erythroxylum novogranatense *(Morr.) Hieron.* **var. truxillense** *(Rusby) Machado* **(E. hardinii** *Machado***; E. truxillense** *Rusby***)** – Trujillo coca, tupa coca ['noble coca']
Erythroxylum steyermarkii *Plowman* – cerecito, hayo, jaillito
Erythroxylum vacciniifolium *Martius* – catuaba
Erythroxylum (Erythroxylon) spp.

Cultivation and chewing of 'coca' [often E. coca var. coca] supposedly began in Bolivia in the region of Machu Yunga. Its use and cultivation spread from there, to become a central part of Incan culture. Incan royalty chewed 'tupa coca', a flavourful coca probably referable to E. novogranatense var. truxillense. Coca use has been traced back to 2500-1800BC, and the herb is still used today by native peoples, mostly in highland areas of the Andes. The species most used are E. coca, E. novogranatense and their variants, where they occur. The coca plant is considered sacred, and is used as an offering to gods. It is chewed during religious rituals and worship, and ceremonies accompany its planting and harvesting. The leaves were also used by Inca shamans or priests in divination, by interpreting the leaf-venation, their pattern when thrown on the ground, or from the flow of green saliva over the fingers [from chewing the leaf]. Some shamans would also smoke the leaf in large amounts to travel to the spirit world, and Kogi shamans of the Sierra Nevada of Colombia chew it mixed with concentrated tobacco paste [see **Nicotiana**]. In the Andes, exchange of coca leaves is considered the most polite way to greet someone, and is a gesture of contact and friendship. Although it has been made into a tea or applied as a poultice, usually for medicinal reasons [such as to treat stomach and tooth aches], coca is otherwise generally chewed and sucked as a quid. Leaves that are curling, turning a darker colour, and just beginning to become brittle are picked for use. They are collected and left in a bag overnight to ferment slightly, before being dried [either toasted over a fire, or sun-dried], losing about 60% of their original weight. The leaves are then stacked to sweat and moisten enough for chewing. They are then usually pressed into bales or sacks for storage, with care to keep them dry.

Leaves are chewed briefly to moisten and break them up, before the

addition of lime [see *Methods of Ingestion* for more on lime reagents], which serves to make the alkaloids more available to the user through the mucous membranes [though breaking down some of the alkaloids to *ecgonine* – see below]. A small pinch or two of lime is carefully added at the beginning, another perhaps 5 mins later, and more every 10-15 mins afterwards. The wad is kept in the mouth [between the teeth and the cheek] and slowly sucked for at least an hour. The correct amount of lime to use is often a process of trial and error to the non-native novice chewer. Sometimes fresh leaves are occasionally added, and after lime has been added, the juice is swallowed in small amounts rather than spat out. Limestone is often used as the source for the lime; those with access to the coast may use seashells (Antonil 1978; Cobo 1990; Davis 1996; Emboden 1979a; Kennedy 1985; Martin 1970; Plowman 1979; Rätsch 1992; Smith 1981; Uscategui 1959; Von Bibra 1865). Today, the readily-available sodium bicarbonate is often used instead, mostly in urban areas. Otherwise, alkaline ashes prepared from plants are still used for the lime reagent, as in Amazonian limes [see below]. For example, in n. Argentina, stems of Chamissoa altissima, Iresine diffusa [see *Endnotes*], **Senecio** bomanii, and S. hieronymii have all been used, with substances such as ground raw potato [see **Solanum**], boiled corn grains, **Citrus** aurantium juice, sugar, salt, and water used as binders (Hilgert 2001).

E. coca var. ipadu is cultivated in parts of the western Amazon, and is no longer known in a truly wild state. It is cultivated by the men, in plots usually removed from those for vegetables. Some tribes make an infusion of the leaves for chest pains. For chewing, the leaves are prepared by toasting on a flat clay oven, turning the leaves often until dry and crisp. They are finely powdered in a large mortar, and finally mixed in equal proportions with the alkaline ashes of another plant [often **Cecropia** spp., sometimes **Musa** spp. leaf]. The Tanimuka of Colombia blow smoke from Protium heptaphyllum resin [see *Endnotes*] over the powder, to improve the taste. This mixture is finely sifted, by beating through the fibres of a bark-bag, in the mortar. Now ready, it is stored in a special container. The Makú prepare it fresh each evening, and thus have less need to store the drug. The preparation is usually used throughout the day [but sometimes only in the evening], and during small ceremonial events. 1-2 spoons of the powder are inserted into the mouth, with an improvised spatula, which is moistened and kept as a quid to be sucked in the sides of the mouth. This dose may be topped up as the old powder is swallowed (Martin 1970; Prance 1972; Schultes & Raffauf 1990; Uscategui 1959).

There are also other, lesser-known cocas used. E. cataractarum is said by the Barasanas to be a very strong wild coca, used by their forefathers – another report states that the leaves are less psychoactive than those of E. coca. E. acuminatum, E. fimbriatum and E. macrophyllum have been used as substitutes for E. coca var. ipadu [or probably E. novogranatense, in the case of E. acuminatum]. E. gracilipes is considered a stimulant in lowland Ecuador. An unidentified Erythroxylum sp., known as 'coca de Monte' or 'ita-jipie' ['coca of the tapir'], is a wild species used by Andoke shamans, and it is stronger than cultivated coca (Rätsch 1998; Schultes & Raffauf 1990). Barks and leaves of E. catuaba and E. vacciniifolium are used in Brazil as aphrodisiacs (Graf & Lude 1977; Mors & Rizzini 1966). Leaf of E. coca is occasionally used in TCM as an anaesthetic and vasoconstrictor (Huang 1993). In India, the bark of E. monogynum ['bastard sandal', 'red cedar'] is considered toxic, though the aromatic heartwood is used as a sandalwood-substitute [see **Santalum**]. Poor people have also been known to eat the leaves as food (Chopra et al. 1965; Watt & Breyer-Brandwijk 1962).

The effect of coca-chewing is that of a mild stimulant, local anaesthetic and appetite-suppressant. It is considered ideal for adjusting to high altitudes and strenuous work, as coca reduces the body's oxygen requirements, stimulates respiration and sustains stamina. The leaves themselves also constitute a highly nutritious food [see below] (Kennedy 1985; Martin 1970; pers. obs.).

Coca-containing wines were popular in Italy and France in the 1860's, and later in the US – the best known was 'Vin Tonique Mariani', a coca-extract in red Bordeaux wine, containing 6mg/oz *cocaine*. It was used and endorsed by Pope Leo XIII, the Prince of Wales, Thomas Edison, Robert Louis Stevenson, H.G. Wells, Jules Verne and other prestigous persons. Its maker also produced a stronger version ['Elixir Mariani'], a coca-extract by itself ['The Mariani'], and throat lozenges containing pure *cocaine* ['Pastilles Mariani']. However, *cocaine* and alcohol interact in the body to produce a substance called cocaethylene, which affects *dopamine* receptors in the same manner as *cocaine*, but has a longer half-life, making such combinations potentially dangerous in excess. Coca-cola™ was developed as competition to Vin Mariani, and the original 'coke' did indeed contain *cocaine* as well as *caffeine*. Now, due to legal restrictions, coca leaves are still used in Coca-cola™, but only in the form of residue, after *cocaine* has been extracted for the pharmaceutical industry. The species used is E. novogranatense var. truxillense (Davis 1996; Karch 1996; Kennedy 1985), desirable due to its flavour. E. novogranatense was briefly cultivated in Java by the Dutch to provide *cocaine* for the pharmaceutical industry, though these plantations lost their financial viability in the 1920's due to a large decline in the price of coca leaves (Plowman 1979).

In the mid-1980s, 'Health Inca Tea' and 'Maté de Coca' imported from Peru were briefly available on the US market, advertised as "decocainized" herbal tea blends. There were several varieties, containing E. coca var. coca and E. novogranatense var. truxillense; they contained 4.8-5.7mg *cocaine* per teabag, and were popular with pensioners for rheumatism relief (Siegel et al. 1986). On a related note, there has recently been a 'trend' in England amongst pensioners – that of smoking 'crack' *cocaine*, apparently both for enjoyment and rheumatic relief.

Although coca is illegal in Colombia [since 1947], the law is selectively enforced; the plant is commonly used as a medicine and tonic by native people, and is commonly grown in household gardens – it is a popular ornamental in the best neighbourhoods of Cali (Davis 1996). The politics of the international *cocaine* trade, and especially the US-headed war against it [including careless aerial spraying of toxic chemicals], have had drastic impact on the well-being and livelihoods of the indigenous people who cultivate coca traditionally, as well as those who simply live in the same areas as coca plantations. Although the chewed leaf is nowhere near as potent or as dangerous as pure *cocaine*, it is treated with the same disdain by the prohibition forces, being the source of *cocaine*. The only problems that have arisen from its native use are through the smoking of coca-paste (Jeri et al. 1978) and use of pure or near-pure *cocaine*, as obtained cheaply from stages of the *cocaine* extraction process used for the illicit trade [see *Producing Plant Drugs*], and not from the use of the herb itself.

This issue is too complex to enter into fully here. However, regardless of the pros and cons of *cocaine* itself, I believe that it is highly unethical to purchase illicit *cocaine*. Such purchases are supporting a trade that ruins the lives of many hard-working peasant folk, who have been left with no practical means to support their families but to grow coca, and attracts destruction and pollution of the environment, whilst reaping enormous profits for a corrupt few.

Coca paste is a crude mixture containing *cocaine* sulphate, *ecgonine*, other coca alkaloids [such as benzoyltropine and *tropacocaine*], and impurities such as kerosene, benzoic acid, methanol and sulphuric acid. It is derived from the early stages of *cocaine* extraction, and sold cheaply to local users. It is often smoked in cigarettes together with tobacco [see **Nicotiana**] and/or **Cannabis**, and has effects similar to smoked crack [free-base *cocaine*] – causing intense euphoria and stimulation, sometimes with simple or even realistic visual, auditory and tactile hallucinations, followed by insomnia, depression, emotional instability, paranoia and other negative personality changes, as well as overwhelming compulsion to continue paste-smoking (Jeri et al. 1978).

Extended or excessive use of 'street' *cocaine* may also lead to psychotic behaviour and hallucinations. Visual hallucinations take the form of fleeting movements in the periphery of the visual field [becoming flashes of light in darkness or dim light, called 'snow lights'], visions of dots, lines, grids and other simple forms [often in black and white], movement or pulsing of objects and surfaces, and occasionally realistic hallucinations [eg. one person saw "…an ashtray change into a frying pan and then into a chicken"]. Tactile hallucinations include the sensation of insects crawling under the skin ['cocaine bugs']; auditory hallucinations include hearing voices or whispers (Siegel 1978). Besides the chronic effects of *cocaine* itself, these effects may also be partially explained by other tropane alkaloids present in 'street' *cocaine*. It is well known that such *cocaine* is never truly pure; at the level of illicit manufacture, '*cocaine*' is a mixture of alkaloids which is by far mostly *cocaine*, as well as trace impurities from the extraction procedure. Each time the drug changes hands in the distribution chain, it is 'cut' or diluted with any number of adulterants, some relatively harmless [mannitol, lactose, dextrose] and some potentially dangerous [quinine, heroin, unknowns] (Lee 1976). Some alkaloids present in 'street' *cocaine* [*tropacocaine*, found at less than 1% of total alkaloid; benzoyltropine, found at up to 15% of total alkaloid] inhibit *acetylcholine* synthesis and *choline* uptake (Meyer et al. 1990), contributing to central anticholinergic symptoms.

Cocaine is usually snuffed intranasally [in 'lines' c.20-30mg per dose] in illicit use, and via this route takes effect in 30-120 seconds, peaking after about 15 minutes, and lasting 1 hour or less. It causes euphoria, local anaesthesia, CNS-excitation and stimulation, followed by a subsequent depression (Platt 1997; pers. comms.). If the drug is readily available, its use can be extremely habituating, often leading to physical and psychological health problems.

Acid hydrolysis of many coca-alkaloids breaks them down to yield *ecgonine*. In the *cocaine* extraction process, this conversion is deliberately used – the *ecgonine* is then converted back to *cocaine* [yielding more than would otherwise be obtainable, due to the conversion of all of the *ecgonine*-derived alkaloids into *cocaine*] (Henry 1939; theobromus pers. comm.). The lime chewed with coca acts to degrade *cocaine* to *ecgonine* (Kennedy 1985).

Note – the following paragraph refers generally to coca including E. coca and E. novogranatense, and their varieties, due to failure to properly distinguish between these in much literature. The work of Timothy Plowman [r.i.p.] was important in showing that 'coca' was represented by a variety of different plants.

Young, rolled leaves of coca are known to contain a higher level of the major alkaloids than fully expanded leaves. Leaf harvesting triggers the

plant to go into a reproductive phase. Alkaloid contents measured at this time may be as follows [for E. coca var. coca] – *cocaine* [0.23-0.96% young leaves; 0.39% unopened flower buds], methyl *ecgonine* [0.24%; 0.13%], hygrine [0.49%; 0.18%], tropinone [0.01%; 0.02%], cinnamoylcocaine [0.27%; 0.17%], cis-cinnamoylcocaine [0.03%; 0.02%], *tropacocaine* [0.02%; 0.06%] and cuscohygrine [only in leaves – 0.03%]. Alkaloids are present in other plant tissues, but at much lower concentrations (Griffin & Lin 2000; Johnson 1996). Seeds from mature fruits have been shown to contain *cocaine* in the endosperm [0.001%] and embryo [0.005%]. Light was necessary for further *cocaine* biosynthesis in developing embryos (Johnson & Elsohly 1991). Other studies found 0.13-0.96% *cocaine* and 0.001-0.53% cinnamoylcocaine in the leaf (Holmstedt et al. 1977; Plowman & Rivier 1983). Coca grown in China has also yielded trevilline, *ecgonine*, benzoylecgonine, ecgonidine methyl ester, hygroline and norecgonine (Huang 1993); coca has also been shown to yield benzoyltropine, dihydrocuscohygrine, truxilline (Duke et al. 1975; Henry 1939), *arecoline* and *nicotine* (Fikenscher 1959; Kennedy 1985). Leaf yields an essential oil [c.0.025% w/w] consisting of 38.9% combined of 2 unidentified dihydrobenzaldehydes, 13.6% methyl salicylate, 16.1% cis-3-hexen-1-ol, 10.4% trans-2-hexenal, 5.2% 1-hexanol, 3.7% N-methylpyrrole, 0.5% N,N-dimethylbenzylamine, and small amounts of unidentifed compounds (Novák & Salemink 1987). Coca is also very nutritious – typical daily consumption [c.100g] more than satisfies the recommended dietary allowance for calcium, phosphorous, iron, vitamin A, vitamin E and riboflavin, and coca leaves are also higher in carbohydrates, protein and fibre than most vegetable foods (Duke et al. 1975). Average *cocaine* levels in the dry season are double those of the wet season (Sauvain et al. 1997). Best *cocaine* production was noted with an average daily temp. of 24°C for the first harvest, and 19°C for the second harvest (Acock et al. 1996). Dried leaves lose all their potency after about 7 months of storage (Chopra et al. 1958). Incidentally, a moth which feeds on E. coca leaves, Eloria noyesi, accumulates *cocaine* from the plant (Groark 1996).

E. argentinum [growing in Sydney Bot. Gardens] yielded 0.2% alkaloids, mostly *tropacocaine*, as well as hygrine and cuscohygrine (El-Imam et al. 1985); another study found an unidentified alkaloid as the major component, followed by *tropacocaine*, 4-OH-hygrinic acid, methylecgonidine, and 3β,6β-ditigloyloxynortropane (Zuanazzi et al. 2001).

E. australe leaves contain variable amounts of alkaloids [0.8% in one report], mostly meteloidine, as well as other tropanes, 6β-hydroxytropan-3α-yl tiglate, 3α-hydroxynortropan-6β-yl tiglate and an unknown base [0.014%, 0.001%, 0.002% and 0.003% yields, respectively, from a different study]; roots yielded 0.001% (+-)-6β,7β-dihydroxytropan-3α-yl benzoate (Griffin 1978; Johns & Lamberton 1967). Leaf, bark, and mature fruits have given positive tests for alkaloids, from Queensland plants. Strongest positives were in leaf from Wandoan [harv. Jun.]. Negative results were obtained in some tests of these plant parts; absence of alkaloids was observed in branches from Rockhampton [harv. Dec.] (Webb 1949). Several leaves, chewed, produced strong throat constriction in one psychonaut, which was felt all the way down to the stomach; the leaves also caused 'gagging' without the urge to vomit. No anaesthesia or other effects were noted (Torsten pers. comm.). The plant grows in n.e. NSW and s.e. Qld, Australia.

E. cataractum yielded 0.2% alkaloids, mostly cuscohygrine and dihydrocuscohygrine – due to the strength ascribed to this species, perhaps cuscohygrine is psychoactive (El-Imam et al. 1985; Ott 1995a).

E. coca var. ipadu has yielded 0.11-0.41% *cocaine* and 0-0.0084% cinnamoylcocaine (Plowman & Rivier 1983).

E. dekindtii leaves from Angola yielded 0.018% alkaloids, consisting of *tropacocaine*, pseudotropine, *ecgonine* and methylecgonine; rhamnose, galactose and sucrose were also detected (Campos Neves & Campos Neves 1968).

E. ecarinatum bark and leaf gave positive reactions for the presence of alkaloids, in some tests; plants were from Danbullah, Queensland [harv. Jul.] (Webb 1949).

E. ellipticum [another north Australian species] stem bark yielded 0.32% crude alkaloids, containing mostly tropine 3,4,5-trimethoxycinnamate, as well as tropine benzoate (Johns et al. 1970). The stems have been used to make pipes (Brock 1988; Levitt 1981), and the Ngarinyman eat the raw gummy exudate from the bark, as a sweet (Smith et al. 1993).

E. gracilipes leaves have yielded 0.0015-0.3% *cocaine*, and 0.0049-0.031% cinnamoylcocaine (Plowman & Rivier 1983).

E. lucidum stem bark yielded hygrine, cuscohygrine, tropinone, tropine, 3-α-acetoxytropane, pseudopelletierine, *nicotine*, littorine and other hygrine derivatives. Leaves yielded traces of *cocaine* [0.0003%] (Brachet et al. 1997; Plowman & Rivier 1983).

E. mamacoca leaves have yielded 0.11% alkaloids, including *tropacocaine* and nortropacocaine (El-Imam et al. 1985); no *cocaine* or cinnamoylcocaine has been found. Although once thought to be a wild ancestor of E. coca, it is defined as a distinct and separate species (Plowman & Rivier 1983).

E. monogynum [an Indian species] is known to contain small amounts of alkaloids in the leaves, mainly cinnamoylcocaine, as well as *ecgonine*, a flavone and essential oil (Agar et al. 1974; Chopra et al. 1965); others found no cinnamoylcocaine (Plowman & Rivier 1983). The root bark has yielded 0.85% tropine derivatives, including tropine, ψ-tropine, 1αH,5αH-tropan-3α-yl 3,4,5-trimethoxycinnamate, 1αH,5αH-tropan-3α-yl 3,4,5-trimethoxybenzoate, 1αH,5αH-tropane-3α,6β-diol 3-(3,4,5-trimethoxycinnamate) 6-benzoate and 1αH,5αH-tropane-3α,6β,7β-triol-3-(3,4,5-trimethoxybenzoate) (Agar & Evans 1976; Agar et al. 1974); the root has been reported to have yielded 0.04% *cocaine*. The wood has yielded 0.085-16.6% essential oil [by steam distillation], consisting of 40% α-*pinene*, 50% diterpene, 1.8% of a diterpene alcohol, and traces of a sesquiterpene (Watt & Breyer-Brandwijk 1962).

E. novogranatense var. novogranatense may contain 1-2.5% alkaloids, consisting of up to 0.47% *cocaine*, 0.04-0.07% 1-OH-*tropacocaine* and 0.107-0.65% cinnamoylcocaine, as well as large amounts of methyl salicylate in the essential oil (Griffin & Lin 2000; Karch 1996; Plowman & Rivier 1983). The higher yields were obtained from the previously mentioned Dutch cultivated herb in Java (Plowman 1979). Twigs yielded 0.13% *cocaine* (Aynilian et al. 1974; Holmstedt et al. 1977). Best *cocaine* production was noted with an average daily temp. of 25°C for the first harvest, with no effect of temp. on the second harvest (Acock et al. 1996).

E. novogranatense var. truxillense has an essential oil containing methyl salicylate, flavonoids and tannins; leaf yields 0.5-1.5% alkaloids, 30-50% of which may be *cocaine* [studies have found 0.42-1.02%], as well as 0.3-0.5% 1-OH-*tropacocaine* and 0-0.93% cinnamoylcocaine (Bruneton 1995; Griffin & Lin 2000; Holmstedt et al. 1977; Plowman & Rivier 1983).

E. pelleterianum was shown to contain 0.00123% *cocaine*, in a 45-year-old herbarium sample (Aynilian et al. 1974), though later analysis found no *cocaine* in this species; *tropacocaine*, 4-OH-hygrinic acid, an unidentified major alkaloid, and another unknown with the same retention time as *cocaine* were found (Zuanazzi et al. 2001).

E. steyermarkii leaves have yielded 0.11% *cocaine*, and 0.0026% cinnamoylcocaine (Plowman & Rivier 1983).

E. vacciniifolium leaves and bark have been found to contain up to 11 alkaloids [c.0.032% alkaloids in leaf], consisting mostly of the tropanes catuabin A [0.01%], catuabin B [0.0005%] and catuabin C [0.00057-0.00064%] (Graf & Lude 1977, 1978).

Traces of *cocaine* have been found in E. areolatum [0.0014%], E. campestre [0.00014%], E. deciduum [0-0.0008%], E. fimbriatum [0-0.0011%, as well as tropine and other bases], E. glaucum [0.0003%; also 0.1% *tropacocaine*, 6-β-benzoyloxytropan-3-α-ol and dihydrocuscohygrine], E. aff. impressum [0.007%], E incrassatum [0.0007%], E. macrocnemium [0.0012-0.0022%], E. panamense [0.0012-0.0014%], E. pulchrum [0.00008-0.0004%, and 0.0001% cinnamoylcocaine], E. rotundifolium [0.025%, and 0.0001% cinnamoylcocaine], and E. shatoma [0.0004-0.0005%, and 0.1% *tropacocaine*]. E. macrophyllum yielded 6 bases which were not identified. E. ulei yielded 0.01% *tropacocaine* and several other alkaloids (Aynilian et al. 1974; El-Imam et al. 1985; Holmstedt et al. 1977; Ott 1995a; Plowman & Rivier 1983).

Erythroxylum coca is a small shrub or tree to 2.5m high, with a woody root; stems branching, twiggy; bark liberally scattered with prominent warty lenticels. Leaves dark green above, paler and glaucous below, alternate, simple, broadly elliptical, 3-8cm long, 2-4cm wide, tapering or somewhat rounded and pointed at apex, wedge-shaped at base, prominent midrib below, often deciduous after current season's growth; petiole short, subtended at axil by a pair of persistent triangular stipules. Flowers fragrant, yellow or yellowish-green, bell-shaped, in clusters of 6-12 in leaf axils, each on a thickened pedicel subtended by a pair of triangular bracteoles. Flowers of 2 kinds – one with stamens of equal length and 3 free styles 2mm long; the other with unequal stamens and 3 free styles 4mm long. Sepals 5, basally-fused into a tube about halfway; petals 5, free, usually with a strap-shaped appendage towards base on inner surface; stamens 10 in 2 series, filaments fused in lower half; anthers 2-locular, dehiscing by longitudinal slits. Ovary superior; carpels usually 3, fused, 3-locular with only 1 fertile; fertile loculus with 1 ovule; styles fused to nearly free. Fruit a red, oblong-ovoid, pointed succulent drupe, 7-10 x 3-4.5mm, furrowed when dry; 1-seeded. Seed distinctly 3-ridged, 6 x 1.5mm (Harden ed. 1990-1993; Parsons & Cuthbertson 1992; Plowman 1979).

Grows wild and cultivated in Peruvian and Bolivian Andes.

E. coca var. ipadu is cultivated in the western lowlands of the Amazon Basin and is generally short-lived, weak, less productive of leaf and *cocaine*, and prone to disease.

E. novogranatense var. novogranatense has smaller, narrower and thinner leaves, with a bright yellowish-green hue; they are elliptic and elongated, with a rounded apex. Stem bark is smooth. Grows in hot, seasonally dry habitat of river valleys in Colombia and n. coast of S. America.

E. novogranatense var. truxillense has small, elliptic, very narrow, rich [at maturity] light green leaves slightly thicker than those of var. novogranatense, and with the scent and taste of 'wintergreen' [see **Gaultheria**]. Leaf midrib ridge is flattened. It grows in dry areas of n. Peru, and although very drought-tolerant, requires irrigation to be cultivated in such areas. A form of E. novogranatense also occurs and is used

to a small degree in n.w. Ecuador, though elsewhere in Ecuador coca use seems to have died out (Bruneton 1995; Davis 1996; Plowman 1979).

E. coca can be grown from cuttings [E. coca var. ipadu is almost always grown from cuttings], and prefers the moist, steamy montana climate. It needs well-drained soils and moderate temperatures, with a constant humidity. E. novogranatense is always grown from seed, and prefers hot, seasonally dry locales; it is highly drought-resistant and tolerates wider temperature variation. The best altitudes for alkaloid yield are generally considered to be 1500-2000m, with temperatures of 18-28°C. Soils should be preferably clayey, rich in humus and iron, and well-drained [rocky]. Cuttings should be about 45cm long, planted 15cm deep. Seeds do not remain viable for long [1-2 weeks] and are enclosed in a hard endocarp; the embryos are killed if the seed is allowed to dry out. Seeds have been germinated successfully in a greenhouse at 20-30°C; if soaked for 5 days initially, they should germinate under shade in about 10 days, and should be watered generously during germination. Seeds should be sown in Dec.-Jan. in shade. When about 60cm high, seedlings are transplanted to clearings in valleys, or terraces on mountainsides. High humidity can bring problems with fungal diseases. Plants are not harvested until they are about 2 years old. Harvesting may take place up to 3 times a year – in April, June and November. New shoots are left to ensure luxurious new growth (Antonil 1978; Davis 1996; Morton 1977; Plowman 1979; Smith 1981).

ESCHSCHOLTZIA

(Papaveraceae)

Eschscholtzia californica *Cham.* – California poppy, cup of gold, gold thimble, railway weed, amapola amarilla, amapola de los indios, amapola de California

The California poppy is the state flower of California, and pickers of the wild flower are subject to stiff fines under state law; it is apparently in need of protection, becoming rapidly wiped out in the wild by land developers. Native Americans ate the leaves boiled or roasted on hot stones, and used the flowers and capsules as a tranquilliser, especially to ease toothache. In Mexico, the petals are used as a mild narcotic, taken smoked, decocted, or in other ways. The herb is now popular in Europe, where it is used to treat insomnia, as well as coughs and hyperactivity in children. It is also one of the Bach flower remedies, used to assist emotional cleansing. The whole plant oxygenates the blood, and aids in absorption of vitamin A (Bremness 1994; Chevallier 1996; Heffern 1974).

All parts of the plant can be dried and smoked for a mild, short-acting euphoria, with no side-effects of note. A concentrated extract is a more potent means of consumption, but does not burn well and requires vapourisation. Internal use via decoction is another option, though experimentation with dosage is required to avoid the potential toxicity of higher amounts (Siegel 1976; pers. obs.). Chevallier (1996) notes that the herb "is not a narcotic… rather than disorientating the user, it tends to normalise psychological function".

E. californica contains opiate-like alkaloids [see **Papaver**, **Argemone**] including *protopine*, sanguinarine [adrenolytic, sympatholytic, AChEI, local anaesthetic, bactericidal], dihydrosanguinarine, berberine [sedative, respiratory stimulant, hypotensive, AChEI], allocryptopine [slight narcotic, anaesthetic, paralyses nerves, stimulates uterus, hypotensive], eschscholtzinine [0.015% from aerial parts], eschscholtzine N-oxide [0.02% from aerial parts], eschscholtzidine, lauroscholtzine, glaucine [adrenolytic, hypotensive, antitussive, inhibits aspiration], chelerythrine [hypotensive, analgesic, AChEI], coptisine [AChEI], isocorydine [sedative, adrenolytic, large doses induce catalepsy], chelirubine [AChEI], chelilutine and magnoflorine [escholine; weak neuromuscular blocker; see **Magnolia**]; as well as glycosides (Harborne & Baxter ed. 1993; Onda & Takahashi 1988; Preininger 1975, 1986; Rastogi & Mehrotra ed. 1990-1993; Ulrichová et al. 1983; Urzua & Mendoza 1986). E. californica growing as a garden-escapee in Stanthorpe, Queensland [Australia], harvested in November, tested strongly positive for alkaloids (Webb 1949). HCN has also been detected in the plant (Watt & Breyer-Brandwijk 1962).

Eschscholtzia californica is an annual or short-lived perennial herb to c.50cm tall, +- glaucous, nearly glabrous, with colourless juice; stems becoming 20-60cm long and falling over in age, branching, decumbent or ascending from a thick taproot. Leaves alternate, ternately compound, the segments linear or oblong, glabrous and slightly glaucous, blue-green, blades 2-6cm long, basal leaves petioled. Peduncles 3-15cm long; torus dilated to form a funnel-shaped base for the pistil, with 2 rims, the inner erect and hyaline, the outer spreading and 2-4mm wide; sepals 2, completely united into a cap (calyptra) pushed off by expanding petals, calyptra variable in size and shape, 1-4cm long; petals usually 4, fan-shaped, 2-6cm long, deep orange to light yellow; outer rim of receptacle spreading, 2-4mm wide; stamens 16-many; filaments short; anthers linear. Ovary cylindric, 1-celled, with 2 placentae; styles short; stigma with 4-6 linear divergent lobes. Fruit a thin, elongated, 10-ribbed capsule 3-8(-10)cm long, 2-valved from base towards apex; seeds grey-brown, round-oblong, 1.2-1.5mm long, reticulate with c.8-10 meshes per row.

Common in grassy and open places; native to California and Oregon, naturalised in Europe. Exhibits wide variation in habit and floral characteristics; at least 50 subspecies have been proposed (Gleason 1952; Munz et al. 1968).

Commonly available in nurseries, widely cultivated in temperate zones. Sow seeds in spring, directly into the garden-bed.

EUPATORIUM

(Compositae/Asteraceae)

Eupatorium berlandieri *DC.*
Eupatorium solidaginifolium *A. Gray* **(Koanaphyllon solidaginifolia** *(A. Gray) King et H.E. Robins***)** – pihol, shrubby thoroughwort
Eupatorium spp. – snakeroot, thoroughwort

E. berlandieri is used as a tobacco-substitute [see **Nicotiana**] by the Apache, and the Papago use E. solidaginifolium in the same manner. The two species are smoked by gulping down lungfuls of the smoke and exhaling slowly through the nostrils, as is the usual method when smoking through a chillum [see *Methods of Ingestion*]. The effect observed is a slight nervous tremor, and the plants are said to make a person 'crazy'. The genus has been credited with narcotic properties (Lipp 1995).

Several other Eupatorium spp. are used medicinally. The Tarahumara use unspecified members of the genus as purgatives (Salmón 1995). E. aromaticum ['wild horehound', 'white snakeroot'] is used as an antispasmodic and diuretic. E. cannabinum ['hemp agrimony', 'water hemp'] of Europe, n. Africa and Asia is used as a tonic, diuretic and immune stimulant. E. collinum ['yerba de angel'] from Central America is a liver tonic, and its aromatic leaves are used as a hops-substitute in brewing beer [see **Humulus**, *Methods of Ingestion*]. E. maculatum and E. purpureum ['gravelroot', 'joe-pye weed', 'queen of the meadow'] roots are widely used by native N. Americans as a stimulant, nerve tonic, sexual tonic, diuretic and antirheumatic, also easing menstrual cramps and treating kidney and bladder stones. E. perfoliatum ['boneset'] is a stimulant, tonic, antiseptic, purgative, and emetic, also inducing sweating and treating cold and flu. E. staechodosum ['ayaoana du tonkin'] of Vietnam is used for its lavender-scented leaves, which are tonic, aphrodisiac and digestive. Some species have also shown antitumour activity (Bremness 1994; Hamel & Chiltoskey 1975; Hendriks et al. 1983; Hutchens 1992; Usher 1974). In TCM, E. fortunei ['ran so'] is used as an antipyretic, emmenagogue, diuretic, and to relieve swelling in dropsy (Haruna et al. 1986).

Eupatorium spp. are often considered toxic to animals, and the chemicals they contain may become concentrated in the milk from cows who have grazed the plants. Symptoms of poisoning have been reported as including "weakness, nausea, loss of appetite, severe vomiting, tremors, liver damage, laboured breathing, jaundice, constipation, prostration, dizziness, delirium, convulsions, coma and death" (Salmón 1995). E. perfoliatum has apparently been used in N. America as an ayahuasca analogue ingredient (Appleseed 2002), but I am unsure how this affects the activity of the brew.

E. cannabinum leaves and flowers have yielded coumarin and taraxasterol (Sagareishvili et al. 1981); leaf exudate yielded the flavonoid aglycones eupafolin, hispidulin [scutellarein-6-methyl ether], pectolinarigenin [scutellarein-6,4'-dimethyl ether], centaureidin, jaceosidin and santin. These flavonoids are also found in some other Eupatorium spp. (Stevens et al. 1995). Also found are the necine-based pyrrolizidines rinderine and supinine. Aerial parts have yielded 0.15-0.68% essential oil, containing *estragole* and many other compounds. Roots have yielded euparin (Hendriks et al. 1983) and eupatoriopicrin (Sagareishvili et al. 1981).

E. fortunei whole plant [harv. Aug.] has yielded a sesquiterpene lactone of the germacranolide type [see **Calea**], eupafortunin [0.002% w/w], as well as the sesquiterpenoid eupatoriopicrin [0.039% w/w] (Haruna et al. 1986); the plant has also yielded the pyrrolizidine alkaloids supinine, rinderine, and a new alkaloid (Liu et al. 1992).

E. triplinerva essential oil has sedative properties in rats (Hendriks et al. 1983).

I have been unable to find any chemical studies of E. berlandieri or E. solidaginifolium.

Eupatorium solidaginifolium is a subshrub with a number of rigidly ascending stems or branches (30-)40-60(-100)cm tall. Leaves opposite, broadly lanceolate, 25-60(-90)mm long, base shortly rounded to truncate, apex long-attenuate and slightly acuminate, subentire, or the larger ones often with 3-5 obscure apressed teeth on each side, essentially glabrous, 3-nerved, upper leaves suppressed; petioles 2-4(-6)mm long. Short bracteate upper branches bearing rounded masses of heads, the entire end of the stem with its several corymb-bearing short branchlets forming a sort of elongate-thyrse; heads usually with only 3-5 flowers; occasionally the bracteal leaves of the peduncles are so close to the involucre as to resemble outer phyllaries; involucre obconic, c.5mm long; phyllaries more than 4, in 2-6 series, essentially uniseriate, lanceolate, very acute, mostly thin

and stramineous except for three darker vertical nerves; corolla lilac-white or pinkish-white, scarcely exserted from involucre, equally 5-toothed terminally; receptacle flat to conic, naked; ray flowers absent; disc flowers few to numerous, perfect. Style branches long and clavate. Achenes usually blackish, subcolumnar or gently narrowed to the base, 5-ribbed; pappus of slender bristles, persistent. Fl. Aug.-Nov.

Frequent in mountains of the Trans Pecos, usually in mesic canyons; Chihuahua, Coahuila, Durango, Arizona and Texas (Correll & Johnston 1970).

EVODIA [Euodia]

(Rutaceae)

Evodia bonwickii *F. Muell.* – kilt
Evodia crispula *Merrill et Perry* – gen
Evodia rutaecarpa *(Juss.) Benth.* **(Boymia rutaecarpa** *Juss.***)** – wu-chu-yu, wu-zhu-yu, goshuyu
Evodia vitiflora *F. Muell.* – toothache tree

'Wu-chu-yu', the dried immature fruit of E. rutaecarpa, has been used in TCM for thousands of years. It is pungent and bitter in character, and has many uses – such as to treat hiccough, excess bile, headache, vomiting, diarrhoea, arthralgia, cold pain in the chest and abdomen, hernia, beriberi, oedema, and oral ulcers [external use]; it stimulates circulation, slightly raises or lowers blood pressure, inhibits some intestinal parasites, and is analgesic, stimulant, carminative, stomachic and antiemetic. The dose is 3-5g, and the herb is considered incompatible with **Salvia** chinensis. It was believed that hanging the herb on the body could repel infection by devils (Hsu et al. 1986; Huang 1993; Keys 1976).

A commercial 5:1 extract of E. rutaecarpa fruit [equivalent to c.25-30g of the herb] has been used successfully in what was thought of as a kind of 'ayahuasca analogue', combined with extract of Indian **Tribulus** terrestris fruit, by at least two people (friendly pers. comm. 1998; Raver pers. comm. 2002). However, later experiments failed to show that the **Tribulus** was acting as an MAOI as had been presumed [see **Tribulus**] (friendly pers. comm. 2001), and the activity of the combination was in retrospect downplayed. In the words of the original bioassayist [who is believed to be a low MAO phenotype, and is a self-confessed 'softhead' – see *Glossary*] – "while I feel there is something there [ie. psychoactivity], it does not live up to what an ayahuasca analogue should do" (friendly pers. comm. 2002). The other known bioassayist described achieving a mild psychedelic effect from the combination (Raver pers. comm. 2002). Thus it is presumed that this E. rutaecarpa extract is psychotropic without the need for any additive plant – or that there is some interaction between E. rutaecarpa and T. terrestris unrelated to MAO activity (pers. obs.). Smaller amounts [a heaped tsp] of the same E. rutaecarpa extract exhibit nöotropic effects, and some may perceive a "mild sense of wellbeing". However, ingestion of a cruder home-made extract [which included oils present in the whole fruit] resulted in strong toxicity. Symptoms included "intense abdominal distress. After some minutes, unproductive vomiting and lengthy dry-heaving. Then not nausea, but pain and an intense burning – felt like it was corroding me internally or leaving me inflamed like a streptococcal food poisoning." This burning sensation was felt to pass through the body with the internal movements of the extract. Due to the time lapse between the bioassay and it being reported, the dose was not remembered with accuracy, though believed to correspond to somewhere between 30 and 60g of dried unripe fruit. No such toxicity was noted with use of the commercial extract mentioned earlier (Trout pers. comm.). See the chemistry of E. rutaecarpa below.

In n.e. Australia, E. vitiflora bark resin is placed against the tooth to relieve toothache. A bark decoction is reportedly rubbed on the body to relieve pains, though the identity of the plant used was not established with certainty (Cribb & Cribb 1981; Lassak & McCarthy 1990). In Papua New Guinea, E. crispula leaves are chewed by the Nkopo as a stimulant for dancing in night-long ceremonies, and the plant is used in rituals to promote equilibrium of natural forces (Schmid 1991). Evodia spp. are also used there in rituals associated with the dead (Paijmans ed. 1976). In the Mt. Hagen area, E. bonwickii bark "is chewed by men during dancing feasts" (Stopp 1963), presumably as a stimulant (pers. obs.); it is said to be psychoactive (Schultes & Hofmann 1980). Rätsch (1998) claimed it is used in PNG to treat psychological ailments, but mis-cited Stopp (1963) [as 'Scott'], who did not give any such information for this species. In the first stage of Bimin-Kuskusmin initiation rites, aromatic leaves of an Evodia sp. known as 'saakop' are crushed and inserted in the nostrils for inhalation [as well as many other plants being ingested] – it is unclear whether psychoactive effects are ascribed to its use (Poole 1987). In Malaya, all parts of an Evodia sp. ['keruin'] are used in the manufacture of dart-poisons (Bisset & Woods 1966).

E. belahe has yielded N-cinnamoyl-*tyramine* (Lundstrom 1989).

E. bonwickii was found to contain alkaloids in unspecified parts (Stopp 1963).

E. merrillii leaves have yielded the furoquinolines *skimmianine*, kokusaginine and confusameline; these compounds were found to act as antagonists of 5-HT2 receptors, in descending order of potency (Cheng et al. 1994).

E. micrococca leaf [harv. Dec.] from Yarraman, Queensland [Australia] tested strongly positive for alkaloids (Webb 1949).

E. rutaecarpa unripe fruit [as used in TCM] contains a variety of compounds, including indole, quinolone and *phenethylamine* alkaloids [0.135% total alkaloids in one analysis] (King et al. 1980). These include mostly evodiamine [8,13,13b,4-tetrahydro-14-methylindolo(2',3':3,4)-pyrido(2,1-b)quinazolin-5(7H)-one; Tschesche & Werner (1967) reported obtaining 1.5-2.45% of a crude mixture of evodiamine and rutaecarpine (see below), though these yields may have been a misprint], as well as 0.15% hydroxyevodiamine [rhetsinine; yield may be a misprint], 0.033% dehydroevodiamine, isoevodiamine, c.0.0003% [in one analysis – see above] rutaecarpine [rhetine; often referred to as a major component along with evodiamine], dihydrorutaecarpine, 14-formyldihydrorutaecarpine (Asahina & Kashiwaki 1916; Chen & Chen 1933; Haji et al. 1994; Kamikado et al. 1978; King et al. 1980; Pachter & Suld 1960; Tschesche & Werner 1967), evodiamide [N-methyl-N-(2-methylaminobenzoyl)*tryptamine*], N-(2-methylaminobenzoyl)*tryptamine* (Shoji et al. 1988), 0.0005-0.0026% *5-methoxy-DMT*, 0.00026% *DMT*, 0.00033% 6-MeO-N-methyl-THβC [N-methyl-*pinoline*] (Yu et al. 1997a, 1997b), 0.0076% goshuyamide-I [2-(2-methylaminobenzoyl)-THβC], 0.0034% goshuyamide-II [3-[2-(3-indolyl)ethyl]-1-methyl-2,4-quinazolinedione] (Shoji et al. 1989), atanine [3-dimethylallyl-4-MeO-2-quinolone] (Perrett & Whitfield 1995), 1.8-2.4% evocarpine [I suspect the yields of this quinolone were printed incorrectly – perhaps a misplaced decimal point or two – as it is otherwise not referred to as a major component] (Tschesche & Werner 1967), dihydroevocarpine [1-methyl-2-tridecyl-4(1H)-quinolone], 1-methyl-2-nonyl-4(1H)-quinolone, 1-methyl-2-undecyl-4(1H)-quinolone, 1-methyl-2-pentadecyl-4(1H)-quinolone (Kamikado et al. 1976, 1978), 2-tridecyl-4(1H)-quinolone, 1-methyl-2-dodecyl-4(1H)-quinolone, 1-methyl-2-[(Z)-5-undecenyl]-4(1H)-quinolone, 1-methyl-2-[(Z)-6-undecenyl]-4(1H)-quinolone (King et al. 1980; Tang et al. 1996), 0.0002% (7S,13bS)-7-carboxy-8,13,13β,14-tetrahydro-14-methylindolo(2',3':3,4)-pyrido(2,1β)quinazolin-5(7H)-one (Danieli et al. 1979), wuchuyine (Chen & Chen 1933), higenamine and synephrine (Hsu et al. 1986). Guanoside 3',5'-monophosphate [traces] (Cyong et al. 1982), evodinone, evogin, gushuyic acids, isorhamnetin 3-O-galactoside and quercetin 3-O-galactoside have also been isolated (King et al. 1980; Yu et al. 1997a). The essential oil [2% yield] contains evodol, limonin ['evodin'] and ocimene ['evodene'] (Asahina & Kashiwaki 1916; Chen & Chen 1933; King et al. 1980). Leaves have been shown to contain dehydroevodiamine [major alkaloid], hydroxyevodiamine (Nakasato et al. 1962), dihydroevocarpine, 1-methyl-2-pentadecyl-4(1H)-quinolone and 1-methyl-2-undecyl-4(1H)-quinolone (Kamikado et al. 1976). Unfortunately, yields for the major components of the fruit are scarce; when yields have been given by some researchers, the way in which they are presented often makes the figures virtually useless for calculating real yields from the herb [such as in Kamikado et al. 1978], and some [ie. Tschesche & Werner 1967] have reported yields which are difficult to believe.

Evodiamine is a diuretic, diaphoretic (Buckingham et al. ed. 1994), increases arterial pressure, acts as a powerful cardiotonic (Shoji et al. 1989), protects against hypothermia [induced by chlorpromazine in mice] (Haji et al. 1994), improves cerebral blood flow and may have cholinergic activity (Yamahara et al. 1989). Dehydroevodiamine reverses *hyoscine*-induced amnesia, acts as an AChEI in vitro (Park et al. 1996), is uterotonic (King et al. 1980), hypotensive in rats, and increased cerebral blood flow in cats. Isoevodiamine increased carotid blood flow in rabbits (Haji et al. 1994). Rutaecarpine increases arterial pressure (Keys 1976), acts as a uterotonic (King et al. 1980), hypotensive, analgesic and circulatory stimulant, and also slightly raises temperature (Hsu et al. 1986); rutaecarpine and limonin inhibit the CYP3A4 form of cytochrome P450, in the presence of the co-factor NADPH [nicotinamide adenine dinucleotide phosphate] (Iwata et al. 2005).

Upon degradation, evodiamine yields β-indolethylamine [rutamine; haemostatic, causes pain, stimulates CNS and plain muscle, stimulates intense uterine contractions, in large doses causes delirium, dyspepsia and intestinal hyperperistalsis]; degradation of rutaecarpine also yields rutamine (Hsu et al. 1986; Keys 1976). An ethanol/water extract [1:1] potently interacted with 5-HT1a receptors, and also interacted with D1 and D2 *dopamine* receptors, α2, β1 and β2 adrenoceptors, muscarinic cholinergic receptors, and H1 *histamine* receptors (Yu et al. 1997a, 1997b). The anti-diarrhoeal activity has been proven experimentally in mice (Yua et al. 2000).

E. vitiflora bark, leaves and branchlets tested strongly positive for alkaloids; the bark resin contains coumarins (Lassak & McCarthy 1990; Webb 1949).

E. xanthoxyloides leaf and bark from Malanda, Queensland [harv. Aug.] tested strongly positive for alkaloids (Webb 1949).

Evodia rutaecarpa is a small, densely foliaged green inodorous tree, velvety-pubescent throughout. Leaves opposite, imparripinnate, 3-45cm

long; leaflets c.5 pairs, subsessile, oblong-acute, usually rounded and oblique at base, margin entire, pellucid-punctate, underside wooly, venation faint; petiole terete, stout. Flowers small, unisexual, in axillary paniculate cymes; cymes brachiate, 7.5-10cm diam., terminal, branches very stout, peduncles very short and stout, tomentose (as are the pedicels and calyx). Flowers c.8mm diam.; sepals 4-5, imbricate; petals 4-5, sessile, valvate or slightly imbricate, nearly glabrous externally, pubescent within; disc 4-5 lobed; stamens 4-5, inserted at base of disc, in female replaced by staminodes, not much exceeding the petals, filaments hairy, subulate; anthers very large, ovate, 2-lobed at base. Ovary deeply 4-lobed, 4-celled; ovules 2 in each cell; style basal; stigma 4-lobed. Fruit of 4 coriaceous, 3-valved, 1-seeded cocci, pustular, 13mm diam.; carpels 4, opening at apex. Seeds oblong.

China, Japan, temperate regions of Sikkim Himalaya, 2100-3000m (Kirtikar & Basu 1980).

EVOLVULUS

(Convolvulaceae)

Evolvulus alsinoides *(L.) L.* **(E. acapulcensis** *Willd. ex Roem. et Schult.***; E. adscendens** *House***; E. albiflorus** *Martens et Galeotti***; E. alsinoides var. sericeus** *(Wall.) Indigenous people of n.e. South Australia chew E. alsinoides var. sericeus as a pituri substitute [see **Duboisia**, **Nicotiana**], due to its mildly 'narcotic' effect. Last century, the herb had a reputation with Asian herbalists as a remedy for fever and dysentery (Cribb & Cribb 1981; Lassak & McCarthy 1990; Low 1990). In Ceylon, E. alsinoides is used as a bitter tonic and antipyretic, and the Hausas smoke the plant to treat chronic bronchitis and asthma. Muslim doctors believe it to strengthen the brain and memory. Likewise, in India, it is believed to brighten the intellect, improve complexion and appetite, and relieve diarrhoea. It is said to also have astringent and anthelmintic properties. Given with cumin and milk, it treats memory loss, nervous debility and fever (Kirtikar & Basu 1980; Nadkarni 1976). E. nummularis has also been reported from India to have weak sedative effects (Chatterjee et al. 1965).

E. alsinoides has yielded an alkaloid, evolvine [exhibits some *epinephrine*- and *ephedrine*-like effects in animal studies] (Krishnamurthy 1959), as well as betaine (Baveja & Singla 1970), triacontane, pentatriacontane, and β-sitosterol (Mehta & Shah 1959). No alkaloids were detected in an Australian specimen [whole plant] from Springsure, Queensland (CSIRO 1990). The plant has been shown to produce ergot-alkaloids [see **Claviceps**, **Ipomoea**] in liquid culture (Nambiar & Mehta 1981). A liquid extract of the herb had some *lobeline*-like effects on the cardiovascular and respiratory systems (Krishnamurthy 1959).

E. arbuscula ssp. canus has yielded 15-norpanasinsan-5β-ol-8-one, 15-norpanasinsan-5,8-dione, and caryophyllene oxide (Huneck et al. 1987).

E. argyreus contains a calystegine [see **Convolvulus**] in the aerial parts (Schimming et al. 1998).

E. nummularis has yielded 3',4',5',7-tetrahydroxy-flavonone, and the glycosides evoluside A and evoluside B (Gupta, D.R. et al. 1985).

E. sericeus [as E. sericeus var. holosericeus] has yielded convolvine, convolvamine, and convolvidine [see **Convolvulus**] , as well as 3.85% anthraquinone glycosides (Fonseca & Salive 1973).

Evolvulus alsinoides is a perennial herb with a small, woody, branched rootstock; stems numerous, often more than 30cm long, prostrate, spreading, slender, wiry, usually clothed with long spreading hairs, sometimes quite glabrous. Leaves numerous, 6-20 x 4-8mm, elliptic-oblong, obtuse, strongly apiculate, usually acute at base, densely clothed with apressed silky hairs; petioles very short, sometimes almost sessile. Flowers light blue, sometimes white, solitary, or sometimes 2 from a pair of lanceolate bracts on the peduncle; peduncles very long, filiform, axillary; pedicels filiform; calyx densely silky, sepals 5, subequal, 4mm long, lanceolate, very acute; corolla 5mm long and wide; stamens 5, filaments slender; anthers ovate or oblong. Ovary 2(rarely 1)-celled; ovules 4; styles 2, distinct from base, each cleft into 2 linear or subclavate stigmas. Capsule 3-4mm diameter, globose, thin, 4-valved; seeds usually 4, glabrous.

In tropical and subtropical areas (Kirtikar & Basu 1980), including Asia, Malesia, Pacific Islands, Africa, and the Americas; in Australia [Queensland, New South Wales, Northern Territory, South Australia, Western Australia], it grows in habitat ranging from sandy plains to rocky outcrops and grassy woodland [with **Acacia** spp. and Eucalyptus spp.] (Harden ed. 1990-1993). The form found in Australia is said to be E. alsinoides var. sericeus, reportedly distinguished by the dense layer of silky hairs on the leaves (Lassak & McCarthy 1990), though given the confusion regarding nomenclatural synonymy [see the huge listings above] I am uncertain what the real story is at this point. Harden ed. (1990-1993) lists E. alsinoides *(L.) L.* as an Australian native, the only native Evolvulus sp. occurring in Australia, with E. alsinoides var. decumbens *(R. Br.) Ooststr.* and E. alsinoides var. villosicalyx *Ooststr.* as the varieties occurring in NSW.

FAGONIA

(Zygophyllaceae)

Fagonia cretica *L.* **(F. arabica** *L.***; F. bruguieri** *DC.***; F. mysorensis** *Heyn. ex Roth***; F. sinaica** *Boiss.***)** – ustarkhar, dusparsha, dhanvayas, dharama, badavard, rosa de la virgen

The leaves and stems of this herb are used in Ayurvedic medicine to purify the blood. In Indian folk medicine, they have been used to treat asthma, fever, thirst, vomiting, dysentery, urinary discharges, typhus and tumours. It is considered to have acrid, bitter, tonic and cooling properties. The bark has also been used to treat scabies. Hill tribespeople of Sind and Afghanistan also use the plant as a fever remedy (Kirtikar & Basu 1980; Nadkarni 1976). Its leaves are used as food for camels and mules (Usher 1974). The fresh plant, or a tea made from it, has a mild cabbage-like flavour [see **Brassica**], and is soothing to the digestive tract (theobromus pers. comm.).

F. cretica leaves have yielded alkaloids, including *harman*, but no *harmine* (Ahmed et al. 1971b), though a later study did find *harmine* in the plant (Iyer & Joshi 1976). In a broad alkaloid screening, leaves, stems and flowers of F. cretica from Pakistan gave negative results (Fong et al. 1972). The whole plant [flowering or in early fruiting stages] has yielded 2.5% saponins [1.5% as F. sinaica], including oleanolic acid (Zaitschek et al. 1971) and hederagenin-derivatives, fagonin, and other triterpenoid saponins (Ahmed et al. 1971a; Iyer & Joshi 1976; Khalik et al. 2000). Also found in the plant were β-sitosterol, stigmasterol, campesterol, and 1-triacontanol (Ahmed et al. 1969). The saponin fraction from the aerial parts has shown analgesic, antipyretic, and antiinflammatory effects (Khalik et al. 2000).

F. glutinosa, F. mollis, and F. parviflora have also been reported to contain *harman* (Shulgin & Shulgin 1997), though this may be in error. These species were analysed along with F. cretica [and specimens identified as F. bruguieri and F. arabica, synonyms of F. cretica], and though they were found to contain [unidentified] alkaloids [ranging from 0.03% in F. parviflora, to 0.17% in F. glutinosa], only F. cretica contained *harman* (Ahmed et al. 1971b). F. glutinosa and F. mollis [flowering or in early fruiting stages] yielded 1.5% and 1% saponins, respectively, including oleanolic acid (Zaitschek et al. 1971).

Fagonia cretica is a small, spiny undershrub with stiff branches, often +- prostrate; twigs slender, terete, striate, glabrous, glandular. Leaves opposite, 1-3-foliate, c.12 x 2.5mm, entire, linear or elliptic, mucronate; petiole very variable, 0-3cm long, sometimes leaf-like; stipules transformed into sharp, slender spines up to 1.2cm long, persistent and continuing growth long after fall of leaves. Flowers solitary, rose-coloured, on peduncles 5-12mm long, arising from between stipules; sepals 5, deciduous, imbricate, ½ as long as petals; petals 5, 6mm long, spathulate with marked claw; disc short, inconspicuous; stamens 10, inserted on the disc; filaments filiform, naked; anthers oblong. Ovary hairy, sessile, 5-angled, 5-celled, tapering into a 5-angled style; stigma simple. Fruit 5mm long, of 5 1-seeded cocci, glandular-pubescent, deeply 5-partite almost to the

axis; cocci dehiscing along the ventral suture and separating from a horny endocarp.

India [Deccan, w. Khanadesh, Cutch, Sind, Baluchistan, Waziristan, w. Rajputana, Upper Gangetic Plain, Punjab], westwards to Afghanistan, Iran, Arabia and Mediterranean (Kirtikar & Basu 1980).

Spanish specimens have flowers in varying shades of purple, rather than the usual rose (theobromus pers. comm.).

FERRARIA

(Iridaceae)

FERRARIA GLUTINOSA

Ferraria glutinosa *(Baker) Rendl.* **(F. bechuanica** *Baker***; F. hirschbergii** *L. Bolus***; F. welwitschii** *Baker***; Moraea glutinosa** *Baker***)** – gaise noru noru, !kaishe

The roots of this iris, only available in April after the rains have come, have sacred uses amongst the Iko bushmen of the Kalahari. Much preparation is deemed necessary before the plant is consumed. A process of cleansing and obedience towards a strict diet takes place. Each man is then rubbed with the flesh and blood of a freshly killed animal, and washed clean, before the decoction of F. glutinosa is prepared. It is drunk [usually at night] for the ritual 'pogo-like' dances employed by Kalahari bushmen to awaken the !kia or ntum energy [see *Influencing Endogenous Chemistry*]. Older men, more experienced in the practice, drink less of the decoction than younger men, as it was primarily used as a 'teaching aid' for raising ntum. However, today knowledge of such affairs is gradually being lost, and only some of the elders retain the necessary knowledge of preparation and use (De Rios 1986; Rätsch 1992).

Ferraria glutinosa is a perennial herb to 90cm tall; corm depressed-globose, brown, 10-40mm diam., 2-4 internodes in length, corm tunics evanescent; stem laxly and often repeatedly branched, terete, sticky below the nodes; aerial parts dying back annually. Leaves several, the lower 2-3 entirely stem-sheathing and membranous; foliage leaves several, usually c.½ as long as stems, equitant, 4-8mm wide, linear to narrowly-lanceolate, decreasing in size above, sometimes lacking at anthesis, sometimes short or not developed at flowering. Inflorescence composed of several flower clusters (rhipidia); rhipidia terminal on main and lateral axes, several, solitary on the branches, 2-6-flowered; spathes herbaceous, outer ones 15-25(-30)mm long, obtuse to acute, inner ones 30-45(-50)mm long; flowers actinomorphic, brown, maroon, purple or yellow, usually spotted and mottled with contrasting colour, faintly scented; tepals free, lanceolate, the outer ones 28-35mm long, the inner 25-28mm long, the claws forming a wide cup c.10mm deep and 15mm diam. At rim, limbs horizontal or recurved, margins crisped; filaments 10-13mm long, united in the lower 8-10mm, free and diverging above; anthers 5mm long, appressed to the style branches, shrinking after anthesis to 2.5mm long. Ovary 5-7mm long; style slender, c.10mm long, concealed by filament column, dividing into 3 flattened branches, these finely fringed above and 4mm long; stigma lobe abaxial, at base of fringe. Capsules 12-20(-25)mm long, globose-ovoid.

In savannah and grassland, mostly in sandy soils, but also in stony ground; Botswana, Zambia, Zimbabwe, Malawi, S. Africa [n. Cape Province], Angola, Namibia (Exell et al. ed. 1960-1993).

FERULA

(Umbelliferae/Apiaceae)

Ferula asafoetida *L.* **(F. narthex** *Boiss.***; F. scorodosma** *Bent. et Trimen***; Narthex asafoetida** *Falc.***)** – asafoetida, assa-foetida, devil's dung, food of the gods, giant fennel, narthex, a-wei, bahleeka, sulanasan, hingra, shing-kun

Ferula hermonis *Boiss.* – zallouh, shilsh el zallouh, kutteira, 'Lebanese viagra'

Ferula sumbul *(Kauffman) Hook. f.* **(F. moschata** *(Reinsch) Koso-Pol.***; F. pseudooreoselinum** *(Regel et Schmalh.) Koso-Pol.***; Euryangium sumbul** *Kauffman***)** – sumbul, jatamansi, musk root

Ferula spp.

When Prometheus stole fire from the gods, he was said to have smuggled it back to humanity within a hollow fennel stem [see **Foeniculum**] (Parsons & Cuthbertson 1992); however, in this case, the plant referred to was actually a Ferula sp., or 'giant fennel' (theobromus pers. comm.). Dionysian ceremonies often featured the use of a 'thyrsus' staff, made from a giant fennel stalk, entwined with ivy, and adorned with pine cones at the tip (Ody 1993). 'Asafoetida' refers to the gummy oleoresin from the roots of F. asafoetida, with a pungent smell similar to garlic in some respects. It is fried before use, as it causes vomiting if taken raw. The Romans used it as a condiment, and it is used sparingly in some Indian cooking, as well as being an ingredient in Worcestershire sauce. It has been used for millenia by Tibetan shamans in the Himalayas, particularly amongst the Bonpo, by whom it is used to drive out spirits, a purpose for which the gum was sometimes mixed with **Acorus**, **Valeriana**, peacock feathers, snake skin and cat dung. The gum is burned as an incense for banishing, but may be taken internally to treat psychic ailments and sexual imbalances. Tibetans have also used it as an aphrodisiac, in doses of 0.3-1g, and as a tonic to reduce the effects of ageing. In Somalia it has been used in making protective amulets, and the ancient Mesopotamians used it as a medicine and prophylactic. As I understand it, if you smelt strongly enough of asafoetida no one would want to come close enough to you to fornicate anyway! In Europe, it has been used to ward off witches and illness, and to 'exorcise' the insane (Bremness 1994; Chevallier 1996; Clifford 1984; Cunningham 1994; Rätsch 1990, 1992; Simonetti 1990). In TCM, it is used as an anthelmintic, and to treat dysentery, malaria and ascites (Huang 1993).

In India, the gum from any Ferula sp. is regarded as a stimulant, expectorant and antispasmodic, though F. asafoetida is favoured as a nervine stimulant and aphrodisiac – in Tibet, its aphrodisiac effects are achieved using 0.3-1g of the gum. In Ayurveda, it is used as a stomachic, laxative, analgesic, carminative and appetite stimulant. In Unani medicine the stem is used as a brain and liver tonic, emmenagogue and anti-inflammatory; the gum is used to treat dizziness, paralysis, asthma, rheumatism, dry cough and eye problems; and leaves are used as a carminative and diaphoretic. The gum also acts as a cardiotonic, diuretic, hypotensive, and anticoagulant (Chevallier 1996; Chiej 1984; Kirtikar & Basu 1980; Nadkarni 1976; Rätsch 1990). It has strong antioxidant properties and may inhibit early stages of cancer growth (Saleem et al. 2001), though some have found it ineffective as an anticarcinogen (Aruna & Sivaramakrishnan 1992). An aphrodisiac effect is alluded to due to the CNS-activity and excitation of the 'urinary and sexual apparatus' (Rätsch 1992). Recently, F. hermonis seeds have been used as a 'herbal Viagra', though they may be toxic if taken for long periods (El-Thaher et al. 2001). F. sumbul is thought to be 'hallucinogenic' (Schultes & Hofmann 1980), and has been proposed as the identity of the valued psychotropic medicinal herb of antiquity 'silphion', written of by Dioscorides; F. asafoetida has also been suggested as representing silphion (Rätsch 1998).

The incense known as 'galbanum' comes from the related central Asian species F. galbaniflua [F. gummosa], and is an oleoresin collected in the same manner as that of F. asafoetida [see below]. It has antispasmodic and expectorant properties, and relieves digestive complaints. In central Asia, F. sumbul is used as an incense and stimulant nerve tonic, and to treat an

array of disorders including hysteria, delirium-tremens, spasms, asthma, diarrhoea and dysentery (Bruneton 1995; Chevallier 1996; Felter & Lloyd 1898; Usher 1974). Its effects have been compared to those of **Valeriana** officinalis. A 66% alcohol tincture made from roots and rhizomes [1:10], taken in a dose of c.15ml, "produced narcotic symptoms, confusing the head, causing a tendency to snore even when awake, and giving feelings of tingling, etc., with a strong odour of the drug from breath and skin which only passed off after a day or two" (Grieve 1931).

Oleoresin from F. asafoetida consists of 25% gum, 4-20% essential oil and 40-65% resin. The essential oil consists of *eugenol*, camphene, myrcene, limonene, linalool, cadinene, fenchone, geraniol, *borneol*, isoborneol, farnesol, cadinol, guaiacol, phellandrene, α-*pinene*, β-caryophyllene, β-selinene, longifoline, and many sulphide derivatives; resin also contains umbelliferone, vanillin, aresinotannol, aresinol ferulate, ferulic acid, valeric acid, asacoumarins A & B, asadisulphide, assafoetidin, foetidin, farnesiferols A-C, and kamolonol. The essential oil from the seed has been expressed in a yield of 1.5%, containing α-*pinene*, phellandrene, α-terpineol, bornyl acetate, geranyl acetate, sec-butylpropenyl-disulphide, myristic acid and a mix of coumarins (Buckingham et al. ed. 1994; Huang 1993; Lawless 1995; Morton 1977; Rastogi & Mehrotra ed. 1990-1993).

F. equisetacea roots have yielded *myristicin*, equisetin [3-MeO-4,5-methylenedioxyphenylethenal] (Bagirov 1979), and equisetan [3-MeO-4,5-methylenedioxyphenylethenoic acid] (Bagirov 1981).

F. galbaniflua oleoresin ['galbanum'] has yielded c.55% resinous compounds, including galbaresenic acid, and galbanum acid; the essential oil contains large amounts of *pinene*, as well as umbelliferone, Δ3-carene, 2-MeO-3-isobutylpyrazine, S-sec-butyl-3-methyl-2-butenethioate, methylallylsulfides, propenyldisulfides, and undecatriene derivatives (Bruneton 1995; Kunz & Wöldicke 1937).

F. hermonis roots yielded sesquiterpenes [jaeschkeanadiol, epoxyjaeschkeanadiol, jaeschkeanadiol benzoate, jaeschkeanadiol p-OH-benzoate] and daucane esters (Galal et al. 2001).

Ferula asafoetida is a perennial herb to 2.4m tall. Leaves 2-4-pinnatifid or 2-4-pinnate, pubescent at least when young, lower leaves 30-60cm, ovate, cauline sheaths large, from which spring simple or scarcely compound umbels; secondary and tertiary pinnae decurrent, entire or very irregularly crenate-serrate; petioles of leaflets winged. Terminal umbel large, compound, leafless, bearing up to 50 ray florets; sometimes involucres of bracts or bracteoles are present; flowers yellow, often polygamous; calyx teeth obsolete; petals 5, epigynous, yellow, ovate, entire, acute, retroflexed, imbricate in bud; stamens 5, epigynous, alternating with petals. Ovary inferior, 2-celled, glabrous, crowned by a large epigynous disc; ovules solitary in each cell, pendulous; styles 2, often dilated at base; stigma minute. Fruit 8 x 5mm, orbicular or ellipsoid, much compressed dorsally, lateral ridges winged, dorsal and intermediate filiform or obscure; seed 1 in each carpel, much dorsally compressed, testa thin, inner face plane.

Warm, temperate, fertile regions; Asia (Chiej 1984; Kirtikar & Basu).

The gum is extracted from the live rootstock of 4- or 5-year old plants at the start of summer. The stem is cut off at ground-level, then the roots are progressively notched, with the gum accumulating at the cuts. It is then collected, once dry (Bremness 1994; Bruneton 1995; Chevallier 1996; Simonetti 1990).

FESTUCA including some endophytes

(Gramineae/Poaceae)

Festuca argentina *(Speg.) Par.* **(F. cavillieri** *St.-Yves***; Poa argentina** *Speg.***)** – Pampa grass, coirón, coirón negro, coirón huecú

Festuca arundinacea *Schreb.* **(F. elatior** *L.***; F. orientalis** *(Hack.) V. Krecz. et Bobrov***; Bromus arundinaceus** *(Schreb.) Roth***; Lolium arundinaceum** *(Schreb.) Darbysh.***; Schedonorus arundinaceus** *(Schreb.) Dumort.***)** – tall fescue, reed fescue, fescue grass

Festuca decumbens *L.* **(Bromus decumbens** *(L.) Koeler***; Danthonia decumbens** *(L.) DC.***; Melica decumbens** *(L.) Weber***; Poa decumbens** *(L.) Scop.***; Sieglingia decumbens** *(L.) Bernh.***; Triodia decumbens** *(L.) P. Beauv.***)** – dronk grass

Festuca hieronymi *Hack.* **(F. erecta var. mutica** *Griseb.***)**

Festuca obturbans *St.-Yves.*

Festuca pratensis *Huds.* **(F. elatior ssp. pratensis** *(Huds.) Hack.***; Bromus pratensis** *(Huds.) Spreng.***; Lolium pratense** *(Huds.) Darbysh.***; Schedonorus pratensis** *(Huds.) P. Beauv.***)** – meadow fescue

(Clavicipitaceae/Balansiae)

Acremonium coenophialum *Morgan-Jones et Gams* **(Neotyphodium coenophialum** *Glenn, Bacon et Hanlin***; Sphacelia typhina** *Sacc.***)**

Epichloë typhina *(Fries) Tulasne* **(Acremonium typhinum** *Morgan-Jones et Gams***)**

Neotyphoideum tembladerae *Cabral et White, sp. nov.*

F. arundinacea is a widespread forage grass, originally from Europe, with at least 35 million hectares of it being cultivated in the US alone. From 75-90% of cultivated F. arundinacea is infected by the fungus Acremonium coenophialum, which is known to produce a variety of chemicals, including psychoactive ergot-type alkaloids [see **Claviceps**]. Infected plants have been responsible for livestock poisoning, including the well-known 'fescue foot' [only affecting cattle], symptoms of which include lameness, weight loss, arched back, fever, swelling and gangrene; death may result if the cattle are not removed from toxic pastures. The disease usually occurs most severely in times of cold weather (Bacon 1995; Hemken et al. 1984; Hungerford 1990; Lamp et al. 1990; Lyons et al. 1986; Petroski et al. 1989; Yates et al. 1969). Horses are affected with reproductive difficulties (Cross et al. 1995).

In some toxic pastures, F. arundinacea may be infected completely by Epichloë typhina (Bacon et al. 1977), which is now known to be very closely related to the Acremonium spp. [see below]. Some cases of fescue foot may be complicated by the fact that weeds of fescue crops, such as Sporobolus poiretii, Andropogon spp., Eragrostis hirsuta and Panicum anceps, as well as other Festuca spp., have been observed to support the fungi **Balansia** epichloë and B. henningsiana [see **Cyperus**/**Balansia**] in summer (Bacon et al. 1975, 1979); and also by the fact that the Acremonium spp. are frequently found growing co-symbiotically with other endophytes (An et al. 1993). Toxic hay of F. arundinacea has also been shown to support mould fungi including Fusarium poae, F. sporotrichioides, F. nivale [F. tricintum], Cladosporium epiphyllum, Alternaria spp., Epicoccum spp., Mucor spp. and Stemphylium spp., some of which produce highly toxic metabolites (Etzel 2002; Yates et al. 1969).

F. argentina, from Argentina, is also responsible for causing stock intoxications ['staggers'], in this case referred to as 'loco' or 'huecú'. In the same country, F. dissitiflora and F. heironymi are also known to cause toxic symptoms. Those associated with F. heironymi have also been called 'tembladera' ['trembling']. Toxic F. argentina is known to be infected with an unidentified Acremonium sp. (Cabral et al. 1999; Casabuono & Pomilio 1997). In S. Africa, Dutch colonists have observed the intoxicating properties which 'dronk grass', F. decumbens, has on stock animals (Bruehl et al. 1994).

F. argentina infected with an Acremonium sp. yielded loline, lolinine, N-methylloline, N-formylloline, 5,6-dehydro-N-acetylloline [see **Lolium**/**Acremonium** for further discussion of loline alkaloids] and *choline* acetate. It is thought that the tremorgenic loline alkaloids are produced by Festuca spp. in response to endophyte infection, though the ergot alkaloids [see **Claviceps**], as found in infected F. arundinacea [see below], are a product of the endophytic fungus [knowledge of this situation has recently been updated – see F. pratensis below]. F. argentina has also yielded the stilbene trans-resveratrol, and the lignans (-)-pinoresinol, (-)-pinoresinol-4-O-β-D-glucopyranoside, (+)-medioresinol-4-O-β-D-glucopyranoside, and (1S,2S,5S,6R)-2-(4-OH-phenyl)-6-(3-MeO-4-OH-phenyl)-3,7-dioxabicyclo[3.3.0]octane (Casabuono & Pomilio 1994, 1997). Neotyphoideum tembladerae has been identified as an endophyte of this species; it has also been observed on F. hieronymi and Poa huecu (Cabral et al. 1999).

F. arundinacea has yielded *harman* and *norharman* (Allen & Holmstedt 1980; Bush & Jeffreys 1975) as well as *melatonin* (Shulgin & Shulgin 1997). When infected with A. coenophialum, it has yielded ergot alkaloids [see **Claviceps**] – predominantly ergovaline [0.0002-0.0006%], as well as *ergine* [sometimes present in levels as high as ergovaline], isoergine, *ergonovine*, *chanoclavine*, *elymoclavine*, *agroclavine*, *penniclavine*, *festuclavine*, ergovalinine, ergonine, ergosine, ergoptine and ergocornine; as well as 0.17-0.5% loline alkaloids [N-acetylloline, N-formylloline, N-acetylnorloline, loline, perloline (highest levels in summer) and perlolidine], the pyrrolopyrazine alkaloid peramine [0.0004%], and ergosta-4,6,8(14),22-tetraen-3-one. A. coenophialum has been shown to produce *ergotamine* in culture. Tests indicate that the levels of ergot alkaloids, as well as perloline levels, may be boosted significantly with high nitrogen fertilisation, using 10millimoles/L of potassium nitrate or ammonium chloride. Alkaloid levels are also boosted in infected plants by witholding water (Annis & Panaccione 1998; Bacon 1995; Belesky et al. 1989; Buckingham et al. ed. 1994; Hemken et al. 1984; Lyons et al. 1986; Petroski et al. 1989; Porter 1995). Animal studies suggest that the alkaloids of A. coenophialum-infected F. arundinacea have agonist properties at D2 *dopamine* receptors (Cross et al. 1995). The endophyte Fusarium nivale has also been isolated from F. arundinacea, and has yielded γ-acetamidobutenolide [4-acetamido-2-buten-4-olide; 4-acetamido-4-OH-2-butenoic acid-γ-lactone; 2-acetamido-2,5-dihydro-5-oxofuran; N-(2,5-dihydro-5-oxo-2-furanyl)acetamide] [weak antibiotic, LD50 in mice 275mg/kg (oral)] and 8α-(3-methylbutyryloxy)-4β,15-diacetoxyscirp-9-en-3α-ol (Casabuono & Pomilio 1997; Yates et al. 1969).

F. obturbans from e. Africa has been found heavily infested with ergot, which appeared to be **Claviceps** purpurea; the fungus yielded 0.32% alkaloids, consisting of 76.9% ergokryptine, 5% ergokryptinine, 5% ergosine, 3.1% ergocornine, 0.6% ergosinine, 4.1% clavine alkaloids, and 5.3% unknown alkaloids (Brack et al. 1963).

F. pratensis infected with Acremonium uncinatum [Neotyphoideum

uncinatum] has yielded up to 0.323% loline alkaloids, concentrated in the inflorescence, especially in the seed embryo; the major alkaloid was N-formylloline, followed by N-acetylloline, N-acetylnorloline, and traces of loline and N-methylloline (Justus et al. 1997). It was suspected that the loline alkaloids were produced by the grasses in response to endophyte infection, previous to a recent study showing A. uncinatum to be capable of producing loline, N-acetylnorloline and N-formylloline in culture [see also **Lolium**] (Blankenship et al. 2001).

Endophytes recorded on other Festuca spp. include Acremonium starrii [on F. arizonica], and the closely related Epichloë typhina [on F. glauca, F. longifolia and F. rubra], once known as Acremonium typhinum (Mogen et al. 1991). F. longifolia has also been observed to support Epichloë festucae (Cabral et al. 1999). E. typhina has also been implicated in causing stock intoxications (Porter et al. 1978), and has yielded *chanoclavine I*, ergosine and ergosinine in culture (Porter et al. 1979), as well as tetraenone[ergosta-4,6,8(14),22-tetraen-3-one] (Bacon et al. 1977).

These endophytes benefit the host grasses by increasing their health, and producing toxic chemicals as a feeding deterrent (Schardl & Tsai 1992).

Festuca arundinacea is a tufted perennial 0.45-2m tall, without rhizomes, sometimes forming large, dense tussocks. Culms mostly erect, usually stout to robust, unbranched, 2-5-noded, rough towards the panicle or smooth. Leaves green; sheaths rounded on back, smooth or rough, with small narrow spreading auricles at apex, minutely hairy on auricles and at the junction with blade; ligules up to 2mm long, membranous; blades long-tapering to a fine tip, 10-60 x 0.3-1.2cm, flat, stiff, rough, or smooth only below. Panicles erect or nodding, lanceolate to ovate, loose and open or contracted, 10-50cm long, green or purplish; axis and branches rough, the latter angular, spreading, bare and undivided in the lower part, usually in pairs, with the shorter one bearing 3 or more spikelets; pedicels up to 8mm long; spikelets elliptic to oblong, 10-18mm long, closely 3-10-flowered, breaking up beneath each lemma at maturity; glumes persistent, slightly unequal to equal, pointed; lower glume narrowly lanceolate, 3-6mm long, 1-nerved; upper glume lanceolate to lanceolate-oblong, 4.5-7mm long, 3-nerved; lemmas overlapping, or later with their margins incurved, lanceolate or oblong-lanceolate in side view, pointed to blunt, 6-9mm long, broadly rounded on the back, awnless, or with middle nerve continued as a fine rough awn 1-4mm long, firm except for membranous upper margins, 5-nerved, rough especially on nerves; paleas as long as lemmas, with rough keels; anthers 3-4mm long. Grain tightly enclosed by lemma and palea. Fl. Jun.-Aug. in northern hemisphere.

Variable in robustness and size, as well as habitat; on dry calcareous soils to heavy soils, meadows, grazed pastures, river and stream banks, rough hill and downs grassland; Europe, n.w. Africa, temperate Asia, N. America (Hubbard 1978), Australia [all states except NT] (Hnatiuk 1990).

Acremonium coenophialum offers its host plant some protection against adverse conditions and insect predators. It occupies the grass more or less without symptoms, growing intercellularly in the meristems of the crown, on the adaxial epidermis of the leaf sheath, on the aleurone layer of the seed, in the root shoot internode adjacent to the vascular tissue in embryos of mature seed, and on the surface of adventitious lateral root primordia of 3-week old seedlings. Usually observed as septate, intercellular, infrequently-branched hyphae running longitudinally in the leaf sheaths; colonies on sterile seedlings sporulating prolifically with production of synnemata which radiate in all directions from small colonies; synnematous hyphae simple, hyaline; synnemata unbranched, up to 1.5mm long; conidiophores phialides of Acremonium-type, formed perpendicularly along whole length of synnemata, unbranched, non-septate, hyaline, smooth, 20-35µm long, 1.25-2.5µm wide at base, 1µm at apex, frequently becoming slightly wider to 3µm just above base; conidia subulate to falcate, hyaline, smooth, 7-12.8 x 2-3µm, produced in small groups of 2-3, forming heads at apex of phialide, frequently only 1 conidium evident, oriented horizontally at phialide apex; chlamydospores absent. Considerable variation in shape of colonies; aerial mycelium varying from dense cottony to sparse, mostly white with pale brown underside, some pale brown on both surfaces.

Other unidentified fungal endophytes, similar in ways to Gliocladium and Phialophora and with penicillate conidiophores, are sometimes found in seed of Festuca spp. in cosymbiosis with Acremonium spp. Incidentally, infected seed will remain viable to produce a plant infected with A. coeniphialum for up to 1 year, longer with freezing (Azvedo & Welty 1995; Bacon et al. 1986; Christensen & Latch 1991; Christensen et al. 1993; Siegel et al. 1995; White & Cole 1985). Also found on Poa autumnalis. P. ampla supports other unidentified Acremonium spp. (Mogen et al. 1991); P. poecila, P. rigidifolia and P. sylvestris also support unidentified Neotyphoideum spp. (Cabral et al. 1999). All Acremonium spp. are now thought to be asexual stages of different strains of Epichloë typhina (An et al. 1993; Schardl & Tsai 1992), and those from Acremonium section albolanosa are now known under Neotyphoideum (Moon et al. 2000).

FOENICULUM

(Umbelliferae/Apiaceae)

Foeniculum vulgare *Mill.* **ssp. capillaceum** *(Gilib.) Holmboe* **var. azoricum** *(Mill.) Thell.* **(F. vulgare var. azoricum** *(Mill.) Thell.***; F. vulgare ssp. sativum** *(C. Presl.) Janch. ex Holub***; F. vulgare var. sativum** *C. Presl.***)** – Florence fennel, finocchio fennel

Foeniculum vulgare *Mill.* **ssp. capillaceum** *(Gilib.) Holmboe* **var. dulce** *Batt. et Trab.* **(F. dulce** *Mill.***; F. vulgare var. capillaceum** *(Gilib.) Paol.***)** – sweet fennel, Roman fennel, dulce fennel, hinojo amargo, hinojo silvestre

Foeniculum vulgare *Mill.* **ssp. capillaceum** *(Gilib.) Holmboe* **var. vulgare** *Mill.* **(F. capillaceum** *Gilib.***; F. foeniculum** *(L.) H. Karst.***; F. officinale** *Allioni***; F. vulgare ssp. piperitum** *(Ucria) Coutinho* **var. vulgare; F. vulgare ssp. vulgare** *Mill.***; Anethum foeniculum** *L.***)** – fennel, common fennel, finocchio selvatico, fenouil, vinkel

Foeniculum vulgare *Mill.* **ssp. piperitum** *(Ucria) Coutinho* **(F. capillaceum** *Gilib.* **ssp. piperitum** *(Ucria) Rouy***; F. piperitum** *(Ucria) C. Presl.***)** – bitter fennel, wild fennel, Italian fennel, Sicilian fennel, cartucci fennel, carosella, hinojo, pepervenkel, pepper fennel

Fennel is one of the oldest cultivated plants, and was held in high regard by the Romans and Greeks. The Romans believed that snakes sucked the juice of the plant to improve their eyesight. Pliny praised its virtues along these lines, declaring that it 'enabled one to see the beauty of nature with greater clarity'. Drunk with wine, it was said to cure snake or plant poisoning. Roman legionnaires and gladiators mixed fennel seeds with their food as a stimulant and tonic [victorious gladiators were crowned with a garland of fennel], while others ate it as an anorexic. The Greek name for the plant, 'marathon' [sometimes as 'marathron'], is derived from a verb meaning 'to grow thin'. Fennel was one of the herbs held sacred to Anglo-Saxons for its power against evil, and the seeds were sometimes put in keyholes to prevent ghosts entering the home. By 812AD, Charlemagne declared it essential in every imperial garden. By the middle ages, it had become much used as a digestive, and the seeds were often chewed during church sermons to allay stomach rumblings (Bremness 1988, 1994; Lawless 1994; Ody 1993; Parsons & Cuthbertson 1992). In Tuscany, Italy, fruits of F. vulgare spp. capillaceum var. vulgare are sometimes used as an amulet to prevent the 'evil eye', placed in a 'breo' bag also containing dried Olea europea ['olive tree'] leaves [which have been blessed in Palm Sunday ceremonies], and attached to men's clothes or cow's horns (Pieroni & Giusti 2002).

The swollen lower stem and leaf bases of 'Florence fennel' [F. vulgare ssp. capillaceum var. azoricum] are eaten as a vegetable, and the roots of this and other fennel varieties are used as a medicine. The root is mainly used only to treat urinary disorders, and its medicinal properties are not as strong as those of the seeds. Leaves may be infused as a nerve tonic, or used in cooking with fish, sauces, soups and stews. The seeds are used to flavour breads, curries and apple pies; they flavour toothpaste, and are an ingredient in some versions of absinthe [see *Methods of Ingestion*, **Artemisia**]; fruits of F. vulgare ssp. capillaceum var. dulce are used as a sweet condiment. Medicinally, they are used to treat indigestion, colic, constipation and irregular menstruation, and as a galactagogue and detoxifier [eg. helping liver repair after alcohol damage]. They are useful as a wash for tired eyes, and in TCM are used for reproductive and urinary disharmonies, and to tone the spleen and kidneys. In India, they are considered stimulant, diuretic, emmenagogic and purgative (Bremness 1994; Muckensturm et al. 1997; Nadkarni 1976; Ody 1993; Watt & Breyer-Brandwijk 1962).

It has been claimed that 5-20 drops of the essential oil taken orally will produce 'hallucinations' [Lawless (1994) wrote that it is 'narcotic in large doses'] and epileptiform convulsions, as well as irritating the liver and kidneys (Gottlieb 1992; Watt 1967). Fennel tea has been known to produce 'agitation' in children or newborns (Bilia et al. 2000b), though the essential oil has been reported to make animals 'timid'. Should not be used by pregnant women. The bitter fennel oils may cause skin irritation (Lawless 1994).

F. vulgare ssp. capillaceum seed [fruit] has yielded 4-7% essential oil, containing c.3-61% *estragole* [lowest in var. azoricum, var. dulce and cultivar 'bronze'], 1-65% *anethole* [highest in the previous varieties], *apiole*, 6-25% fenchone [lowest in var. azoricum], *myristicin* [not detected in wild plants, but found in var. dulce], 2-10% limonene, chavicol, 1-6% *pinene*, camphene, 10-nonacosanone and seselin. The bitter oils may contain 18-22% or more fenchone, while sweet oils contain little or none. Leaf essential oil of F. vulgare ssp. capillaceum var. azoricum contained mostly [c.65%] trans-*anethole*, with lesser amounts of limonene, *estragole*, fenchone, 10-nonacosanone and other compounds. F. vulgare ssp. capillaceum var. dulce leaf essential oil contained c.60% trans-*anethole*, 10% phellandrene, 2% *estragole* and other compounds. F. vulgare ssp. capillaceum cultivar 'bronze' leaf essential oil contained c.58% trans-*anethole*, 20% fenchone, 4% *estragole*, and other compounds. Leaf essential oils distinguish F. vulgare ssp. capillaceum var. vulgare into three chemotypes –

those dominant in *estragole*, those dominant in trans-*anethole*, and those dominant in both *estragole* and *anethole* (Harborne et al. 1969; Harborne & Baxter ed. 1993; Lawless 1995; Muckensturm et al. 1997; Nadkarni 1976; Tardy 1905b; Watt & Breyer-Brandwijk 1962). *Myristicin* has been reported from leaf of F. vulgare (Harborne et al. 1969). Teas made from F. vulgare ssp. capillaceum var. dulce fruits contained mainly trans-*anethole*, p-anisaldehyde, *chlorogenic acid*, and quercetin-3-O-β-D-glucuronide. The traditional method of infusing the crushed fruit [2.5g] in just-boiled water [150ml] was the most efficient in extracting these compounds, compared with decoction in a microwave-oven [which resulted in lower yields of trans-*anethole*, as well as a higher relative proportion of p-anisaldehyde (possibly due to degradation of trans-*anethole*) and the other compounds], infusion or decoction of uncrushed fruit, or infusion of commercial fennel tea-bags in warm water (Bilia et al. 2000b).

F. vulgare ssp. piperitum, an uncultivated perennial differing with its short, rigid-lobed leaves, and narrow umbels with small fruits, does not bear the typical fennel aroma, and yielded no *anethole* or other phenylpropenes of interest in one analysis (Muckensturm et al. 1997). A later study, using a greater variety of wild Italian specimens, found there to be at least 5 chemotypes. Aerial parts yielded 0.04-0.38% essential oil [w/w]. Plants from Bologna and Parma were dominant in trans-*anethole*, *estragole*, and α-phellandrene; plants from Catania were dominant in trans-*anethole*, α-*pinene*, and α-phellandrene; plants from Ancona, Firenze, Livorno, Macerata and Pesaro were dominant in *estragole* and α-phellandrene; plants from Brindisi, Caltanisetta, Napoli and Taranto were dominant mostly in *estragole*, as well as α-*pinene*; and plants from Bari contained mostly α-phellandrene. Fenchone, limonene, *camphor*, and many other compounds were present in small amounts. All of these except the Bari specimens were believed to be wild hybrid material (Piccaglia & Marotti 2001).

Foeniculum vulgare is a robust, erect perennial or biennial herb to 2.5m tall, highly aromatic when crushed [smell similar to aniseed – see **Pimpinella**]; stems striate, glabrous, sometimes glaucous, rigid when mature, conspicuously jointed at the nodes, branched, filled with a white spongy pith, developing a small hollow when old. Leaves alternate, +- triangular in general outline, to 45cm long, 3-4-pinnate with finely divided ultimate segments which are narrowly linear to capillary, filiform, acuminate, cartilaginous at apex, 5-50mm long, usually widely-spaced, and not lying in the same plane; petioles with conspicuous light-coloured V-shaped sheaths at base, petioles of upper leaves usually 3-6cm long; many leaves formed at base of plant, reducing in size and number at top. Inflorescences terminal compound umbels to 15cm diam., rays stout, 4-30, flowers yellow, 2-3mm diam., short-stalked; bracts and bracteoles usually none; sepals absent; petals 5, yellow, oblong, strongly inrolled, scarcely narrowed to involute apex; stamens 5; carpels (1-)2; ovules 1 in each loculus, pendent; styles (1-)2, often thickened at base. Seeds grey-brown or yellowish-brown, 2 sections 3-8(-10.5)mm long, narrowly ovoid or ovoid-oblong, scarcely compressed, pointed apex, rounded base, arched with 5 prominent ribs, aromatic and tasting of aniseed [in some chemotypes].

In open, sunny sites with moderate rainfall, common on roadsides, drains, park tracks etc.; native to s. Europe and w. Asia, now widespread as a weed in temperate areas worldwide; occurs prolifically in southern states of Australia, and to ½ way up the east coast (Parsons & Cuthbertson 1992; Tutin et al. ed. 1964-1980).

May germinate at any time of year, flowering through summer after reaching 18-24 months of age; sets seed in autumn and winter, dies back in winter (Parsons & Cuthbertson 1992).

GALBULIMIMA

(Himantandraceae)

Galbulimima belgraveana *(F. Muell.) Sprague* **(G. baccata** *F.M. Bail.***; G. nitida** *Sprague***; G. parviflora** *Sprague***; Eupomatia belgraveana** *F. Muell.***; Himantandra baccata** *(F.M. Bail.) Diels***; H. belgraveana** *(F. Muell.) Diels***; H. nitida** *Bak. f. et Norman***; H. parviflora** *Bak. f. et Norman***)** – agara, kombe, galbulimima

The leaves and bark of this tree are consumed by some tribal warriors in areas of Papua New Guinea, to make them fierce before battle. The Nokopo use its leaf to hold lime for painting the face of a male infant in his first initiation. The plant has been used as a drug in several ways. Some decoct the bark and leaves, and add this to an extraction of a **Homalomena** sp. ['ereriba'], the combination being drunk; some simply chew the bark and leaves of agara and leaves of ereriba together; some chew the bark by itself, and may also rub it on their legs to be absorbed through the skin. The effects consist of a 'violent intoxication' with 'spectacular visions', followed by a deep somnolent dream-like state, in which one can learn from spirits. The Gimi are known to chew the bark in order to enter trance "for information about puzzling situations or forthcoming events". The symptoms described are said to be the same with either of the substances [**Galbulimima** or **Homalomena**] alone (Emboden 1979a; Glick 1967; Hamilton 1960; Paijmans ed. 1976; Schmid 1991; Schultes & Hofmann 1980).

One person experimented with chewing 10g dried, powdered agara bark, swallowing the last of it after 10min. Effects manifested after 30min., with drowsiness, mydriasis, increased heart rate, impaired concentration and dizziness leading to a relaxed hypnagogic state, wearing off with some euphoria after c.2hrs (Thomas 2005).

G. belgraveana is very variable in chemical makeup, differing from one tree to the next even in the same patch. One study found 0.21% alkaloids in leaves, and 0.33% in bark. Plants from n. Queensland [Australia] contained 12 different alkaloids, but at least 28 different alkaloids have been found in the species. Main alkaloids isolated were himbacine [hypotensive, antispasmodic, antagonist of muscarinic *acetylcholine* M2 & M3 receptors], himgravine [hypotensive], himbosine [hypotensive, antispasmodic], himandrine [hypotensive, antispasmodic] and himbadine [antispasmodic]; other alkaloids include himbeline [depressant, hypotensive], himandridine [depressant, hypotensive, antispasmodic], himandravine [CNS depressant], himgaline [alkaloid G; antispasmodic], alkaloid GB.5 [alkaloid K; hypotensive], alkaloid GB.7 [alkaloid H; hypotensive, antispasmodic] and alkaloid GB.18 [alkaloid J; CNS depressant, hypotensive, weak antispasmodic] (CSIRO 1990; Hartley et al. 1973; Zholos & Bolton 1997). In an early screening, bark harvested in October [Boonjie, Queensland] tested strongly positive for alkaloids (Webb 1949). The fruits contain an essential oil with a **Juniperus**-like odour, as well as traces of alkaloids (Webb 1948).

Galbulimima belgraveana is a tree to 35m, to 60cm thick above buttresses; buttresses, if present, to 3m high, 1m wide, 5-20cm thick; bole straight and cylindrical; crown densely compact; outer bark grey to greyish-brown, often scaly and pustular; underbark mottled greenish to yellowish-brown, inner bark pale brown rapidly changing to red-brown when exposed, bitter-tasting and resinous-smelling; twigs +- terete, lepidote; twigs, undersides of leaves, petioles, inflorescence and fruit densely to sparsely covered with copper-coloured peltate overlapping scales. Leaves otherwise glabrous, papillose, glossy, yellow- to dark-green, entire, margins slightly recurved, ovate, oblong or elliptic, (5-)6-16 x (2-)3-8cm, apex rounded, obtuse, acute or acuminate, sometimes slightly retuse, base obtuse, acute or +- attenuate; midrib deeply sulcate above, strongly raised beneath, venation embossed on both surfaces, 8-20 pairs of nerves ascending towards apex; petiole 1-2.5cm long, channelled above. Flowers bisexual, solitary, axillary on peduncle with 2 small bracts, globose to ovoid in bud, 1-2 x 1-1.5cm prior to anthesis; peduncle 1-2.5cm long with bracts 2-3mm long; calyptrate calyx and corolla lepidote, irregularly circumsessile, rupturing near base; petals absent; stamens (13-130) and staminodes (inner 13-20; outer 20-23) white, linear-lanceolate, 1-2 x 5-15mm, stamens sometimes to 2.5cm long, stamens and outer staminodes reflexed, inner staminodes +- all erect, fleshy and tapering to apex, slightly dilated at base; anthers 1-2mm long, 1-2cm from base of stamens. Ovary superior, lepidote, globose, 1-2mm long, narrowing apically into style; single locule with solitary, ventrally attached ovule; carpels free, spirally arranged on conical receptacle; plumose styles free at first, later cohering into a gelatinous mass. Fruit 1.5-3cm diam., persistently scaly, reddish, fleshy, resinous smell, +- globose; single flattened seed in each carpel. Fl. & fr. throughout the year.

Canopy tree, especially in Nothofagus spp. forest, 5-2700m; Moluccas, New Guinea, New Britain, Australia [Qld.] (Womersley ed. 1978).

GALIUM

(Rubiaceae)

Galium aparine *L.* **(G. australe** *Reiche***; G. chilense** *Hook. f.***; G. chonosense** *Clos***; G. larecajense** *Wernham***; G. pseudoaparine** *Griseb.***; G. vaillantii** *DC.***)** – cleavers, goose grass, sticky weed, sticky willie, bedstraw, hug-me-close, bedstraw, hexenhaar, hexengarn

Galium dregeanum *Sond.* **(G. mucroniferum var. dregeanum** *(Sond.) Puff***)**

Galium odoratum *(L.) Scop.* **(Asperula odorata** *L.***)** – woodruff, sweet woodruff, odorous aspérule, cleavers, queen of the wood

Galium rotundifolium *L.*

Galium witbergense *Sond.*

G. aparine is a very common weed in many temperate zones, and its young leaves may be cooked and eaten like a vegetable. The seedpods may be roasted and ground to be used as a coffee-substitute [see **Coffea**], as they have been in Ireland. Clusters of the stem were also once used by Swedish peasants to filter milk (Low 1991b; Von Bibra 1855). Tea made from the dried leaves has been reputed to be effective against insomnia (Cribb & Cribb 1981). The herb is considered a diuretic tonic which may be used to treat eczema, psoriasis, sunburn, arthritis, urinary infection, gonorrhea and liver diseases, as well as stimulating the lymphatic system. The roots, like those of many other Rubiaceous plants, yield a red dye. In Germany, G. aparine has been known as 'hexenhaar' ['witches hair'] and 'hexengarn' ['witches yarn'], suggesting some association with magic. The related G. odoratum is added to liqueurs and fruit salads, and an infusion

of the leaf is antispasmodic, mildly sedative, diuretic and tonic to the liver. The fresh, bruised leaf has anticoagulant properties, and has been used as a poultice for wounds (Bremness 1994; De Vries 1991; Tierra 1988). In Belgium and Germany, aerial parts of G. odoratum gathered before flowering are fermented in sweet white wine for 2 days to produce 'Maitrank' ['drink of May', or 'May wine'], a beverage reputed to have inebriating properties beyond those of the alcohol content alone. Maitrank is consumed in festivals in late May, due to the seasonal nature of the main herbal additive (Aardvark 2001).

Amongst the Southern Sotho in Africa, a decoction of the roots of G. dregeanum and G. rotundifolium is used "to ensure intelligence and judgement in the aspirant witch-doctor". For medicinal purposes, the same preparations are used by the Sotho in Basutoland to treat sore throats, respiratory problems, and colic (Watt & Breyer-Brandwijk 1962). The Basuto have reportedly used G. witbergense ['seharane'] in combination with other plants, especially a suspected Myosotis sp. ['sethuthu'; see *Endnotes*], to treat people suffering from hysteria. The preparation is said to give them dreams of medicinal plants they must collect for their cure (Laydevant 1932). The Nkopo of Papua New Guinea use a Galium sp. ['yirk daap' or 'wung naap'] in a paste with other plants in secretive rituals called 'kwik' (Schmid 1991).

G. aparine whole plant was shown to contain c.0.03% alkaloids in one alkaloid screening (Hultin & Torssell 1965). Aerial parts from flowering plants [growing in Anatoli, Turkey] have yielded *harmine* and *protopine* as the major alkaloids, as well as (+-)-vasicinone, (-)-1-OH-deoxypeganine, and (-)-8-OH-2,3-dehydrodeoxypeganine [see **Peganum**] as minor alkaloids (Sener & Ergun 1989); also found in the herb are iridoids [asperuloside and monotropein (see **Monotropa**)] (Swiatek & Komorowski 1973), flavonoids [luteolin], coumarins, n-alkanes and tannins. Roots have also yielded iridoids [including asperuloside and deacetylasperulosidic acid], polyphenolic acids [including caffeic acid, p-coumaric acid, gallic acid and p-OH-benzoic acid], and anthraquinones [alizarin, xanthopurpurin and galiosin] (Wren 1988). Seedlings produce nordamnacanthal, an anthraquinone aldehyde with insect antifeedant properties, though levels decrease as the plants develop (Morimoto et al. 2002).

G. odoratum has yielded asperuloside, and c.1% coumarin (Bruneton 1995), which has hypnotic and sedative properties in large doses (eg. see MacRae & Towers 1984b).

G. verum also tested positive for alkaloids [0.03%], as did G. mollugo [0.003%] (Hultin & Torssell 1965). G. verum, G. mollugo, G. palustre and G. schultesii were shown to contain monotropein and asperuloside (Swiatek & Komorowski 1973).

Galium aparine is a sticky annual herb; stems (20-)80-180cm long, slender, weak, ascending or usually scrambling, especially over other plants, sometimes erect in open places, usually unbranched, retrorsely hispid, often stout and more hairy at the nodes, +- square, 4-angled cross-section. Leaves up to 20-60 x 3-8mm, in whorls of (4-)6-8(-9), linear to narrowly lanceolate or oblanceolate, cuspidate at apex, tapering to base, papillose-hairy above, margin and midrib retrorsely hispid, midrib sunk above, prominent below. Ultimate branches of inflorescence often without bracts; pedicels long, fruiting pedicels straight, divaricately spreading, 5-20mm long; small flowers in 1-3-flowered axillary cymes, becoming cymose-paniculate on older plants; corolla 1.5-1.7mm diam., white, rotate or slightly campanulate; petals 4, acute, involute, inflexed in bud; stamens (3-)4, filaments short; anthers small, exserted. Ovary ovoid, with hooked hairs, 2-celled, with 1 ovule in each cell; styles 2, short; stigma capitate. Fruit ovoid, 1.5-3.5(-5)mm wide, covered with short hooked bristles, separating into 2 indehiscent carpels, sometimes only 1 carpel maturing. Fl. Mar.-Aug. [n. hem.].

Woods, scrub, hedges, cultivated ground; native to Europe, except n.e. Russia and parts of the Arctic; otherwise a cosmopolitan weed (Abrams & Ferris 1960; Tutin et al. ed. 1964-1980; pers. obs.).

GANODERMA

(Polyporaceae/Ganodermataceae)

Ganoderma applanatum *(Pers. ex Wallr.) Patt.* – artist's conk, ancient ling zhi

Ganoderma capense *(Lloyd) Teng*

Ganoderma japonicum *(Fr.) Lloyd* **(G. lucidum var. japonicum** *(Fr.) Bres.***)** – Japanese glossy Ganoderma

Ganoderma lucidum *(W. Curt. ex Fr.) Karst* **(G. lucidum** *(Leyss. ex Fr.) Karst***; Polyporus lucidum** *Leyss. ex Fr.***)** – ling zhi, ling chih, mannentake, denguru shyamu, dhami chyau, jhankri cha, bonpo shamaup, mushroom of immortality, red reishi

Ganoderma neojaponicum *Imaz.* – purple-black reishi

Ganoderma oregonense *Murr.* **(G. sequoiae** *Murr.***; Polyporus oregonensis** *(Murr.) Kauffmann***)**

Ganoderma sinense *Zhao, Xu et Zhang* – zhi chih, zi zhi, Chinese black reishi

Ganoderma tsugae *Murr.* **(Polyporus tsugae** *(Murr.) Overh.***)** – song shan ling zhi ['pine tree fungus', 'pine wound']

G. lucidum has been highly revered in Chinese and Japanese medicine for at least 4,000 years, sharing a similar position of pride to ginseng [see **Panax**]. It was believed to constitute an elixir of immortality, and as such many of its common names translate to such praises as 'herb of spiritual potency', 'divine mushroom of immortality', and the Japanese '1,000 year mushroom' ['mannentake']. It may be that the reputation for life extension was in part derived from the hard, petrified consistency of the mushroom; likewise, its use in aphrodisiac elixirs may have stemmed partly from the hardness of its form. Such claims for giving immortality are no doubt exaggerated, but the mushroom's healing properties are by no means mythical. There are many Chinese legends telling of men being sent on perilous journeys to find a single 'ling zhi' as the last hope for a mortally ill master, succesful procurement of such a fungus bringing about a miraculous recovery when administered. Ling zhi has always been rare and difficult to find, growing often in dangerous and inaccessible forests. The rarest type is the 'antlered' form, an abnormal growth of self-explanatory shape, which forms when growing in darker spots high in carbon dioxide. Nowadays, the mushroom is still used in the far east, both for its numerous medicinal applications, and as a talisman to ward off evil. Cultivation techniques have been perfected, allowing greater public access to the wonderful benefits of this mushroom, as well as making it more affordable (Hobbs 1995; Rätsch 1990, 1992; Stamets 1993; Willard & Jones 1990). Recently in Nepal it has been found that Kirati, Sherpa and Tamang shamans use this mushroom for shamanic flying, though it is unclear whether it is consumed for this purpose or only invoked with its mantra - some consider it the 'strongest' shamanic mushroom, although it would not seem to be so from a western psychopharmacologic viewpoint. The species is also used in Nepal to "increase shakti" [spiritual energy], divine and diagnose illness [placed externally on the patient], and to revitalise the dying. It is said to be potentially dangerous if too much is taken or the correct mantra not used (Müller-Ebeling et al. 2002), although from a medicinal perspective it is known to be quite safe [see below].

Apparently, mountain gorillas are quite keen on G. applanatum. Dianne Fossey observed these creatures gnawing on the fungus even when still attached to the host tree, due to their difficulty in removing the fruiting bodies. When they do suceed in removing a specimen, the gorillas will often bicker over the rights to its possession (Schaecter 1997).

In Vietnam, and some other parts of s.e. Asia, G. australe and G. lucidum are said to sometimes be used by thieves to drug their victims, in order to rob them quietly (Heim 1963b). Incidentally, there exists a church in Chignahuapan, Puebla [Mexico] where a specimen of G. lobatum is venerated in a shrine; on its undersurface is sketched the crucified Christ, with the sun and the moon on either side (Guzmán 1990). This illustrates a characteristic of Ganoderma spp. – when still fresh, contact with the porous underside of the cap causes a darkening due to surface bruising, allowing pictures to be drawn with a fingernail or stick.

G. lucidum has many actions on the body. It is considered an adaptogen [protecting from biological, environmental and social stress], reduces blood fat, stimulates and strengthens the immune system, lowers high blood pressure, and acts as a peripheral anticholinergic, muscle relaxant, analgesic, antiinflammatory, antiallergenic [inhibits *histamine* release], antioxidant free-radical scavenger [also oxygenating the blood, which alleviates elevation sickness], antiviral, cardiotonic, expectorant, antitussive, liver protectant and detoxifier. It improves adrenocortical function, treats heart disease, inhibits platelet aggregation, inhibits bacteria [Bacillus pneumoniae, Staphylococcus spp. and Streptococcus spp.], acts as a preventative against bronchitis [also inducing regeneration of bronchial epithelium], and increases RNA & DNA synthesis in bone marrow where immune cells are made. It has antitumour, anti-HIV, and slight antiulcer activity. It also protects against ionising radiation, if taken before and after exposure. As part of the complex immune system activity, extracts of the mushroom augment immunoglobulin G, expand memory of T cells and enhance their activity, and aid in immune-related sensitivities such as chronic pneumonia, liver disease, cancer and rheumatism (Hobbs 1995; Willard & Jones 1990).

The mushroom may also be mildly psychoactive, with effects usually described as a CNS-depressant or hypnotic (Hobbs 1995; Stamets 1999; Willard & Jones 1990). Though my own experiments with G. lucidum, G. applanatum, and what was thought to have been G. sinense confirm the mild sedative-hypnotic effects [with some batches more than others], a friend has experienced opposite effects, finding the suspected G. sinense to be very stimulating, even euphoric. This could probably not be explained by placebo effect, as I had told her that the only psychoactive effects she would experience might include mild sedation or calming [I had given the mushroom to her as a tonic medicine, rather than as a psychotrope] (pers. obs.). However, others deny that Ganoderma spp. are psychoactive at all (Rätsch pers. comm. 2002).

Ganoderma spp. are very non-toxic, and the amount to be consumed depends on the severity of the need for healing. If one is fortunate enough to have good quality specimens, about 5g may suffice for a regular dose. In case of greater illness, more than twice this amount may be used, though less is required when appropriately blended with other healing herbs. One

source recommends a decoction of 120-200g to treat mushroom poisoning. Ganoderma spp. are usually prepared by chopping or grinding to powder, though they are quite tough and soaking before hand may be useful. The mushroom is then decocted in water for 20-30 minutes, and the water consumed after cooling. A good specimen will yield several more brews from the same batch. The mushrooms may also be prepared in a tincture. The best quality is usually found with G. lucidum [harder to find; generally reddish in colour], though G. japonicum, G. neojaponicum and G. sinense share similar properties and potency, and are more readily available. The other species listed above also have medicinal properties of a similar nature, though less potent and less wide-ranging in activity. G. applanatum, for example, may require a decoction dose of 30g or more. The antlered forms are considered even better than the normal forms of G. lucidum, and caps of Ganoderma spp. are more potent than stems. When shopping for whole specimens, look for a smooth, glossy surface with no insect damage, preferably also with undamaged spore surface beneath the cap. Many people feel cleansed and refreshed after a cup of Ganoderma tea, and find the health-giving effects quite noticeable. Like all tonic and medicinal herbs, it is best consumed regularly over an extended period (pers. comms.; pers. obs.).

G. applanatum has yielded ganoderic acid AP, ganoderenic acids F, G, H & I, furanoganoderic acid, applanoxidic acids A-D and isoergosterone (Buckingham et al. ed. 1994).

G. capense cultured mycelium has yielded the pyrrole alkaloids ganoine and ganodine, the purine alkaloid ganoderpurine (Yu et al. 1991), *adenosine*, adenine, uracil and uridine (Zhang et al. 1986), a sleep-promoting substance also known as SPS-A (Komoda et al. 1990).

G. lucidum contains a wide array of chemical types, most of which synergise to produce the above effects. Isolated have been an unknown alkaloid, an unknown glycoprotein, polysaccharides [ganoderans A, B & C, β-D-glucan, β-D-glucan D-6, GL-1, FA, FI & FI-1a], *adenosine*, a protein [LingZhi-8], a steroid [ganodosterone], triterpenes [ganoderic acids, ganodermic acid, ganodermadiol, ganodermanodiol, ganodermenonol, lucidal, lucidadiol, ergosterol, fungisterol] and oleic acid (González et al. 1999; Hobbs 1995; Willard & Jones 1990).

Ganoderma applanatum is a very large grey-brown bracket fungus, 10-60cm across, 5-30cm wide, 2-8cm thick, +- flat, semicircular, hard, corky and glabrous, margin acute; upper surface knobbly, radially wavy or wrinkled, concentrically grooved and zoned, broadly attached, sessile, covered with a hard, wrinkled crust, often discoloured reddish- or cocoa-brown from deposited spores; flesh cinnamon-brown, thinner than the tube layer, bitter taste, very tough and fibrous; pores 4-5 per mm, white, bruising brown, circular; tubes 7-25mm long in each annual layer, brown; spores brown, warty, broadly ellipsoid, flattened at one end; basidia 4-spored.

Infrequently throughout the year, parasitic on trunks of broad-leaved trees, particularly beech, causing an intensive white rot; also grows on bamboos and conifers. Common throughout US, infrequent in Europe, also found in Australia [ACT, NSW, Vic, Tas] (Hobbs 1990; Jordan 1995; Phillips 1981; Shepherd & Totterdell 1988).

Ganoderma lucidum is a large, mahogany-brown to reddish, kidney-shaped bracket fungus arising from a lateral stem. Cap 4-30cm diam., 2-4cm thick, fan or kidney-shaped, margin pallid when young, +- flattened, radially wavy or wrinkled, concentrically grooved and zoned, later turning purple-brown or blackish, conspicuously glossy as if varnished; flesh cinnamon-brown, tough and fibrous, velvety; stem up to 250 x 10-30mm, dark brown, glossy, hard, hollow, stuffed with fibrous, velvety flesh; pores white, bruising brown, becoming brown with age, circular, 4-5 per mm; spores rusty pallid-brown, warty, broadly ellipsoid, flattened at one end; basidia 4-spored. Taste bitter. Summer to late autumn.

Solitary or in small groups on stumps of broad-leaf deciduous trees, favouring oak in Europe, though most wild specimens in Japan are found on old plum trees [see **Prunus**]. Europe, Asia, also on east coast of US, especially the Gulf coast and the southwest. Rare (Hobbs 1995; Jordan 1995; Phillips 1981).

The mushroom Microporellus dealbatus, of s.e. North America, resembles a ghostly white form of G. lucidum or similar Ganoderma spp. It is not regarded as being edible, but there is no record of toxicity, probably due to its hard consistency, which would tend to discourage ingestion.

GAULTHERIA

(Ericaceae)

Gaultheria anastomosans *(L. f.) Kunth* – borrachero
Gaultheria procumbens *L.* – wintergreen, checkerberry, boxberry, teaberry, mountain tea, salvador tea
Gaultheria sp. – uva camarona

In the Peruvian Andes, an unidentified Gaultheria sp. ['uva camarona'] is said to have been used as a hallucinogen, though there is little solid information on the plant and its use (Schultes & Hofmann 1980, 1992). In Colombia, G. anastomosans is known as 'borrachero' ['intoxicant'], hinting at psychotropic useage (Rätsch 1992). They are related to the common N. American G. procumbens, the leaves of which were made into a refreshing tea [see **Camellia**] during the War of Independence. The Inuit of Labrador, Canada, eat the berries as food, and use the leaves to treat paralysis, headache, muscle aches and sore throats. The Cherokee use the root to treat indigestion, and the leaf to treat cold; they have also chewed the leaves as a tobacco substitute [see **Nicotiana**] and to treat dysentery. The berries are sometimes used today in tarts and cakes. The essential oil ['oil of wintergreen', 'wintergreen oil'] is used to flavour sweets, toothpaste and root beer [see **Sassafras**]; it is stimulant, astringent, antirheumatic and diuretic (Bremness 1994; Frohne & Pfänder 1983; Hamel & Chiltoskey 1975). It is now considered toxic due to its content of methyl salicylate [see below]. Although for many people it is not a problem, one child died after ingesting 4ml methyl salicylate, and another child experienced "severe metabolic acidosis" from 10ml; other deaths have been reported. Symptoms of toxicity may include nausea, vomiting, convulsions, pulmonary oedema, pneumonia and acidosis (Battaglia 1995).

G. procumbens essential oil contains 96-99% methyl salicylate [a naturally-occuring precursor to aspirin (acetylsalicylic acid), the other being salicylic acid], formaldehyde and gaultheriline. Methyl salicylate is not actually found in the plant, yet it is formed by hydrolysis from the glycoside gaultherin [monotropitoside] (Frohne & Pfänder 1983; Lawless 1995) when the leaves are macerated in water for 24hrs before steam distillation of the oil (Bremness 1994).

Gaultheria procumbens is an erect shrub 10-20cm tall, leafy stems arising from a horizontal rhizome, bearing a few leaves crowded near summit. Leaves alternate, persistent, glabrous, elliptic-oblong, 2-5cm long, 1/3-2/3 as wide, rarely narrower or subrotund, margin entire or crenulate; petioles 2-5mm long. Flowers 5-merous, usually white, in racemes or panicles, or solitary in or just above axils, closely subtended by 2 bracteoles; pedicels nodding, 5-10mm long; calyx saucer-shaped, deeply divided; corolla tubular to campanulate, shallowly lobed, 7-10mm long, the rounded lobes c.1mm long; stamens included, filaments short, flat; anthers oblong, the pollen-sacs nearly or quite separate, each tipped with 2 erect appendages. Ovary 4-5-celled, wholly or partly superior; style short, columnar; stigma truncate. Fruit a dry or mealy bright red berry, 7-10mm diam. Fl. Jul.-Aug.

Dry or moist woods, in acidic soil; Newfoundland to Manitoba, s. to Virginia, Kentucky and Minnesota, and in mountains to Georgia (Gleason 1952).

GEOTRICHUM

(Moniliaceae)

Geotrichum candidum *Link. ex Fr.* **(Endomyces geotrichum** *Butler et Petersen***; Oidium lactis** *Pers.***; Oospora lactis** *(Fres.) Sacc.***)** – lipstick mould, sour rot, rubbery rot

G. candidum is a mould fungus that may cause sour-rot in some fruits, particularly lemons and limes [see **Citrus**], as well as tomatoes. The fungus usually only invades damaged fruit, and is spread by Drosophila spp. flies, though it can also be spread by human contact. It sometimes spoils cream and UHT milk if manufacturing machinery is poorly cleaned, and has likewise been found in margarine, cottage cheese and low-fat cheese. Sometimes it is found as a wood-decayer on interior painted surfaces. It may commonly infest the intestines of carpet pythons [Morelia spilota variegata], and sometimes causes necrosis of the scales and underlying skin in captive specimens; such an infection calls for immediate intensive cleaning of the snake's habitat, and veterinary attention (Hocking & Pitt 1996; McKenzie 1996; Simpson 1996).

G. candidum has been shown to yield the ergot alkaloids *ergine*, *elymoclavine*, *agroclavine* and ergosine [see **Claviceps**, **Ipomoea**] (El-Refai et al. 1970), as well as wybutoxine (Buckingham et al. ed. 1994). Ingestion of the fungus would be unwise, as it may contain aflatoxins [see **Aspergillus**], and can cause a disease known as 'geotrichosis', affecting oral, bronchial, pulmonary and/or intestinal parts of the body. Inhalation of the spores can cause chronic asthma (Hocking & Pitt 1996; Stamets & Chilton 1983).

Geotrichum candidum mycelial turf is cushion-like, somewhat powdery, white, with age becoming pinkish to reddish, and later dull orange; hyphae prostrate, with few septa; conidiophores short, erect, septate, producing conidia in chains at their apices; conidia short, cylindrical, truncate at both ends, 5-10 x 4μ, hyaline (Gilman 1957; Stamets & Chilton 1983). When rotting **Citrus**, it usually affects mature or over-ripe fruit that has been stored for a long time, first appearing as a pale, soft area of decay, later developing into a creamy, slimy surface growth. In tomatoes, it appears as light greenish-grey lesions which may extend from end to end of the fruit; plant tissue later weakens and gives off a sour odour, and the creamy-white mould may become visible on the flesh.

Grows best at 25-30°C, growth largely inhibited below 5°C; can grow to some degree in anaerobic conditions. Found worldwide in soil (Hocking & Pitt 1996).

GINKGO

(Ginkgoaceae)

Ginkgo biloba *L.* – ginkgo, maidenhair tree, bai guo, ying hsing, yen xing, pei go su, silver apricots

This is the oldest surviving species of tree, which 200 million years ago shared the planet with dinosaurs. Its range was drawn back into the region of China during the last ice age, where it later became much used in traditional medicine, and was cultivated around Buddhist and Taoist temples; in Japan it is also held sacred and was planted at Shinto temples. The plant is generally found only in cultivation today. Its wood, which has been used to manufacture fine items, repels insects, and the whole tree is remarkably resistant to pests, diseases and pollution. In TCM, the root ['bai guo gen'] is decocted in doses of 10-15g to treat spermatorrhoea or wet dreams; the nut kernels ['bai guo', 'ying hsing'] are decocted in a dose of 10-15g, and have an affinity for the kidneys, heart and lungs. They are sedative, antitussive, astringent, cardiotonic, digestive, anthelmintic, and an 'antidote' for alcohol poisoning. They are eaten as a food in Asia, and are served in Japanese bars to eat while drinking cold beer; in Japan, the grilled nuts are believed to be a male aphrodisiac. A few days after falling from the mother plant, the outer layer of the kernels begins to decompose, emitting a rancid odour; contact may cause skin-irritation. The nuts must be cooked before becoming edible, and consumption of more than 7 at one sitting may cause toxic symptoms. Western medicine is concentrating mostly on the leaves ['yen xing', 'pei go su'], which have been used in many ways by the Chinese – externally for skin sores and freckles, and internally for asthma, coughs, diarrhoea, frostbite, and to benefit the brain. Ginkgo is said to have been an ingredient of the famed 'soma' [see **Amanita**] (Corrigan 1993; Huang 1993; Keys 1976; Rätsch 1990).

Today, the demonstrated benefits of ginkgo leaf are impressive. It improves peripheral circulation, particularly increasing blood flow to the brain, acts as a neuroprotective agent [eg. against hypoxia, seizures and peripheral nerve damage], acts as an antioxidant free-radical scavenger, inhibits blood-platelet aggregation, increases synaptosomal *serotonin* reuptake, and increases synthesis of *dopamine* and *norepinephrine*. An extract from the yellow autumn leaves also strengthens blood vessels. Ginkgo leaf may be useful in treating vertigo, headache, impaired memory, stroke, senility, dementia, shock, asthma, coronary thrombosis, tinnitus, bladder infections and burns; as well as boosting the immune system and improving cerebral function [alertness, learning, and biofeedback with the endocrine system] (Bremness 1994; Bruneton 1995; Corrigan 1993; Fünfgeld ed. 1988; Huang 1993; Joyeux et al. 1995; Ramassamy et al. 1992; Smith, P.F. et al. 1996).

Ginkgo should not be taken with aspirin, paracetamol, *ergotamine*/*caffeine* combinations, or warfarin, as haemorrhage may result due to drastic increase in blood flow. When taking ginkgo, the diuretic thiazide should not be taken, as hypertension may result (Fugh-Berman 2000). The ginkgolic acid in leaf preparations may cause 'poison-ivy like' toxic reactions, and commercial preparations should not contain more than 5ppm ginkgolic acid (Blumenthal ed. 1998). Some commercial ginkgo preparations have unexpectedly been found to contain colchicine in levels that may damage the foetus in pregnant women (Nielsen 2001). This may be a contaminant of some compound preparations; colchicine has otherwise not been reported from G. biloba itself (pers. obs.). The seeds have caused toxicity when consumed in excess, such as in cases of 'gin-nan food poisoning' in Japan, when they have been eaten as a famine food. Symptoms usually include convulsions and unconsciousness, and sometimes death results; animals have also developed limb paralysis and auditory hyperalgesia. As would be expected, infants are more vulnerable to the toxicity. The toxicity is due largely to 'ginkgotoxin' [4-O-methylpyridoxine], possibly acting by inhibiting formation of *GABA* from *glutamic acid* in the brain, as well as antagonising vitamin B6 (Wada et al. 1988).

G. biloba leaves have yielded 0.2-0.53% sesquiterpenoids, partially consisting of the ginkgolides and bilobalides; as well as flavonoids, such as kaempferol [MAOI, protects against NMDA-induced neurotoxicity], quercetin and isorhamnetin derivatives [isorhamnetin also acts as an MAOI], amentoflavone [BZ-receptor agonist], epicatechin acetate, epigallocatechin, ginkgetin, isoginkgetin, bilobetin, bilobalone, stigmasterol, β-sitosterol, d-glucaric acid, anacardic acid, shikimic acid, ginkgolic acid [ginkgoic acid; 6-(8-pentadecenyl)salicylic acid] and derivatives of zeatin. Terpene levels are highest in leaves [ginkgolide A and bilobalide reaching a maximum at the end of summer and beginning of autumn]; roots and shoots yield lower levels [0.24% and 0.02-0.09%, respectively], decreasing as the plant ages. Seeds have yielded c.0.01% 'ginkgotoxin', ginkgolic acid, 6-tridecylresorcylic acid, 6-(pentadec-8-enyl)resorcylic acid, glucose, fructose, sucrose, fat, protein and starch (Blumenthal ed. 1998; Bruneton 1995; Corrigan 1993; Flesch et al. 1992; Fünfgeld ed. 1988; Huang 1993; Lobstein-Guth et al. 1989; Rastogi & Mehrotra ed. 1990-1993; Sloley et al. 2000; Wada et al. 1988).

Ginkgo biloba is a large resinous tree to 40m tall, straight, glabrous, with grey bark. Leaves deciduous, alternate, partly in clusters of 3-5 on spurs, slender-stalked, flat, fan-shaped, +- incised or divided at apex, usually bilobed, fern-like, up to 5-7.5cm across, veins parallel. Flowers dioecious, the staminate in catkin-like strobili; anthers borne in stalked pairs on a slender axis; female flowers on long stalks, usually with 2 ovules, scales absent, fecundation by mobile sperm-cells. Fruit drupe-like, obovoid to ellipsoid, c.2.5cm long, with a yellow epicarp and a pulpy, ill-smelling pericarp; kernel ovoid, angular, white.

Common in gardens; Japan, all over China (Borrell 1996). Many trees cultivated as ornamentals are males, to avoid the annual pile-up of smelly fruit. For propagation, collect fruit after falling, remove the pulp [with rubber gloves on] and clean the seed under running water and with scrubbing in fine sand [this should be done outside or in a well-ventilated area]. Plant in moist sand kept at 15-21°C for several months [during this time the embryo develops fully], then lower temperature to c.4°C for another few months, during which the seedling should emerge. Can also be propagated from cuttings of the hardwood, taken in winter. Frost hardy and resistant to pollution (Glowinski 1997). Trees do not produce sexual organs until 20-30 years old (Corrigan 1993).

G. biloba can not be mistaken for any other tree, and its soft, leathery leaves are a pleasure to harvest.

GLYCYRRHIZA

(Leguminosae/Fabaceae)

Glycyrrhiza glabra *L.* **(G. glandulifera** *Waldst. et Kit.***; G. hirsuta** *Pall.***; G. violacea** *Boiss.***)** – liquorice, licorice, sweet wood, palu dushi, yashti madhu

Glycyrrhiza inflata *Batalin* **(G. eurycarpa** *P.C. Li***)** – gan cao, Chinese licorice

Glycyrrhiza uralensis *Fisch. ex DC.* **(G. asperrima var. desertorum** *Regel***; G. asperrima var. uralensis** *Regel***; G. glandulifera** *Ledeb.***)** – gan cao, gan tsao, mi tsao, guo lao ['venerable national treasure'], Chinese licorice, Manchurian licorice

Liquorice is a herb that has been cultivated for centuries for its sweet, medicinal root. Used since at least 500BC, the Scythians are said to have introduced it to the Greeks, and it spread across the world from there. It has commonly been used as a sweetener and flavouring in sweets, medicines, foods, tobacco [a food and medicine for some – see **Nicotiana**], soft drinks, liqueurs, soy sauce, beers, toothpaste, mouthwash etc. (Bremness 1994; Fraser 1995; Morton 1977; Ody 1993). Liquorice root [usually G. glabra] has long been used in Ayurvedic medicine, and the Ayurvedists seem to have recognised the same virtues in it that the Chinese have [see below]. They likewise use it for respiratory [combines well with ginger – see *Endnotes*], digestive, nervous and circulatory complaints. They consider it a "restorative and rejuvenative food… [which]… calms the mind, nurtures the spirit; nourishes the brain and increases cranial and cerebrospinal fluid, promoting contentment and harmony; improves voice, vision, hair and complexion and gives strength" (Frawley & Lad 1986). In women, it is said to be an aphrodisiac (Rätsch 1990). In TCM, liquorice root [usually G. uralensis or G. inflata] is used in most herbal formulas as a kind of 'co-ordinator' for the other herbs, as it has an affinity for all the organs, and harmonises and prolongs the effects of the other constituents – as well as, of course, improving the overall taste (Huang 1993; Reid 1995; pers. obs.). *Glycyrrhizin*, the major constituent of the root, is roughly 50 times sweeter than sugar (Morton 1977)!

Liquorice root stimulates the adrenal cortex and reduces vitamin C levels there, stimulates interferon production [leading to activity against tumour-production and hepatitis], can potentiate and prolong cortisol action, and inhibits release of melanin-stimulating hormone from the pituitary. It is expectorant, sedative, tonic, antiinflammatory, anticonvulsant, demulcent to lungs and bronchi, emmolient to stomach ulcers, antipyretic, laxative, diuretic, antitussive, strengthens the immune system and reduces cholesterol and blood sugar. It is also effective in protection against many toxins by transforming them in the liver to insoluble products [see *glycyrrhizin* and glycyrrhinic acid below], and protects liver function. It can inhibit the production of antibodies, which is useful in organ transplants (Bremness 1994; Huang 1993; Reid 1995). In rats, a rhizome extract was hypotensive, and countered the effects of barbiturate-induced narcosis (Rastogi & Mehrotra ed. 1990-1993). The Chinese once used liquorice to treat poisoning from 'henbane' [see **Hyoscyamus**] and **Datura**, and decocted with soy beans [Glycine max] it has been used as a broad-spectrum antidote for poisons. It is now known to also have a 'detoxifying' effect on chloral hydrate and *cocaine* hydrochloride (Chin & Keng 1990).

The rhizome has shown adverse reactions with some pharmaceutical drugs. Interaction with oral contraceptives may cause hypertension, oedema, and hypokalaemia; taken with hydrocortisone, vasoconstriction may result; the drug also potentiates prednisolone, and they should not be combined (Fugh-Berman 2000). Liquorice may usually be taken in doses of 2-30g. It may be decocted or infused, though more is needed for infusions, and infusions can be performed more times on the same batch of herb. Continuous use can lower metabolism, decrease thyroid func-

tion, and lead to water retention, hypertension and potassium depletion. People with cardiac or kidney problems, hypertensives, overweight people and those having difficult pregnancies should avoid using liquorice too much (Chevallier 1996; Huang 1993; International...1994; Keys 1976; Morton 1977; Watt & Breyer-Brandwijk 1962). Some people claim it potentiates their *mescaline* experiences (pers. comm.), which may be related to the little-known MAOI activity of some liquorice constituents [ie. *glycyrrhizin*, glycyrrhisoflavone, glicoricone, genistein, glycocoumarin, licopyranocoumarin, licocoumarone, licofuranone, licochalcone A, licochalcone B, liquiritigenin, isoliquiritigenin and (-)-medicarpin] (Hatano et al. 1991; Pan et al. 2000; Tanaka et al. 1987).

G. glabra root yields 5-20% *glycyrrhizin*, occurring as the calcium and potassium salts of glycyrrhinic acid; after water hydrolysis it gives 1 molecule of glycyrrhetic acid [glycyrrhetinic acid] and 2 of glucuronic acid. *Glycyrrhizin* is an acidic triterpene glycoside, with structural similarity and similar activity to corticosteroids – it protects against saponin toxicity and is antitussive and antibacterial (Bruneton 1995; Huang 1993; Morton 1977; Segal et al. 1977; Watt & Breyer-Brandwijk 1962). Glycyrrhinic acid can lower the toxicity of *strychnine*, *histamine*, arsenate, snake venom, diptheria toxin, tetanus toxin and others (Huang 1993). Also found are the coumarins umbelliferone, herniarin and licopyranocoumarin; the flavonoids *apigenin*, liquiritin, isoliquiritin [both oestrogenic], neoliquiritin, liquiritigenin, isoliquiritigenin, rhamnoliquiritin, rhamnoisoliquiritin and formononetin; the glycosides liquiritoside and isoliquiritoside; licochalcones A & B, licocoumarone, licorione [inhibits gastric secretion, anti-ulcer], FM 100 [anti-ulcer, lowers gastric acidity and secretions], LX [immunosuppressant], 18-β-glycyrrhetic acid [antitussive], 28-OH-glycyrrhetic acid, glycyramarin [bitter principle], 22,23-dihydrostigmasterol, asparagin and many other compounds. The root may also contain c.20% starch, 3.8% glucose, 2.4-6.5% sucrose and 0.8% fat (International… 1994; Morton 1977; Watt & Breyer-Brandwijk 1962). Canavanine has been found in the seeds of this species, as well as in G. echinata (Bell et al. 1978; International... 1994).

A Glycyrrhiza sp. from n.w. China, used medicinally in Japan as 'seihoku-kanzo', yielded glicoricone, licofuranone, licopyranocoumarin, echinatin and genistein (Hatano et al. 1991).

Plants grown in saline soils contained greater concentrations of *glycyrrhizin*, compared to those grown in non-saline soils. *Glycyrrhizin* was found to increase in concentration in the roots as the plant grew, though there was no significant seasonal variation; highest concentrations were found in the top parts of the roots, as well as the horizontal rhizomes and other side-roots (Lerman 1972). In Japan, G. glabra [seeds sown in April, 38°N] roots were highest in isoliquiritigenin glycosides in October, though *glycyrrhizin* content continued to increase until November. Three year old plants were also richest in active constituents in October harvests. Thicker roots were the most potent (Hayashi et al. 1998).

Glycyrrhiza glabra is a perennial herb, glandular and often viscid; stems 50-100cm, stem & petioles pubescent, sometimes scabrid. Leaves imparripinnate; leaflets 9-17, 20-40(-55)mm long, elliptical, ovate to oblong, obtuse, sometimes mucronate, often viscid; stipules membranaceous, caducous. Inflorescence lax, elongate racemes; racemes exceeded by their subtending leaves, at least at anthesis; calyx weakly bilabiate; corolla strongly zygomorphic, whitish-violet, 8-12mm; 5 petals, 2 or more sometimes connate; stamens more than 5, diadelphous or monadelphous. Ovary a single unilocular carpel; style 1. Legume up to 30mm, linear-oblong, compressed, straight, glabrous or glandular-setose, sutures straight, indehiscent or tardily dehiscent. Seeds (2-)3-5.

G. glandulifera *Waldst. et Kit* refers to variants with glandular-setose legumes (Tutin et al. ed. 1964-1980).

Dry, open habitats; s. & e. Europe, w. Asia; cultivated and frequently naturalised.

May be grown from seed [soaking in conc. sulfuric acid for 30min. is said to aid germination (theobromus pers. comm.)]; usually from root cuttings or division. Plant in fertile, prepared soil 60-120cm apart. Likes deep, moist well-drained soil. Roots [rhizomes] are harvested in autumn, before the plants set fruit, from 3-4 year old plants. Plant tops are high in nitrogen, and make excellent compost. Remnants of roots are usually left in the ground to regenerate. Roots are washed and shade-dried, reducing moisture content from 50% to 10% (Morton 1977).

Members of this genus have strong weedy potential, due to their deep and vigorous root growth. Once a plant has become established it can be very difficult to remove completely, as even small pieces of buried root can later regenerate (pers. obs.).

GNAPHALIUM

(Compositae/Asteraceae)

Gnaphalium obtusifolium *L.* **(G. polycephalum** *Michx.***)** – sinjachu, rabbit tobacco, ladies tobacco, everlasting, life everlasting, makawiririotapanahi

Gnaphalium polycephalum *L.* – white balsam, old field balsam, sweet-scented life everlasting, Indian posy

Gnaphalium uliginosum *L.* – marsh cudweed

G. obtusifolium has been smoked in N. America as a milder, more aromatic substitute for tobacco [see **Nicotiana**], acting as a mild narcotic-hypnotic, causing dizziness in the uninitiated. The flowers have also been used as a pillow stuffing to ease insomnia (Emboden 1979a). The Cherokee use the plant as a decoction for colds, and as an antispasmodic. It is applied as a local anaesthetic, smoked for asthma, and made into a syrup for coughs. For persons suffering from diptheria, the decocted liquid may be blown down the throat through a **Eupatorium** stem (Hamel & Chiltoskey 1975). The Winnebago blow its smoke to revive a sick person (Kindscher & Hurlburt 1998). Other native N. Americans have used the leaves as a poultice for bruises. G. keriense of New Zealand is also used to treat bruises in the same way (Usher 1974).

G. uliginosum is used in Russia to treat high blood pressure, and is sometimes taken in parts of the British Isles to relieve catarrh. The plant is reputed to have aphrodisiac and antidepressant properties (Chevallier 1996). Juice of G. polycephalum is also reputed to have aphrodisiac properties, and the herb has been used in N. America as an astringent and diaphoretic (Felter & Lloyd 1898). G. luteoalbum ['jersey cudweed', 'karkar'], a widespread weed in Australia, was decocted by indigenous people of the Mitchell River region [Queensland] to treat general conditions of sickness (Lassak & McCarthy 1990). In Meghalaya, India, it is used to make flower wreaths and garlands for use in 'graveyard ceremonies' (Neogi et al. 1989). The Suto of southern Africa burn G. luteoalbum and G. undulatum in a room to drive away sickness. G. luteoalbum has been suspected of causing stock intoxications, but feeding experiments with rabbits did not reveal any toxicity (Watt & Breyer-Brandwijk 1932).

G. obtusifolium aerial parts have yielded 0.1% gnaphaliin [5,7-dihydroxy-3,8-dimethoxyflavone] and 0.01% methylgnaphaliin (Hänsel & Ohlendorf 1969; Opitz et al. 1971); obtusifolin and 3,5,7-trihydroxy-6,8-dimethoxyflavone have also been found in the plant (Buckingham et al. ed. 1994).

Gnaphalium obtusifolium is an annual, sometimes biennial, fragrant erect herb, c.10-80cm tall; stem thinly white-wooly, commonly becoming subglabrous or sometimes a little glandular towards base. Leaves alternate, numerous, entire, linear-lanceolate, to c.10 x 1cm, obtuse to acuminate, sessile, white-wooly beneath, above green, from glabrous to slightly glandular or slightly wooly above. Inflorescence panicle-like, branched and many-headed except in depauperate plants, flat- or round-topped and often elongate, the final clusters with the heads somewhat glomerate, disciform; involucre campanulate, yellowish-white or somewhat dingy, wooly only near base, c.5-7mm high, bracts +- imbricate, scarious at tip or nearly throughout; flowers yellow-whitish, numerous outer ones slender and pistillate, the few inner ones coarser and perfect; corolla tubular; anthers caudate; style-branches rounded or truncate, exappendiculate. Pappus of capillary bristles, sometimes thickened at summit, sometimes united at base; pappus-bristles distinct, falling separately. Achenes glabrous, small, terete or slightly compressed. Fl. Jul.-Oct.

Open, often sandy places; Nova Scotia to Manitoba, south to Florida and Texas.

G. obtusifolium var. saxicola is a lax, slender form less than 25cm tall, leaves wider and less wooly beneath, involucre usually less imbricate.

Along cliffs and ravines in south central Wisconsin (Gleason 1952).

GOMORTEGA

(Gomortegaceae)

Gomortega keule *(Mol.) Baillon* **(G. nitida** *R. et P.***; Lucuma keule** *Mol.***)** – keule, queule, hualhual

The Mapuche of Chile consume the fresh fruit of this small tree for its intoxicating, perhaps entheogenic, effect; it is also made into chicha [see *Methods of Ingestion*]. The fresh fruit is richer in essential oil than the dried fruit, and is considered more potent than the latter. Little else is recorded of this plant, the entire range of which is within 160 square kilometres in central Chile (Emboden 1979a; Rätsch 1998; Schultes & Hofmann 1980).

G. keule bark has yielded 6,8-dimethoxy-coumarin and 8-OH-6-MeO-coumarin (Espinoza et al. 1982). Some coumarins have sedative-hypnotic activity in large doses (MacRae & Towers 1984b).

Gomortega keule is a tree to 15m tall, copa pyramidal; trunk erect, cylindric, to 60cm diam.; bark greyish, rugose, with small, deep, longitudinal fissures; branches long, perpendicular to trunk, ascending towards apex; branchlets smooth, glabrous, green-yellowish to greyish. Leaves perennial, simple, opposite, decussate, coriaceous, fragile, aromatic, dark-green on upper side, light-green beneath, 5-10 x 2-4.5cm, oblong-lanceolate, ovate-elliptic to lanceolate, base attenuate, margin entire, slightly revolute; nerves prominent, secondary nerves immersed; petiole to 8-15mm long, 2-2.5mm thick, with ferrugineous hairs on underside. Inflorescence racemose, few-flowered, with (3-)7(-9) flowers, 3.5-5cm long, curving downwards; rachis and peduncle pubescent, rachis compressed, slightly

quadrangular; flowers hermaphroditic, creamy-green, 5-7mm diam.; perigonium of 6-8 unequal tepals, 2.5-5mm long to 2-2.3mm wide, oblong-ovate, obtuse to acute, concave, and pubescent on both sides; stamens in 2 unequal series, outer stamens 3-4, foliaceous, pubescent, 2.5-3mm long, inner stamens 6-7, to 2mm long, with 2 globose basal glands, pedicellate, ½ length of filaments; anthers of variable size, opening by 2 opercules. Ovary inferior, 2-3 locular, with ovule in each locule; style conical, 1.5-2.5mm long, pubescent, especially in base; stigma white, with 2-3 lobes. Fruit a drupe, obovate-globose, 3.5-7cm long, 3.5-5cm diam., yellow in maturity; seeds ovate-lanceolate, 10-13mm long x 5-6mm wide, enclosed by heavy and 'rocky' endocarp.

In disturbed ground, preferring north-facing slopes, associated mainly with Aextoxicon punctatum, Persea lingue, **Drimys** winteri [see **Canella**, **Drimys**], Weinmannia trichosperma; endemic to Chile, area of distribution now much reduced, in the Cordillera of the coast between the south of Rio Maule and Provincia de Arauco (Rodriguez et al. 1983).

GRAMMOSOLEN

(Solanaceae)

Grammosolen dixonii *(F. Muell. et R. Tate) Haegi* **(Newcastelia dixonii** *F. Muell. et R. Tate***)**

Grammosolen truncatus *(Ising) Haegi* **(Anthotroche truncata** *Ising***)**

This Australian genus of only two species is a source of hallucinogenic tropane alkaloids. Both plants yielded roughly the same constituents.

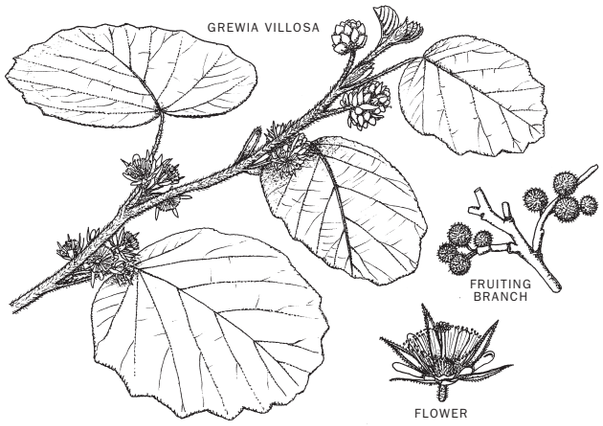
G. dixonii [mature specimen, harv. Aug.] yielded 0.004% alkaloids from aerial parts, and 0.03% from roots; the alkaloids consisted of *hyoscyamine*, *hyoscine*, and their apo-derivatives, as well as 3-α-acetoxytropane from aerial parts, and valtropine and 6-OH-*hyoscyamine* from roots (Evans & Ramsey 1983).

Grammosolen dixonii is a shrub, densely tomentose with non-glandular and inconspicuous glandular hairs; branches wooly-tomentose. Leaves crowded, alternate, often imbricate, simple, almost sessile or with petiole to 3mm long. Inflorescence a cyme, terminal on short, lateral leafy branches; flowers bisexual, actinomorphic, subtended by pairs of opposite or subopposite bracts; calyx cupular, 5-lobed, the lobes more than 1mm long; corolla narrowly tubular with spreading limb, drab white with violet striations, limb with (4-)5(-6) long, narrow lobes, volutive in bud; stamens 5, unequal, inserted at base of corolla tube; filaments pubescent at base; anthers unilocular, not cohering, dehiscing by a semicircular slit. Ovary bilocular; stigma capitate, very shortly bilobed. Fruit a smooth capsule, opening from apex by 4 valves, +- enclosed by calyx; seeds subreniform.

In deep sandy soils, often in disturbed mallee-spinifex areas; Murray region, n. Yorke Peninsula, n.e. Eyre Peninsula [S.A.] (Haegi et al. 1982).

GREWIA

(Tiliaceae)



Grewia bicolor *Juss.* **(G. salvifolia** *Heyne ex Roth, non L.***)** – al-basham, mogwana, kongolubi

Grewia mollis *Juss.*

Grewia polygama *Roxb.* **(G. helicterifolia** *Wall.***; G. hirsuta** *Vahl.***; G. retusifolia** *Pierre***)** – dog's balls, dysentery plant, plain currant, emu berries, yukk ponk mintjak, kangarn, karoom, ouraie, kou-nung, mamurrinya

Grewia villosa *Willd.* – mallow raisin, berchaga, gangetî, hlukayebe

Grewia spp. are now known for their content of β-carboline alkaloids, though the many members of the genus are often used in a variety of ways where they are found. Many bear edible fruits, barks suitable for making cordage, and wood for bows, spear shafts, and other instruments. G. asiatica [G. subinaequalis] root bark is used in tropical Asia to treat rheumatism, and the fruits relieve stomach complaints. G. carpinifolia from India and tropical Africa is used as a leaf decoction to remove head lice. The root of the s.e. Asian G. paniculata is decocted to treat fever, coughs and abdominal pains; the wood is distilled to yield acetone. 'Kanila' bark [G. salutaris] is used in Malaysia and Indonesia externally, rarely internally, as a paste to treat bruising (Usher 1974). In India, G. tiliaefolia bark mucilage is used as an emetic, with Panicum miliaceum flour, to treat 'opium' poisoning [see **Papaver**] and dysentery (Nadkarni 1976).

G. bicolor root is used by the Nuba of Sudan as a tranquilliser (Jaspers et al. 1986); it is also used in Sudan as an abortifacient (Mohamed et al. 1990). In Botswana, fruits of G. bicolor, G. flava ['moretlwa'], G. monticola ['mogwana'], G. occidentalis [tentative i.d.], G. pachycalyx ['mogwana'], G. rogersii [tentative i.d.] and G. subspatulata [also 'mogwana'] have been used as ingredients of 'khadi' mead [see *Methods of Ingestion*, **Delosperma**, **Sceletium**] (Hargreaves 1999).

In the Andaman Islands, G. microcos leaves are used as cigar wrappers for 'tobacco' [see **Nicotiana**]. Leaves of G. polygama are sometimes smoked in pipes as a tobacco substitute by the Wik Monkan of the Gulf of Carpenteria [Australia], when real tobacco is unavailable. The sweet fruit pulp is widely eaten as a food in n. Australia (Thomson 1939). Its crushed leaves are held against the teeth to relieve toothache. The Ngarinyman decoct the whole plant to treat stomach upsets and diarrhoea. The plant acts as an antiseptic, and is also used to treat sores and dysentery (Aboriginal Communities 1988; Lassak & McCarthy 1990; Smith et al. 1993).

G. bicolor root has yielded the β-carboline alkaloids *harman*, 6-OH-*harman*, and 6-MeO-*harman* [iso-*harmine*]; as well as campesterol, β-sitosterol, β-sitosterol-3-O-glucoside, stigmasterol, lupeol, and betulin (Jaspers et al. 1986); it also appears to contain a peptide with *serotonin*-like effects (Mohamed et al. 1990).

G. mollis root [harv. Nov., Kenya] yielded 0.0062% 6-OH-*harman* (Rosler et al. 1978), though c.0.062% would have been obtained if the whole crude extract was purified.

G. polygama root and leaves contain triterpenes and steroids (Aboriginal Communities 1988). Leaf from Rockhampton, Queensland [harv. Dec.] tested weakly positive for alkaloids. Tests on root bark of the same plant, as well as on leaf, stem and fruit [combined] from Yarraman [harv. May], were negative (Webb 1949).

G. villosa root has yielded *harmine*, *harmaline*, *harmol*, *harmalol*, *harman*, 6-OH-*harman* and 6-MeO-*harman* (Bashir et al. 1986, 1987); as well as 19-OH-uvaol, quinovic acid, β-sitosterol-3-O-glucoside (Bashir et al. 1983), sucrose, glucose and galactose (Bashir et al. 1987).

Grewia villosa is a coarse-leaved shrub to 3-4.6m tall. Leaves reniform to suborbicular, to 12cm long, nearly as wide, denticulate and often lobulate, +- cordate at base, digitately 5-7-nerved, tertiary nerves parallel and conspicuous; stipules broadly oblanceolate. Flowers reddish-brown, in axillary or lateral (rarely terminal) few-flowered crowded leaf-opposed cymes; common peduncle solitary and shorter than the petiole, +- branched above; pedicels very short and stout; buds densely villous; sepals valvate; petals free, contorted, imbricate or valvate; stamens usually numerous, free; anthers 2-celled. Ovary superior, 1-4-celled; ovules on axile placentas; style usually simple; stigma always lobed. Fruits entire, to 3cm long, depressed-globose, scarcely lobed, pilose and tuberculate.

Drier savannah regions, often on rocky hills; tropical Africa [Senegal, French Sudan, Ivory Coast, Gold Coast, Nigeria], Arabia and India (Hutchinson & Dalziel 1954-1972).

GRIFFONIA

(Leguminosae/Caesalpiniaceae)

Griffonia simplicifolia *(M. Vahl ex DC.) Baill.* **(Bandeiraea simplicifolia** *(M. Vahl ex DC.) Benth.***; Schotia simplicifolia** *M. Vahl ex DC.***)** – toto, totolimo, kpokirikpo, gbogotri

The durable stems of this African shrub are used for walking sticks, or woven into baskets after baking them to become pliable. The stems and roots are also commonly used as chew-sticks. The leaves yield a black dye, and in Nigeria they are put inside chicken sheds to kill lice. Root starch is used by Peki women as a face powder. In Ghana, dried ripe fruits are sometimes made into whistles and feeding spoons for babies. In the Ivory Coast, a leaf decoction is reputed to be aphrodisiac, emetic, purgative, antitussive, and 'pelvic decongestant', as well as relieving diarrhoea. Also, in Ghana, the leaves are fed to sheep and goats to stimulate reproduction (Burkill 1985-1997; Dwuma-Badu et al. 1976). The seeds are now widely used as a natural source of *5-hydroxytryptophan* [*5-HTP*], extracted and marketed by health supplement companies.

G. simplicifolia dried seeds may contain over 1% *5-HTP* (Bell & Fellows 1966); 6-10% has been found in fresh, mature seeds. Immature seeds contain mostly *5-HTP*, as well as indole-3-acetyl-*aspartic acid* and other unidentified indoles. Germinating seeds contain *5-HTP*, 5'-OH-indole-3-acetic acid and an unidentified 5-OH indole. Pods contain c.0.1-0.2% each of *5-HTP* and *serotonin* [*5-HT*]. Leaves of young plants, grown

in England, contained *5-HTP*; leaves of mature plants, grown in Ghana contained mostly *5-HTP* [peaking at c.1.2% Nov.-Jan., also peaking Apr.-May] and *5-HT* [peaking at c.1.3% Feb.-Apr.], as well as *tryptophan* [0.2%, only in Apr.-May] (Fellows & Bell 1970). Roots also yielded *5-HTP*, griffonin and griffonilide (Dwuma-Badu et al. 1976; International... 1994); stems have also yielded *5-HT* (Smith 1977b). Complications similar to mild *serotonin* syndrome have been observed following interaction between *5-HTP*-rich commercial extracts of G. simplicifolia and smoked **Sceletium** anatomicum, and for this reason caution is advised (friendly pers. comm.; theobromus pers. comm.).

Griffonia simplicifolia is a hard-wooded shrub, usually lianous. Leaves simple or unifoliate, not bilobed, +- ovate, rounded, or widely cordate at base, rounded or shortly obtusely acuminate at apex, 6-12 x 3-6cm, glabrous and shining, prominently 3-nerved at base; stipels mostly absent. Inflorescence mostly showy, greenish flowers numerous in pyramidal racemes, at length reflexed, zygomorphic, rarely subactinomorphic; bracteoles sometimes large and enclosing flower in bud, softly tomentose, with a curled hook-like branch at base; sepals 5; calyx with 5 distinct lobes in bud, united at base into a long tube, softly tomentose outside, c.1cm long; petals 5, the upper one inside in bud, the others variously imbricated; stamens 10, free or variously connate; anthers various, sometimes opening by terminal pores. Ovary superior, 1-celled, 1-carpellate. Fruits obliquely oblong, inflated, up to 4-5cm long, blackish and reticulate; stipe slender, 1-1.5cm long, pubescent; pods explode on drying.

Grass savannah; Liberia, Ivory Coast, Togo, Nigeria, Ghana, Gabon, Congo (Hutchinson & Dalziel 1954-1972).

GUIERA

(Combretaceae)

Guiera senegalensis *Lamarck*

This west African shrub is used to treat rheumatic pain, chest infections and dysentery, and as a galactogogue after childbirth. The plant has CNS-depressant and antiinflammatory activities, and relieves diarrhoea (Mahmoud & Khalid 1997). When given to mice [i.p.], the leaf extract detoxified [in vitro] venom from the snakes **Naja** nigricollis and Echis carinatus (Abubakara et al. 2000).

G. senegalensis root has yielded several β-carboline alkaloids [*harman*, *tetrahydroharman* and leptocladine (2-methyl-1,2,3,4-*tetrahydroharman*)]; tannins are also present. Leaves have yielded 0.008% 5-methyldihydro-flavasperone, a napthopyran, as well as saponins and tannins. Flavonoids and mucilage are also found in the plant (Combier et al. 1978; Koumare et al. 1969; Mahmoud & Khalid 1997; Odebiyi & Sofowora 1978; Shulgin & Shulgin 1997).

Guiera senegalensis is a small shrub, covered with scattered black dots; branchlets softly tomentellous. Leaves opposite or subopposite, oblong-elliptic, rounded or slightly cordate at base, mucronate at apex, 3-5 x 1.5-3cm, softly tomentose grey on both surfaces with scattered black glands beneath; petiole without a pair of glands. Yellowish flowers in dense, shortly pedunculate involucral heads, the heads c.1cm diam.; bracts enclosing the flowers in bud, ovate, c.7mm long; petals very narrow, 4-5; calyx tube adnate to ovary; stamens 4-10, rarely more; filaments inflexed in bud; anthers versatile, didymous, opening lengthwise by slits; disc epigynous. Ovary inferior, 1-celled; style simple; ovules 2-6, suspended from apex of ovary by slender funicles. Fruit linear, radiating, 3-4cm long, crowned by persistent perianth, densely silky-villous.

Abundant in sandy wastes and semi-desert areas; Senegal, Gambia, Mali, Guinea-Bissau, Guinea, Niger, n. Nigeria (Hutchinson & Dalziel 1954-1972).

GYMNOCALYCIUM

(Cactaceae)

Gymnocalycium achirasense *H. Till et Schatzl ex H. Till* **(G. monvillei ssp. achirasense** *(H. Till et Schatzl ex H. Till) H. Till***)**
Gymnocalycium asterium *Y. Ito ex Castellanos*
Gymnocalycium baldianum *(Spegazzini) Spegazzini* **(G. sanguiniflorum** *(Werdermann) Werdermann***)**
Gymnocalycium calochlorum *(Boedeker) Ito* **(G. proliferum** *(Backeberg) Backeberg***)**
Gymnocalycium carminanthum *Borth et Koop*
Gymnocalycium comarapense *Backeb.*
Gymnocalycium denudatum *(Link et Otto) Pfeiffer ex Mittler*
Gymnocalycium gibbosum *(Haworth) Pfeiffer* **(G. brachypetalum** *Speg.***; G. chubutense** *(Speg.) Speg.***; G. gerardii** *(Boedeker) Ito***; G. reductum** *(Link) Pfeiff. ex Mittl.***; Cactus gibbosus** *Haw.***; Echinocactus gibbosus** *De Candolle***; E. mackieanus** *Hooker***; E. nobilis** *Haw.***; E. reductus** *Schum.***)**

Gymnocalycium oenanthemum *Backeb.*
Gymnocalycium paraguayense *(Schumann) Schütz*
Gymnocalycium quehlianum *(F. Haage ex Quehl) Vaupel ex Hosseus*
Gymnocalycium ragonesei *Castellanos*
Gymnocalycium riograndense *Card.*
Gymnocalycium riojense *Fric ex Till et Till*
Gymnocalycium stellatum *Speg.*
Gymnocalycium striglianum *Jeggle ex H. Till*
Gymnocalycium triacanthum *Backeb.* **(G. platygonum** *(H. Till et W. Till) Pilbeam* [misapplied]**; G. riojense** *Fric ex H. Till et W. Till***)**
Gymnocalycium uebelmannianum *Rausch*
Gymnocalycium valnicekianum *Jajó* **(G. bicolor** *Schütz***; G. grandiflorum** *Backeb.***; G. immemoratum** *Castell. et Lelong***; G. kurtzianum** *(Guerke) Br. et R.***; G. mostii** *(Guerke) Br. et R.***; G. tobuschianum** *Schick***)**
Gymnocalycium vatteri *Buining* **(G. ochoterenae ssp. vatteri** *(Buin.) Papsch***)**

This genus of mostly small, globular cacti could easily have fallen within the group of plants known as 'peyote', 'peyotl' or 'peyotillo' in n. Mexico [see **Lophophora**], if only they grew in that region – they are instead confined to South America. Some Gymnocalycium spp. look superficially very similar to **Lophophora** spp., except for the presence of spines. It has been temptingly mentioned, through anecdotal information, that 'peyote-like' cacti are used shamanically in parts of South America, though such use is never openly discussed. It has been thought possible that Gymnocalycium spp. and/or Matucana spp. may be involved [see *Endnotes*] (Trout & Friends 1999; Trout pers. comm.). The chemistry of the genus, once obscure, has recently been illuminated by the work of Czech chemist Roman Štarha. All yields given are from fresh cacti, though it should be noted these analyses have been performed on seedlings cultivated in Europe, and wild populations or mature plants would be expected to yield higher levels of alkaloids.

G. achirasense yielded 0.00007% *mescaline*, 0.00013% N-methylmescaline, 0.00025% N,N-dimethylmescaline, 0.00159% *tyramine*, 0.00045% N-methyltyramine, 0.00129% *hordenine* and 0.00097% anhalamine [6,7-dimethoxy-8-OH-THIQ; see **Lophophora**].

G. asterium yielded 0.00013% *mescaline*, 0.00031% N-methylmescaline, 0.0005% N,N-dimethylmescaline, 0.00089% *tyramine*, 0.00012% N-methyltyramine, 0.001% *hordenine*, 0.00011% O-methylanhalidine, 0.00054% anhalamine, and traces of anhalidine [6,7-dimethoxy-8-OH-2-methyl-THIQ], *anhalonidine*, anhalonine [6-MeO-1-methyl-7,8-methylenedioxy-THIQ], *pellotine* and lophophorine [1,2-dimethyl-6-MeO-7,8-methylenedioxy-THIQ].

G. baldianum yielded <0.0001% *mescaline*, <0.0001% *tyramine*, c.0.001% *hordenine*, and <0.0001-0.001% each of anhalinine [6,7,8-trimethoxy-THIQ], anhalidine, anhalamine, *anhalonidine*, anhalonine, *pellotine* and lophophorine.

G. calochlorum yielded c.0.001% *hordenine*, 0.0001-0.001% each of *mescaline*, *tyramine*, and *anhalonidine*, and <0.0001% N-methylmescaline, anhalinine, anhalidine, anhalamine and *pellotine* (Štarha 1996).

G. carminanthum yielded 0.00006% *mescaline*, traces of N-methylmescaline, 0.0008% N,N-dimethylmescaline, 0.00007% *tyramine*, traces of N-methyltyramine, 0.00016% *hordenine*, 0.00007% O-methylanhalidine, 0.00088% anhalamine and traces of *anhalonidine* (Štarha et al. 1998).

G. comarapense yielded <0.0001% each of *mescaline*, N-methylmescaline, N-methyltyramine, *hordenine*, anhalamine and *pellotine*, and 0.0001-0.001% *tyramine* (Štarha 1995a).

G. denudatum yielded traces of *mescaline*, 0.00008% N-methylmescaline, 0.00073% N,N-dimethylmescaline, 0.00066% *tyramine*, 0.00061% N-methyltyramine, 0.00052% *hordenine*, 0.00025% O-methylanhalidine, 0.00006% anhalinine, 0.0001% O-methylanhalonidine [MAO-A inhibitor (Bembenek et al. 1990)], 0.00048% anhalamine, and traces of anhalidine and *anhalonidine* (Štarha et al. 1998).

G. gibbosum was found to contain a mix of alkaloids, believed to consist of *mescaline*, anhalamine and lophophorine (Ducloux 1930); a later analysis found no *mescaline*, but 0.001% each of N-methyltyramine, *hordenine*, anhalamine, anhalinine, O-methylanhalidine and O-methylanhalonidine, 0.0001-0.001% each of N-methylmescaline, anhalidine, anhalonine,

pellotine and lophophorine, and <0.0001% *tyramine*, N,N-dimethylmescaline and *anhalonidine* (Štarha et al. 1997).

G. horridispinum yielded 0.0001-0.001% *mescaline*, c.0.001% each of *hordenine* and *tyramine*, and <0.0001% each of N-methyltyramine, N-methylmescaline and anhalinine (Štarha 1996).

G. leeanum yielded *mescaline* [tentative], *tyramine*, N-methyltyramine, *hordenine*, anhalonine [tentative] and lophophorine [tentative] (Ducloux 1930; Shulgin & Shulgin 1997).

G. mesopotamicum yielded traces of *tyramine*, N-methyltyramine, *hordenine*, *mescaline* and N-methylmescaline, 0.00279% N,N-dimethylmescaline, 0.0019% anhalamine and 0.00005% *anhalonidine* (Štarha et al. 1998).

G. monvillei yielded <0.0001% *mescaline*, c.0.001% *hordenine*, 0.0001-0.001% each of *tyramine*, N-methyltyramine, anhalonine, *anhalonidine* and *pellotine*, and <0.0001% each of N-methylmescaline, N,N-dimethylmescaline, anhalinine, anhalidine, anhalamine, O-methylanhalidine, O-methylanhalonidine and lophophorine (Štarha et al. 1997).

G. moserianum yielded 0.00007% *mescaline*, 0.00151% N-methylmescaline, 0.00071% N,N-dimethylmescaline, 0.00077% *tyramine*, 0.0001% N-methyltyramine, 0.00011% *hordenine*, 0.00007% O-methylanhalidine, 0.00007% anhalidine, 0.00007% anhalinine, 0.00007% O-methylanhalonidine, 0.00014% *anhalonidine*, 0.00215% anhalamine, 0.00012% *pellotine*, and traces of anhalonine and lophophorine (Štarha et al. 1998).

G. netrelianum yielded 0.0001-0.001% each of *mescaline* and *hordenine*, and 0.0001% each of *tyramine*, N-methylmescaline and *pellotine* (Štarha 1995a).

G. nigriareolatum yielded 0.00006% *mescaline*, 0.00006% N-methylmescaline, 0.00009% N,N-dimethylmescaline, 0.00047% *tyramine*, 0.00008% N-methyltyramine, 0.0014% hordenine, 0.00012% O-methylanhalidine, 0.00019% anhalamine and 0.00012% *anhalonidine* (Štarha et al. 1998).

G. oenanthemum yielded <0.0001% each of *mescaline*, N-methylmescaline, N,N-dimethylmescaline, N-methyltyramine, anhalidine, anhalamine, anhalonine, O-methylanhalidine, O-methylanhalonidine and lophophorine, 0.0001-0.001% each of *tyramine*, *anhalonidine* and *pellotine*, and c.0.001% *hordenine* (Štarha et al. 1997).

G. paraguayense yielded 0.00011% *mescaline*, 0.00041% N-methylmescaline, 0.00427% N,N-dimethylmescaline, 0.00047% *tyramine*, 0.00104% N-methyltyramine, 0.00043% *hordenine*, 0.00505% O-methylanhalidine and 0.00017% *anhalonidine* (Štarha et al. 1998).

G. quehlianum yielded <0.0001% each of *mescaline*, N-methylmescaline, N,N-dimethylmescaline, anhalinine, anhalonine, *anhalonidine*, *pellotine* and lophophorine, 0.0001-0.001% each of *tyramine*, N-methyltyramine and O-methylanhalonidine, and c.0.001% *hordenine* (Štarha et al. 1997).

G. ragonesei yielded traces of *mescaline*, N-methylmescaline and N,N-dimethylmescaline, 0.00009% *tyramine*, 0.00005% N-methyltyramine, 0.0035% *hordenine*, 0.00048% O-methylanhalidine, 0.00006% anhalidine, 0.00109% anhalinine, 0.00007% O-methylanhalonidine, and traces of *anhalonidine* and *pellotine* (Štarha et al. 1998).

G. riograndense yielded 0.0001-0.001% each of *mescaline* and *tyramine*, and 0.0001% each of N-methylmescaline, N-methyltyramine, *hordenine*, anhalinine, anhalidine, *anhalonidine*, anhalonine, *pellotine* and lophophorine (Štarha 1995a).

G. riojense yielded 0.004% *hordenine*, 0.002% *tyramine*, and <0.0001% each of *mescaline*, N-methylmescaline, N-methyltyramine, anhalinine, *anhalonidine*, O-methylanhalonidine and *pellotine* (Štarha et al. 2002).

G. stellatum yielded <0.0001% each of *mescaline*, N,N-dimethylmescaline, N-methyltyramine, anhalamine, O-methylanhalonidine and lophophorine, 0.0001-0.001% each of *tyramine*, N-methylmescaline, anhalinine, anhalonine, *anhalonidine* and *pellotine*, and c.0.001% *hordenine* (Štarha et al. 1997).

G. striglianum yielded c.0.001% each of *mescaline*, N-methylmescaline, anhalamine and *pellotine*, and 0.0001% each of *tyramine*, *hordenine*, anhalinine, anhalidine, anhalonine, *anhalonidine* and lophophorine (Štarha 1995a).

G. triacanthum yielded traces of *mescaline*, N-methylmescaline, N,N-dimethylmescaline and *tyramine*, 0.00005% N-methyltyramine, 0.00054% *hordenine*, 0.00015% O-methylanhalidine, 0.00014% anhalinine, 0.00006% *anhalonidine* and traces of anhalidine (Štarha et al. 1998).

G. uebelmannianum yielded 0.0001-0.001% each of *mescaline*, *tyramine*, N-methyltyramine, *hordenine*, anhalinine, anhalamine, *anhalonidine*, O-methylanhalonidine and *pellotine*, and 0.0001-0.001% each of N-methylmescaline, N,N-dimethylmescaline, anhalonine, anhalidine, O-methylanhalidine and lophophorine (Štarha et al. 1997).

G. valnicekianum yielded c.0.001% *hordenine*, 0.0001-0.001% each of *tyramine* and *anhalonidine*, and 0.0001% each of *mescaline*, N-methyltyramine, anhalinine, anhalonine, *pellotine* and lophophorine (Štarha 1995a).

G. vatteri yielded 0.0001-0.001% each of *mescaline*, N-methylmescaline, N-methyltyramine, *anhalonidine* and *pellotine*, c.0.001% each of *tyramine*, *hordenine* and anhalinine, and <0.0001% each of anhalidine, anhalonine and lophophorine (Štarha 1996).

Gymnocalycium vatteri is a solitary globular cactus, matt olive green, to c.4cm high, 9cm diam.; ribs 8-16, broad, c.2.5cm high; areoles greyish, each with 1-3(-5) yellowish-brown, adpressed spines. Flowers diurnal, white, sometimes with reddish centre, c.5cm long, 4cm diam.; tube and ovary with large, blunt, membranous scales, with completely bare axils. Fruit blue-grey when ripe; seed glossy brown, to 1mm long, mussel-shaped.

Fl. summer.

Cordoba, Argentina. Needs good light; minimum temp. 10°C (Cullmann et al. 1986; Innes & Glass 1991).

GYMNOPILUS

(Agaricaceae/Cortinariaceae)

Gymnopilus aeruginosus *(Pk.) Sing.* **(Pholiota aeruginosa** *Peck***)** – midoritake ['green mushroom'], magic blue gym
Gymnopilus braendlei *(Pk.) Hesler*
Gymnopilus intermedius *(Sing.) Singer*
Gymnopilus lateritius *(Pat.) Murrill*
Gymnopilus liquiritiae *(Fr.) Karst.*
Gymnopilus luteofolius *(Peck) Sing.* **(Pholiota luteofolia** *(Peck) Saccardo***)**
Gymnopilus luteoviridis *Thiers.*
Gymnopilus luteus *(Peck) Hesler*
Gymnopilus pampeanus *(Speg.) Singer* **(G. spectabilis ssp. pampeanus** *(Speg.) Sing.***)**
Gymnopilus punctifolius *(Pk.) Sing.*
Gymnopilus purpuratus *(Cooke et Mass.) Singer* **(Flammula purpurata** *(Cooke et Masse.) Sacc.***)**
Gymnopilus sapineus *(Fr.) Maire* **(Pholiota sapinea** *sp. auct.***)**
Gymnopilus spectabilis *(Fr.:Fr.) A.H. Sm.* **(G. junonius** *(Fr.:Fr.) P.D. Orton***; G. spectabilis var. junonius** *(Fr.:Fr.) Kühner et Romagn***; Pholiota spectabilis** *(Fr.:Fr.) P. Kumm.***)** – o-warai-take ['big laughing mushroom'], giant laughing mushroom, big gym
Gymnopilus subpurpuratus *Guzmán-Davalos et Guzmán*
Gymnopilus validipes *(Peck) Hesler*
Gymnopilus viridans *Murrill.*

Known in Japan as 'o-warai-take' ['big laughing mushroom'], G. spectabilis is known to be 'intoxicating', as has been observed in several documented cases. One woman, in Cleveland, 1942, took "a few nibbles" of a specimen she had found, and later experienced "glorious visions of colour and sounds of music, with no feeling of discomfort whatever"...she later returned to normal and said that "if this were the way one died of mushroom poisoning, she was all for it"! Also, a man in Massachusetts, 1966, ate 2-3 caps fried in butter [he also gave some to his wife and his neighbour], and felt "disconnected" and "woozy" 15mins later. He experienced pleasant colour intensifications, and thoughts were scattered, even though his mind felt sharp (Buck 1967; Sanford 1972; Walters 1965). This species is now used as a non-traditional entheogen on a small scale in parts of the eastern US (pers. comm.). In the mountains of Oguni, Japan, this species is eaten as food, after boiling and discarding the water (Kusano et al. 1986). G. validipes has also caused accidental inebriation in two people from Michigan who mistook the mushrooms for Armillaria mellea [see below] (Hatfield & Valdes 1977; Hatfield et al. 1978).

The Yurimagua of Amazonian Peru once prepared a "strongly intoxicating" potion from a type of mushroom growing on fallen trees, mixed with a "kind of reddish film that is found usually attached to rotting trunks". The latter growth was said to be "very hot to the taste." This practice seems to now be extinct. Of the potion, it was reported by Jesuit missionaries that "No person who drinks this brew fails to fall under its effects after three draughts of it, since it is so strong or, more correctly, so toxic". The mushroom has been proposed to be **Psilocybe** yungensis (Schultes 1967a). Jochen Gartz suggested that the mushroom is more likely a Gymnopilus sp., G. purpuratus being an excellent candidate (Gartz 1996). However, Gartz seems to have confused the mushroom with the "reddish film", by referring only to mushrooms that "appeared on fallen trees as a kind of reddish growth with a spicy taste". He also notes that **Psilocybe** spp. "grow almost exclusively on wood sprigs and tree bark debris" (Gartz 1996). **Psilocybe** yungensis is, however, known to grow on "very rotten wood" (Guzmán 1983).

The subjective effects from active Gymnopilus spp. have been described by modern-day experimenters as being different from *psilocybin/psilocin* alone. Sedation, body numbness, and mild *psilocybin*-like effects are often described, with some also mentioning an alcohol-like component to the experience (Byron pers. comm.; Hoodoo pers. comm.). The psychotropic effects of the other compounds found in these species [especially in G. spectabilis, the most thoroughly studied species] have not been investigated in humans. Human bioassays seem to indicate that these lesser-known compounds are physiologically active.

A bioassay of G. liquiritiae from Japan [thanks to Hoodoo] produced

results quite different from those attributable to *psilocybin/psilocin*. A dose of 5g dry fruiting bodies was chewed thoroughly and swallowed over the course of 25 minutes, immediately after which a mild numbing of the tongue was noted. The fungi were less fibrous than most **Psilocybe**s, and thus easier to chew. Smaller fruiting bodies were generally far more bitter than the larger ones. Apart from the intense bitterness, the taste was not strong or objectionable. Occasional brief, mild bouts of nausea were experienced earlier in the experience, but these were easy to overcome. The effects developed slowly and almost imperceptively over the next 1-2hrs, first noted as a greatly increased sensitivity to the volume of music. No other auditory enhancement or distortions were noted. The effects mainly consisted of a gentle, relaxed inebriation that is difficult to describe. The body as a whole felt 'soft and fuzzy'; physical contact was similarly 'velvety' and pleasant, but sexual feelings were suppressed. No visual alterations were noted, other than a slight softening of focus, which disappeared when an object was looked at directly. Thought processes seemed not to be affected at all, and a general feeling of pleasant lucidity and contentment was present throughout. Overall, the experience lasted c.6hrs, with no after-effects. At the dose used in this experiment, I was left with the impression that the effects of G. liquiritiae are pleasant and interesting, but not psychedelic in any great sense (pers. obs.). However, at least some Japanese specimens have been found to contain *psilocybin* [see below].

G. aeruginosus specimens from Michigan and Washington [as well as N. American specimens of unstated origin] were shown to contain *psilocybin*, though specimens from Ohio (Hatfield & Valdes 1977; Hatfield et al. 1978) and Japan contained none (Koike et al. 1981). Also found are the styrylpyrone-derivatives bis-nor-*yangonin* [0.1%] and hispidin [up to 1%] (Hatfield & Brady 1971); bis-nor-*yangonin* and hispidin are related to the kava-pyrones [see **Piper 2**], but the former compound appears to be inactive at up to 50mg/kg in rats (Hatfield et al. 1978). However, the researchers were evaluating it for 'hallucinogenic' activity, so this does not necessarily mean that bis-nor-*yangonin* is totally inactive (pers. obs.).

G. aurantiophyllus was shown to contain 0.1-1% bis-nor-*yangonin* and <0.1% hispidin (Hatfield & Brady 1971); no *psilocybin* was detected in specimens from Washington (Hatfield et al. 1978).

G. braendlei has been found to contain *psilocybin* (Allen et al. 1992), <0.1% bis-nor-*yangonin* and up to 1% hispidin (Hatfield & Brady 1971).

G. decurrens has yielded bis-nor-*yangonin* (Hatfield & Brady 1969).

G. fulgens from the Netherlands did not contain *psilocybin* (Stijve & Kuyper 1988).

G. intermedius has yielded *psilocybin* (Allen et al. 1992).

G. lateritius has been shown to contain *psilocybin* (Guzmán et al. 2000).

G. liquiritiae from Japan has yielded 0.012-0.029% *psilocybin* (Koike et al. 1981), though specimens from Alaska contained none (Hatfield et al. 1978). Japanese specimens have been found to be active from [1-]5g dry (Hoodoo pers. comm.).

G. luteofolius is presumed to be active, due to its bluish or greenish bruising reaction (Stamets 1996), though *psilocybin* was not found in samples from Washington and Michigan (Hatfield et al. 1978); it was found to contain <0.1% each of bis-nor-*yangonin* and hispidin (Hatfield & Brady 1971).

G. luteoviridis has yielded *psilocybin* (Allen et al. 1992).

G. luteus from Michigan was shown to contain *psilocybin* in only 1 of 3 collections (Hatfield et al. 1978); *psilocybin* was also detected in N. American specimens of unstated origin (Hatfield & Valdes 1977).

G. obscurus was found to contain more than 3% bis-nor-*yangonin* and 0.1-1% hispidin (Hatfield & Brady 1971).

G. pampeanus is sometimes considered a variety of G. spectabilis, and similarly has a very bitter taste (Southcott 1996); it might possibly also be psychoactive, though no *psilocybin*, *psilocin* or *serotonin* were found in Brazilian specimens (Stijve & de Meijer 1993).

G. punctifolius has been shown to contain 0.42-3% bis-nor-*yangonin* and 0.21-3% hispidin [upper values estimated based on chromatographic and mass-spec. data] (Hatfield & Brady 1971; Repke et al. 1978); no *psilocybin* was found in specimens from Washington (Hatfield et al. 1978).

G. purpuratus [both cultivated and 'wild-harvested' from introduced patches in Germany – see below] yielded high levels of alkaloids – 0.15-0.32% *psilocybin*, 0.15-0.29% *psilocin*, and 0.01-0.05% *baeocystin*. *Psilocin* levels drop quickly in storage. 'Wild' specimens contained slightly greater alkaloid levels than the cultivated specimens, though the difference was not very significant. The bitter taste is not present in European specimens (Gartz 1991, 1996), but is in Australian specimens (Shepherd & Totterdell 1988; Young 1994).

G. sapineus has been shown to contain *psilocybin* (Guzmán et al. 2000).

G. spectabilis from Michigan was shown to contain *psilocybin* in 2 of 5 collections; *psilocybin* was also found in collections from Ohio and Ontario, and N. American collections of unstated origin. Those from California, Idaho, Massachusetts, New Mexico, Washington, England, and Europe have not been found to contain *psilocybin* or similar indoles (Hatfield & Brady 1969; Hatfield & Valdes 1977; Hatfield et al. 1978; Kusano et al. 1986; Stijve & Kuyper 1988). Based on these chemical analyses, and reports of willing ingestion, it has been generalised that specimens from western states of the US are +- inactive, whilst those from eastern states are active; however, it has been suggested that positive results with this species may be due to misidentification (pers. comms.). This would not be unlikely as many Gymnopilus spp. look quite similar superficially, and can be difficult for the novice [and even some supposed 'experts'] to tell apart (pers. obs.). Japanese specimens have been believed to be psychoactive, but *psilocybin* has not been found in them (Koike et al. 1981; Kusano et al. 1986); human bioassays of up to 10g [d/w] of Japanese specimens have produced only mild relaxation and non-psychedelic visual disturbances (Hoodoo pers. comm.).

Other compounds identified in G. spectabilis include bis-nor-*yangonin* [0.03% w/w] and hispidin [0.0016% w/w] (Hatfield & Brady 1969, 1971), the bis-nor-*yangonin* derivative methyl-5-OH-7-p-OH-phenyl-3-keto-4Z,6E-heptadienoate, polyisoprenepolyols named gymnoprenols [including 0.013% (w/w) gymnopilene], 4,6-decadiyne-1,3,8,10-tetraol [0.003% w/w], 4,6-decadiyne-1,3,8-triol [0.003-0.015% w/w], ergosterol [0.006-0.02% w/w], ergosteryl peroxide [0.0006-0.035% w/w], cerevisterol [0.006% w/w], galactitol, *choline* [0.35% w/w], palmitic acid [0.003% w/w] and α,α'-trehalose [0.039% w/w] (Findlay & He 1991; Kusano et al. 1986; Nozoe et al. 1983a). Three of the gymnoprenols have been renamed gymnopilins. The gymnopilins were shown to be 'neurotoxic' in unpublished animal studies [in that they depolarise nerve cells], and are reportedly the bitter principles in the mushroom (Nozoe et al. 1983b; Tanaka et al. 1993). The doses used to elicit neurotoxicity in animals were not given. Human experiments with this species have not displayed signs of neurotoxicity at usual doses [several specimens or less] (pers. comms.). I suspect that the emphasis on the supposed neurotoxicity of these compounds, without the research data being available for public scrutiny, may stem from a misguided attempt to discourage ingestion.

At least in this species [G. spectabilis], bitterness does not seem to correlate with psychoactivity. In specimens collected over several years from the same tree stump, bitterness was observed to increase with the apparent age of the organism. Collections made in early years were barely bitter at all. The specimens were strongly active at a dosage of 100g fresh [or 10g dried], though some effects were noticeable at 10g fresh [1g dried] (Byron pers. comm.).

G. subpurpuratus is thought to possibly contain *psilocybin* due to its greenish bruising reaction (Allen et al. 1992).

G. validipes from Michigan yielded 0.12% *psilocybin*, and also gave *psilocin* when subjected to hydrolysis (Hatfield & Valdes 1977; Hatfield et al. 1978).

G. ventricosus [from Pacific n.w. US], which is often mis-identified as G. spectabilis, did not contain any *psilocin* or *psilocybin* (Beug & Bigwood 1982; Hatfield et al. 1978).

G. viridans from Ontario was shown to contain *psilocybin* (Hatfield et al. 1978), as were N. American specimens of unstated origin (Hatfield & Valdes 1977).

The related Pholiota mutabilis has yielded *phenethylamine* (Lundstrom 1989).

Pholiota squarroso-adiposa was found to contain bis-nor-*yangonin* [estimated 1.8%] and hispidin [est. >0.04%] (Brady & Benedict 1972).

Gymnopilus purpuratus has a cap 15-42(-200)mm across, flesh thin, broadly convex without umbo, evenly covered by minute fibrillose pointy scales, purplish to ruby on yellow background, dry; margin inrolled at first, incurved later, occasionally stained blue. Stem not hollow, up to 6-10 x 30-80mm, very rarely up to 15cm tall, cylindrical to slightly club-shaped, coarse fibrils, striated, +- smooth, pale yellowish-brown above, concolorous with cap below, lower stem area and base bruising greyish-blue to greenish when injured and with age, flesh thick. Cortina sulphur yellow to yellowish-brown, almost appendiculate along margin, fibrous at apex without forming a true annulus; disappears with age. Gills close, golden yellow at first, rusty yellow later due to maturation of spores, edges concolorous with lamellae, adnate to sinuate (to slightly decurrent). Basidia c.35µ long, club-shaped, 4-spored; spores 6-12.5 x 4.3-7.3µ, elliptical to almond-shaped, punctate, yellowish- to ochre-brown. Smell none; taste bitter.

Gregarious on rotten wood. Native to Australia [S.A., Vic., W.A.] and S. America [Chile, Argentina]; it has also appeared spontaneously in e. Germany [possibly from imported S. American grain coated with traces of spores, which were fed to pigs in Germany, the manure being liquified and mixed with wood chips for composting] (Gartz 1996; Shepherd & Totterdell 1988; Young 1994). Late summer to early winter (Phillips 1981).

G. spectabilis grows in east to southeast N. America, Europe and the British Isles [it has been recorded from Australia, but this might be a confusion with G. pampeanus]. It has a very bitter taste and closely resembles G. ventricosus, an inactive species (Stamets 1996). It is also sometimes confused with Armillaria mellea ['honey mushroom'], an edible medicinal mushroom used by the Chinese to increase blood flow to the brain and heart, and as an analgesic and anticonvulsant; it has shown some antihypertensive and antibiotic actions (Hobbs 1995). A. mellea is said to be inedible when raw, producing severe gastro-intestinal upsets (Bresinsky

& Besl 1989).

G. pampeanus is found in South Australia from April to May, on stumps and sometimes roots of Pinus spp. and Eucalyptus spp. (Grgurinovic 1997).

Gymnopilus spp. are also sometimes potentially confused with the deadly toxic Galerina spp. [such as Galerina autumnalis (Pholiota autumnalis)] (Stamets 1996) and Pholiotina spp. – consult a good guide-book for descriptions of these.

HAMMADA [including Haloxylon]

(Chenopodiaceae)

Hammada articulata *(Moquin) Bolòs et Vigo* **(Caroxylon articulatum** *Moq.***; Haloxylon articulatum** *Bunge***)**

Hammada articulata var. scoparia *(Pomel) Iljin* **(H. articulata ssp. scoparia** *(Pomel.) Bolòs et Vigo***; H. scoparia** *(Pomel) Iljin***; Arthrophytum scoparium** *(Pomel) Iljin***; Haloxylon scoparium** *Pomel.***)**

Hammada leptoclada *(Popov) Iljin* **(Arthrophytum leptocladum** *Popov ex Iljin***; Haloxylon leptocladum** *(Popov. ex Iljin) Korovin***)**

Hammada wakhanica *(Pauls.) Iljin* **(Anabasis wakhanica** *Pauls.***; Arthrophytum wakhanicum** *(Pauls.) Iljin***; Haloxylon wakhanicum** *Eug. Kor.***)**

Haloxylon persicum *Bunge, ex Boiss. et Buhse* **(Arthrophytum ammodendron var. acutifolium** *Minkw.***; A. persicum** *Sava***)**

These herbs have no indigenous uses that I am aware of, except for Haloxylon persicum, which is used in central Asia for fuel, forage, wood, and stabilising sand dunes (Komarov ed. 1936). The chemistry of some of these plants, which contain β-carboline alkaloids, makes them potentially useful MAO-inhibitors for use in ayahuasca analogues [see *Methods of Ingestion*]. The presence of *tryptamine*-, *phenethylamine*-, piperidine- and tetrahydroisoquinoline-alkaloids is also of interest.

H. articulata has yielded carnegine as a major alkaloid [see **Carnegiea**], as well as N-methyl-isosalsoline (Carling & Sandberg 1970).

H. articulata var. scoparia has yielded *tetrahydroharman* and *N-methyltryptamine* [*NMT*] (Shulgin & Shulgin 1997).

H. leptoclada leaf and stem have yielded 0.4-3.7% alkaloids, including *tetrahydroharman* [0.092%], 2-methyl-1,2,3,4-*tetrahydroharman* [leptocladine; 0.722%], 2-methyl-THβC, 3-methyl-THβC, and *NMT* [0.088%]; 1-year old shoots at flowering yielded 3.7% alkaloids [0.575% *NMT*] (Orazkuliev et al. 1964, 1965; Platonova et al. 1959; Rousseau et al. 1967; Shulgin & Shulgin 1997; Yurashevskii 1939, 1941); the herb has also yielded N-methyl-*phenethylamine* (Smith 1977a) and allantoin (Yurashevskii 1941).

H. wakhanica has yielded 2-methyl-1,2,3,4-*tetrahydroharman* (Shulgin & Shulgin 1997) and *NMT* (Smith 1977b).

The closely-related Haloxylon persicum has yielded 5.4% alkaloids, including *anabasine* as a major alkaloid, with smaller amounts of *nicotine* and cotinine, which is an auto-oxidation product of *nicotine* (Habib et al. 1975; Muhtadi & Hassan 1981), and thus might not actually occur in the fresh plant.

Haloxylon salicornicum has yielded 8 alkaloids from the leaves and stems, which combined have an LD50 in mice of 6.2mg/kg [i.p.] (Sandberg 1962; Sandberg et al. 1960). The alkaloids include betaine, haloxine [a piperidine derivative] (Sandberg 1972), halosaline, aldotripiperideine (Michel et al. 1967), *tyramine*, N-methyl-*tyramine* and synephrine (Smith 1977a).

Hammada leptoclada is a perennial sub-shrub, 25-60cm high, stem rugged, profusely branched, branches opposite, covered with greyish bark, joints brittle; fresh branches somewhat rigid, not succulent, glabrous, smooth, cylindric or terete, pale green or glaucescent. Leaves opposite, thickish, rather stiff, subulate, subcylindric, terete, short, 1-3mm long on green shoots, +- obtuse, subappressed to stem or scarcely spreading. Inflorescence broadly paniculate, of elongated spikes; flowers solitary, in axils of scale-like bracts, perfect, 5-merous, with lateral herbaceous bracteoles; bracteoles green, orbicular, rotundate, +- stiff, margins narrowly membranaceous or scarious, obtusely keeled in panicle, widely spaced, as long as or slightly shorter than flower; perianth segments leafy or subherbaceous, with basal tufts of flexuous hairs, margins membranaceous or scarious, obtuse, winged in fruit just above middle, wings subrotundate or suborbicular, membranaceous, rounded at base, horizontally expanded to 7-8(-10)mm; stamens 5; anthers oblong-oval to rounded-oval; filaments connate for much of length to a hypogynous disc, deeply compound at base, lobed, alternating with staminodes; staminodes semiorbicular glandular-ciliate, thickened at margin, reaching beyond middle of perianth, lobes semiorbicular or subtruncate, glandular or glandular-fimbriate. Ovary 1-locular, superior, with 1 basal ovule; disc semiorbicular, papillose-fimbriate; stigmas 2-5, subsessile, short, thick. Fruit 2-2.5mm diam., apex concave, loosely enclosed by lobes of fruiting perianth; seed horizontal, with spiral embryo. Fl. Apr.-May.

Gravelly slopes, in pebbles, pebbly- and sandy-desert, saline sand borders, 'clayey solonchak soils'; central Asia (Komarov ed. 1936).

HEDYOSMUM

(Chloranthaceae)

Hedyosmum toxicum *Cuatrec.* **(H. cumbalense** *H. Karst.***; H. granizo** *Cuatrec.***)** – granicillo, granicillo pequeno, chisco de monte, granizo, granizo de paramo, chavarquero, guayusa, guayusa hembra

Hedyosmum translucidum *Cuatrec.* – granicillo del grande, granizo, granizo morada, guayusa, sachguayusa, aquaquin

H. toxicum is used near Pasto, Colombia, on rare occasions, due to its great strength. Its aromatic leaves are decocted and drunk as a strong intoxicant, violent emetic and stomach tonic. An infusion may be used to treat stomach trouble, colic and chills; the leaves are also sometimes used to flavour, and probably strengthen, alcoholic beverages. H. translucidum is used in the Putumayo of Colombia – the aromatic leaves are made into a hot infusion, which is taken as a tonic, stimulant and digestive. The common name of 'guayusa' given to these plants suggests that they may be regarded as substitutes for **Ilex** guayusa (Schultes & Raffauf 1990; Todzia 1988). Their chemistry is obscure.

Hedyosmum toxicum is a dioecious, aromatic shrub or columnar tree 1-7m tall, with a narrow crown; trunk gnarled with prop-roots; bark grey, smooth, slightly fissured; wood white, soft, turning orange exposed to air; young stems quadrate, purple, smooth to verrucose, glabrous to scurfy or hirsute; older stems terete, smooth, glabrous, often hollow, with leaf-scars; internodes 0.5-2.2cm long, nodes swollen. Leaves narrowly elliptic, elliptic to obovate, 1.1-5.3 x 0.5-1.8cm, apex acuminate, base rounded to truncate, margins serrate with ascending, often white-tipped teeth 2.5-4mm distant, crassulate-coriaceous, smooth, shiny, glabrous, dark green above, lighter beneath with margins white to purple-black when fresh; midveins impressed above, raised and glabrous to hirsute below; free portions of petioles purple, 0.1-0.4cm long, smooth to verrucose to scurfy, glabrous to hirsute, inflated, flared at apex, quadrangular, each distal margin with 2 caducous, fimbriate, stipular appendages 1-2mm long that continue down sheaths as raised ciliate to fimbriate lines, extending to 0.5mm beyond free portion of petioles. Male inflorescence green, terminal, in a solitary spike 2.1-4.4 x 0.6-1cm; subtending leafy bracts 0.1-1.1cm long; rachis with basal annulus; peduncles 1-2mm long or sessile; stamens 90-160 per spike, congested, becoming 0.5-1mm distant on axis; anthers yellowish-green, 1.5-3 x c.1.5mm. Female flowers usually terminal, sometimes axillary, composed of a solitary cymule, subtended by a pair of yellow, green or purplish leafy bracts 0.1-1.8cm long (enclosing flowers completely except for stigmas), cymules with 2-8 clustered flowers, 5-10mm long and wide, terminal cymules sessile, axillary ones on rachis 2-5mm long; flowers trigonous, 4-6 x c.2mm, with or without a pore on each face; perianth lobes 1.5-2mm long, basally united, with free portions triangular, acute; stigmas green to purple, linear, terete, 2-4mm long with very short papillae. Fruiting cymules purple to black, globose, 0.9-1.5cm diam.; seeds trigonous, c.3mm long, brown, smooth. Fl. and fr. all year.

In elfin, cloud and subpáramo forest from 2700-3500m; Colombia to Peru (Todzia 1988).

HEIMIA [including Decodon]

(Lythraceae)

Heimia montana *(Griseb.) Lillo*

Heimia myrtifolia *Cham. et Schlecht.* **(Decodon myrtifolius** *Kuntze***; Nesaea myrtifolia** *Desf.***)** – abre-o-sol ['sun-opener'], herba da vida ['herb of life'], quiebra arado ['plow breaker'], quiebra yugo

Heimia salicifolia *Link* **(H. syphilitica** *DC.***; Decodon salicifolius** *Kuntze***; Nesaea salicifolia** *Kunth***; N. syphilitica** *Steud.***)** – sinicuiche ['twisted foot'], sinicuilche, sinicuil, yerba de las animas ['herb of the spirits'], cuauxihuitl, huauchinolli, hauchinal, jarilla, grandadillo, anchinol, xoneculli, chapuzina, rosilla de puebla

Decodon verticillatus *(L.) Ell.* – swamp loosestrife, water oleander

The flowers of H. salicifolia have been observed adorning the statue of the Aztec deity Xochipilli [see **Turbina**] (Wasson 1973). This plant is prepared into a magical beverage by inhabitants of the highlands of Tamaulipas and Veracruz, Mexico. Healers prepare the plant by soaking the wilted [or dried] crushed leaves in water and leaving the mixture to ferment in the sun for a day. The leaves are then pressed out and discarded; at this point some sources say the beverage is consumed, others say it is left for further fermentation before consumption. Some say it is sometimes mixed with alcoholic beverages to add strength. Indigenous users claim the drink helps them to remember past events from long ago. It causes a pleasant drowsiness and giddiness, mild intoxication, darkened vision, hypothermia, slowed heart-rate, mildly reduced blood pressure, di-

lation of coronary vessels, and skeletal muscle relaxation. The most interesting aspect of the experience is an auditory factor, where sounds seem to be far away or distorted. No negative effects are reported, but overindulgence can cause a yellowish tinge to vision the next day. Continued overuse reputedly leads to memory deficits. Experiments by western psychonauts have produced variable results, some experiencing the effects, others not noticing them. Medicinally, the plant is said to act as a general tonic, sudorific, antipyretic, haemostatic, emetic, laxative, diaphoretic, diuretic, astringent, antisyphilitic and vulnerary. It is used to treat chest complaints, dysentery, indigestion, slow-healing ulcers, dermatitis contracted from **Rhus**, and inflammation of the womb after childbirth (Blomster et al. 1964a; Jiu 1966; Malone & Rother 1994; Ott 1993; Rätsch 1992; Schultes & Hofmann 1980, 1992; Tyler 1966). It has been said to cause "violent perspiration" (Webb 1948), though no modern-day users of the plant have reported this, that I am aware of.

Around 10g of dry leaves, or the equivalent wet amount, is said to constitute a single dose (Gottlieb 1992). Others have reported a "heaped handful" of leaves to be sufficient for one person (pers. comm.). A single experiment with a smaller, unweighed quantity [a small cupped-handful] of H. salicifolia leaves [from a plant growing in Melbourne, Australia], prepared by the traditional method, produced inconclusive results. A mild relaxation and anxiolysis were the only perceptible effects at this dose (pers. exp.). The most interesting effects noted from H. salicifolia have resulted from smoking concentrated extracts of the herb. Both an "unspecified resin" and a 28x extract were used by two psychonauts, the latter in a smoked dose of "2 cones" through a water-pipe. The experience lasted 30-90 minutes, was positive in nature, and involved strong visual effects – one of the psychonauts reported "snakes flowing in and out of his body". A smokeable extract of this herb may be prepared with acetone as the solvent, using a small amount of ammonia for basifying (Torsten pers. comm.).

There has been much confusion regarding the taxonomy of Heimia spp., many researchers regarding it to be a monotypic genus, with H. salicifolia as the only representative. Others hold that H. myrtifolia differs enough in its morphology and natural range to be considered a separate species. Under this view, Mexican plants are H. salicifolia and S. American plants are H. myrtifolia (Blomster et al. 1964a; Douglas et al. 1964). It was only recently that H. montana [from s. Bolivia and n. Argentina] was recognised as another member of this genus. Although difficult to distinguish morphologically, it is now believed these 3 species can be differentiated by chromatographic comparison (Rother 1990).

H. montana aerial parts have yielded 0.05-0.16% *cryogenine* [vertine], 0.03-0.22% lythrine, 0.001-0.22% lyfoline, 0.01% lythridine, 0.003-0.25% demethylvertine, 0.003% heimidine, 0.006% alkaloid H-17, 0.003% H-18, 0.017% H-19 and 0.02% H-20. Nesodine was detected by TLC in an analysis of a different harvest (Rother 1990).

H. myrtifolia has yielded 0.0055% *cryogenine* [see below], 0.177% lythrine, 0.003% lythridine (Douglas et al. 1964) and nesodine [detected by TLC] (Rother 1990).

H. salicifolia foliage has yielded up to 1.4% quinolizidine alkaloids, including 0.199-0.86% *cryogenine*, 0.18-0.66% lyfoline, 0.055-0.66% lythrine, 0.09-0.55% nesodine, 0.0013% heimine, lythridine, 0.0023% sinine, 0.0042% sinicuichine, vesolidine, cryofoline, and traces of heimidine, demethylvertine [both tentatively detected by TLC], demethyllasubines I & II, anelisine, abresoline and demethylabresoline. Sitosterol [0.01%] and l-mannitol [1.4%] have also been isolated. Roots and seeds are alkaloid-free. Seedlings [5-10 days old] have yielded *cryogenine* and decodine. *Cryogenine* is often stated to be "the active component", however, a synergistic action should be expected as the activity of an extract differs from that of *cryogenine* alone (Appel et al. 1965; Blomster et al. 1964a; Dominguez et al. 1975; Douglas et al. 1964; Hörhammer et al. 1973; Kaplan & Malone 1966; Malone & Rother 1994; Rother 1990; Rother et al. 1965; Rother & Schwarting 1975; Tyler 1966).

D. verticillatus aerial parts have yielded 0.06-0.42% alkaloids, including [as % of total alkaloids] 0.5% *cryogenine*, 10.2% verticillatine, 0.5% vertaline, 6.4% decodine, 0.7% decaline, 0.5% decamine and 7% decinine (Ferris 1962).

Heimia salicifolia is a slender deciduous shrub to (1.5-)3m tall, usually much smaller, glabrous throughout. Leaves mostly opposite, sessile to short-petioled, linear-oblanceolate to linear-lanceolate, c.(1-)5 x 1cm, apex obtuse to acute, base attenuate. Flowers solitary and short pedunculate in the axils, inodorous; peduncle to 2mm long; calyx broadly campanulate, (4-)5-9mm long, with triangular acuminate lobes that become closely connivent over the capsule; petals 5-6(-7), orange-yellow, oval to obovate, (10-)12-17mm long, fugacious; stamens 10-18. Ovary 3-6-locular; style slender; stigma capitate. Capsule globose, 4-celled, c.4mm diam., loculicidally dehiscing. Fl. Mar.-Jun. in natural habitat.

Along resacas, streams, or in wet soil in brushlands; Rio Grande plains of s. Texas, south through Texas and Mexico to S. America; also in Jamaica, and naturalised near Brisbane, Australia (Correll & Johnston 1970; Hewson & Beesley 1990). Can be difficult to distinguish from other Heimia spp. (Malone & Rother 1994).

Cultivate by sowing the tiny seed thinly on top of a fine, firmly packed soil; water with mist or by perfusion from the bottom, keeping shaded and moist until seeds germinate. Gradually introduce to full light, and let soil dry between waterings; thin and transplant carefully [root systems are large] when about 3cm tall. May be grown in a permanent outdoor position in hot climates – elsewhere, they should be kept in large pots and brought inside for winter. Prefers well-drained soil and infrequent but thorough waterings. May also be propagated from cuttings or layers (Grubber 1973). Seedlings may take a long time to put on much growth after germination (pers. obs.), though they grow quickly after this (pers. comms.).

HELICHRYSUM

(Compositae/Asteraceae)

Helichrysum aureonitens *Sch. Bip.* **(H. helodes** *Hiern***)**
Helichrysum decorum *DC.*
Helichrysum epapposum *Bolus* **(H. flavum** *Burtt Davy***)**
Helichrysum foetidum *(L.) Moench* **(Gnaphalium foetidum** *L.***)** – imPepo, im pepho, muishondblaar, everlasting
Helichrysum gymnocomum *DC.*
Helichrysum herbaceum *(Andrews) Sweet* **(H. squamosum** *(auct. non. Jacq.) Thunb.***; Xeranthemum herbaceum** *Andrews***)**
Helichrysum italicum *(Roth.) G. Don.* – curry plant, cari, canugioro, canugiulo, hoja santa, imortelle, Italian everlasting
Helichrysum kraussii *Sch. Bip.* **(H. steetzii** *(Vatke) O. Hoffm.***)** – imPepo, im pepho
Helichrysum leiopodium *DC.* **(H. asperifolium** *Moeser***; H. nudifolium** *(L.) Less.***; H. quinquenerve** *(Thunb.) Less.***; Gnaphalium nudifolium** *L.***)**
Helichrysum odoratissimum *(L.) Sweet* **(Gnaphalium odoratissimum** *L.***)**
Helichrysum platypterum *DC.* **(Cassinia alba** *O. Hoffm.***; Gnaphalium amplum** *Kuntze***)**
Helichrysum stenopterum *DC.* **(Achyrocline stenoptera** *(DC.) Hilliard et Burtt***)** – imPepo, im pepho

Zulu shamans in South Africa inhale the fumes of H. foetidum, H. stenopterum and/or H. decorum to enter a trance-state; H. aureonitens may also be so used (DeSmet 1996, 1998; Schultes & Hofmann 1980). H. kraussii is reportedly similarly used as a magical incense in Natal. Shamans or diviners harvesting the plant take special care to leave the roots in the ground (Cunningham 1993). In addition, the Zulu burn leaves and stems of H. aureonitens, H. epapposum, H. gymnocomum, H. herbaceum, H. leiopodium, H. odoratissimum and/or H. stenopterum "to invoke the goodwill of the ancestors" (De Smet 1998). The flowers of H. foetidum produced euphoric opiate-like effects, when smoked by several subjects (E pers. comm.). H. stenopterum is used in the form of a deodorant lotion or body wash by Zulu women. H. foetidum has also been applied to 'festering sores' as a dressing to aid the healing process. H. leiopodium is used by the Suto as a steam-bath, to relieve a person who is having nightmares, or suffering fever. A decoction of H. platypterum root is drunk by Suto men as a sexual tonic, to "renew their virility". Ash prepared from a Helichrysum sp. is drunk mixed with beer by the Bikita of Zimbabwe, to 'cure' epilepsy (Watt & Breyer-Brandwijk 1932). In Italy, H. italicum is used to treat migraine, respiratory illnesses, rheumatism, allergies, and eye and skin disorders, amongst other medicinal uses (Opitz et al. 1971). In the Tuscany region, the aerial parts of the wild plant are burned on Christmas eve to prevent the 'evil eye' and bring good omens (Pieroni & Giusti 2002).

H. aureonitens aerial parts have yielded aureonitol, galangin, caryophyllene epoxide, triterpenes and hydrocarbons (De Smet 1998).

H. cooperi flowers yielded 2.23% helichrysin [6'-O-methyl-chalcononaringenin 4'-glucoside], a chalcone flavonoid glucoside, as well as (-)-2-O-methyl-chiroinositol and luteolin 7-glucoside (Wright 1976).

H. decorum aerial parts have yielded a dihydrochalcone derivative (De Smet 1998).

H. foetidum has yielded helichrysin from the involucral leaves.

H. italicum aerial parts have yielded gnaphaliin [see **Gnaphalium**]; flowers have yielded linalool, sitosterol, ursolic acid, 3 diketones and a caffeic acid-derived diterpene (Opitz et al. 1971).

H. leiopodium leaves and roots have yielded helichrysin (Watt & Breyer-Brandwijk 1962).

H. maracandicum flowering aerial parts have yielded the coumarins *scopoletin*, iso-*scopoletin*, umbelliferone and aesculetin (Baimukhametov & Kamissarenko 1990).

H. stenopterum aerial parts have yielded 0.09% γ-curcumene, 0.02% α-curcumene, 0.06% γ-curcumene-endoperoxide, 0.01% caryophyllene, 0.01% aromadendrene and 0.24% combined phloroglucinol derivatives (Jakupovic et al. 1986).

Plants from the genus Helichrysum have also yielded α-pyrone derivatives (Jakupovic et al. 1986).

Helichrysum stenopterum is an erect herb to 50cm tall, little or

not branched, thinly wooly throughout, sometimes almost hairless; stems with narrow wings descending from leaf margins. Leaves alternate, well-spaced, spreading, entire, narrow, mostly sessile, tapering to a fine point, margin slightly recurved, c.4cm x 6mm, usually densely white-hairy on both sides. Inflorescence rather loosely branched with dense, compact clusters of numerous flower heads; involucral bracts yellow, c.3mm long, pointed, slightly longer than florets; receptacle flat or convex, surface pitted, honeycombed or bearing scales or bristles; florets few or many, mostly bisexual; corolla cylindrical, usually hairless, 5-toothed, yellow; anthers tailed and appendaged. Ovary often ribbed or angled; style often swollen at base, branches blunt-tipped. Pappus of bristles, rough or feathery at tip. Fl. Apr.

Swamps; Usutu forests, Hawane Falls, Ukutula – S. Africa, up to 1300m (Compton 1976).

HELICONIUS [including Agraulis]

(Nymphalidae, subfamily Heliconiinae)

Heliconius charitonia *(L.) Kluk* **(H. charithonia** *(L.) Latreille***; Papilio charitonia** *L.***)** – zebra longwing
Heliconius cydno ssp. galanthus *Bates*
Heliconius erato ssp. petiveranus *Doubleday* **(H. demophon** *Ménétriés***; H. erato ssp. demophon** *Ménétriés***)** – small postman
Heliconius ethilla ssp. eucoma *Hübner*
Heliconius ismenius ssp. clarescens *Butler*
Heliconius melpomene ssp. rosina *Boisduval* – postman
Heliconius sara ssp. thamar *Hübner* **(Nereis thamar** *Hübner***; Papilio rhea** *Crama***)** – small blue Grecian
Heliconius wallacei ssp. flavescens *Weymer* – blue Grecian
Heliconius spp. – longwings, passionvine butterflies
Agraulis vanillae *(L.) Boisduval et Leconte* **(Dione vanillae** *(L.) Hübner***; Papilio vanillae** *L.***)** – gulf fritillary

These are a complex group of butterflies with a life-cycle similar to that of the glasswing butterfly [see **Acraea**]. As with **Acraea**, larvae of some Heliconius spp. feed on plants of the family Passifloraceae, including **Passiflora**, accumulating the cyanogenic and β-carboline compounds characteristic of many of these plants. The cyanogenic compounds, however, are generally considered of primary importance in this relationship, as the accumulation of these compounds renders the larvae and butterflies distasteful and toxic to predators (Spencer 1988). They are generally much longer-lived than most other butterflies, with an average lifespan of several months, as compared to 10 days for many species [though some butterflies do overwinter]. They have also evolved relatively large brains and excellent memory, with their brain learning centres being much larger than usual. The creatures are very variable in appearance, due to their ability to acquire new markings to suit changing environments (Murawski 1993).

Adult butterflies, which had been fed as larvae on β-carboline-containing plant material [plant species not noted by Cavin & Rodriguez], were analysed by HPLC/MS, and shown to contain small amounts of β-carboline alkaloids. As well as those listed below, the samples also contained 6-MeO-*harman* and *harmaline* as confirmed by TLC (Cavin & Rodriguez 1988) – it is not clear whether this applied to all samples analysed. Cavin & Bradley (1988) tested for the presence of *harman*, *norharman* and *harmine* only, but noted that other β-carboline alkaloids were probably present, also. Many Heliconius spp. also contain the pigment 3-OH-L-kynurenine in their wings (Tokuyama et al. 1967). This compound might have psychotropic effects [see kynurenine in *Neurochemistry*]. A Heliconius sp. was found to contain xanthommatin in the wings (Numata & Ibuka 1987).

H. charitonia larvae, fed on **Passiflora** biflora, accumulated mostly *harmine* and *norharman*, with only minor levels of *harman* (Cavin & Bradley 1988). H. charitonia ssp. tuckeri is known to feed on P. incarnata (McGuire 1999).

H. cydno ssp. galanthus contained mostly *norharman*, with smaller amounts of *harman* and *harmine* (Cavin & Rodriguez 1988). H. cydno is known to feed on **Passiflora** ambigua, P. auriculata, P. biflora, P. coriacea, P. costaricensis, P. guazumaefolia, P. lancearia, P. laurifolia, P. oerstedii, P. pittieri, P. quadrangularis and P. vitifolia (Spencer 1988).

H. erato ssp. petiveranus contained mostly *harmol*, *harmine* and *norharman*, with small amounts of *harman* and *harmaline* (Cavin & Rodriguez 1988). H. erato is known to feed on **Passiflora** alata, P. amethystina, P. auriculata, P. biflora, P. caerulea, P. capsularis, P. chelidonea, P. coriacea, P. cuneata, P. cuspidifolia, P. edulis, P. gracillima, P. hahnii, P. incarnata, P. jileki, P. laurifolia, P. miersii, P. misera, P. organensis, P. pohlii, P. pulchella, P. punctata, P. resticulata, P. rhamnifolia, P. rubra, P. sidaefolia, P. suberosa, P. talamacensis, P. tricuspis, P. trifasciata, P. truncata, P. tuberosa, P. vespertilio, P. violacea, P. warmingii, Dilkea parvifolia and Tetrastylis ovalis (Spencer 1988).

H. ethilla ssp. eucoma contained similar proportions of *norharman* and *harmine*, and traces of *harman* (Cavin & Rodriguez 1988). H. ethilla is known to feed on **Passiflora** alata, P. alba, P. amethystina, P. bahiensis, P. cyanea, P. edulis, P. eichleriana, P. garckei, P. jileki, P. kermesina, P. miersii, P. oerstedii, P. picturata, P. racemosa, P. recurva, P. rhamnifolia, P. setacea, P. sidaefolia, P. vellozii, P. violacea and Tetrastylis ovalis (Spencer 1988).

H. melpomene ssp. rosina contained mostly *norharman*, with only traces of *harman* and *harmine* (Cavin & Rodriguez 1988). H. melpomene is known to feed on **Passiflora** acuminata, P. alata, P. ambigua, P. bahiensis, P. capparidifolia, P. coccinea, P. cyanea, P. edulis, P. eichleriana, P. glandulosa, P. jileki, P. laurifolia, P. ligularis, P. maliformis, P. menispermifolia, P. misera, P. nitida, P. oerstedii, P. quadriglandulosa, P. serrato-digitata, P. spinosa, P. tricuspis, P. tuberosa, P. violacea, P. vitifolia and Tetrastylis ovalis (Spencer 1988).

H. ismenius ssp. clarescens larvae, fed on **Passiflora** biflora, accumulated mostly *harmine* and *norharman*, with moderate levels of *harman*; the faecal excretions contained mostly *norharman*, and *harmine* was present only in traces, or not at all. Eggs of grown butterflies fed on this species also contained 6-MeO-*harman*. With larvae fed on P. oerstedii, *norharman* was predominant. In butterflies developed from larvae that had been fed on **Passiflora** costaricensis or P. quadrangularis, the alkaloids were retained, but mostly in the form of *norharman* (Cavin & Bradley 1988).

H. sara ssp. thamar contained similar proportions of *norharman*, *harman* and *harmine* (Cavin & Rodriguez 1988). H. sara is known to feed on **Passiflora** auriculata, P. candida, P. cirrhiflora, P. costata, P. edulis, P. faroana, P. jileki, P. mansii, P. mucronata, P. pentagona, P. rhamnifolia, P. spinosa, P. suberosa, P. truncata and Tetrastylis ovalis (Spencer 1988).

H. wallacei ssp. flavescens contained small amounts of *harman*, with only traces of *norharman* and *harmine* (Cavin & Rodriguez 1988). H. wallacei is known to feed on **Passiflora** coccinea, P. glandulosa, P. quadriglandulosa and P. vitifolia (Spencer 1988).

Agraulis vanillae larvae, fed on **Passiflora** biflora, were shown to contain a high proportion of *harman*, with minor levels of *norharman* and *harmine* (Cavin & Bradley 1988). A. vanillae is also known to feed on P. incarnata both in the wild and in cultivation (McGuire 1999).

Heliconius butterflies lay their eggs [often individually, as some Heliconius larvae are cannibalistic] usually on **Passiflora** spp. [to guard against consumption by rampant larvae, some passionvines grow small yellow protrusions to mimic eggs, giving the impression they are already occupied – some also secrete a sugary substance to attract wasps and ants, which eat the larvae and eggs]. The eggs, often yellow, are smaller than a grain of rice, +- ovate with flattened ends like a barrel, and longitudinally ribbed. After hatching, the small caterpillar, often with long black spines, eats its egg and then sets to work on the **Passiflora** vine; over the next 2 weeks it sheds and grows 4 times; the next 2 weeks sees progression to pupa [chrysalis] stage, and finally to adult butterfly. The adults have rather elliptic wings, and a slow, unwavering flight pattern; they often roost together in groups at night. They feed on nectar and pollen, as well as rotting fruit, dung and urine. Their colours are often mimicked by other species, to take advantage of the reputation of Heliconius spp. to predators as being distasteful.

Heliconius spp. are distributed from the tip of Florida, south through the Caribbean, and Central & South America; usually found near disturbed sites and forest edges in tropical zones. Species and subspecies of Heliconius are known to interbreed in the wild, making for a taxonomist's nightmare (Murawski 1993; Watson & Whalley 1975).

HELICOSTYLIS and BROSIMUM

(Moraceae)

Helicostylis pedunculata *Benoist* – takini
Helicostylis tomentosa *(Poepp. et Endl.) Rusby* **(H. affinis** *Steud. ex Miq.***; H. duckei** *Hawkes***; H. obtusifolia** *Standl.***; H. podogyne** *Ducke***; H. poeppigiana** *(Mart.) Trécul***; Greeneina affinis** *(Steud. ex Miq.) Kuntze***; G. poeppigiana** *(Mart.) Kuntze***; Olmedia asperula** *Standl.***; O. poeppigiana** *Mart.***; O. polycephala** *Pittier***; O. tomentosa** *Poepp. et Endl.***; Trymatococcus guanabarinus** *Duarte***)** – takini[?], letterhout, manletterhout
Brosimum acutifolium *Huber* **ssp. acutifolium** *C.C. Berg* **(B. acutifolium** *Huber***; Brosimopsis acutifolia** *(Huber) Ducke***; Piratinera acutifolia** *(Huber) Pittier***)** - takini, takweni, tauni, mururé, tamamuri, iari

In Surinam, French Guiana and possibly n.e. Brazil 'takini' trees are considered sacred by the Carib, Galibi and Arawak; the latter group figure it in their mythology relating to the origin of shamanism. The bark is considered the most important part - it is slashed deeply to yield a sap or latex, first flowing translucent, then red and slightly frothy. It is this red sap which is used to prepare a shamanic intoxicant. The Arawak, in their shamanic initiation ceremonies, used the fumes of the latex in conjunction with tobacco [see **Nicotiana**]. Wayãpi and Palikur shamans drink the latex [c.500ml per dose, taken all at once] and smoke the bark to become allied with the spirits of the tree. Newly initiated Cariña shamans are given

two small gourds of takini latex to utilise in their practice. It is also used by some 'bushinenge' [descendants of runaway African slaves] in Surinam. The latex is considered mildly toxic, and hallucinogenic. For a long time takini was thought to be referable to H. pedunculata and/or H. tomentosa (Buckley et al. 1973; Moretti et al. 2006; Schultes & Hofmann 1980; Schultes & Raffauf 1990), but it is now known to be B. acutifolium ssp. acutifolium [however, the Palikur recognise 3 types of takini, so it may be that other plants are also used, if they are not simply varieties of the same species]. This, as well as B. utile and probably other members of the genus, are better known for their medicinal use in the Amazon to treat rheumatism and inflammation; side effects may include sweating and spinal pains (Moretti et al. 2006). B. utile latex has also been used to treat indigestion and asthma, and as a tonic and purgative. The Tikuna decoct bark of an unidentified B. sp. known as 'palo sangre' and 'toa-ta-a-ru-nai' with **Tabernaemontana** aff. divaricata to relieve pain from menstruation and childbirth (Schultes & Raffauf 1990).

H. scabra latex is said to be "very toxic", and in Brazil, H. coriacea latex is used as a fatal poison (Schultes & Raffauf 1990).

B. acutifolium ssp. acutifolium latex from French Guiana was found to contain *bufotenine* [23.4-25µg/ml in red latex, 0.7µg/ml in white latex] (Moretti et al. 2006); trunk bark has yielded small amounts of the flavonoids liquiritigenin, isoliquiritigenin, hydroxylonchocarpin, hydroxyisocordoin, luteolin, naringenin [see **Citrus**], 3,7-dihydroxy-4'-methoxyflavan, 4'-OH-7,8-(2",2"-dimethylpyran)flavan, 4'-OH-7,8-(3"-OH-2",2"-dimethylpyran)flavan, 7,4'-dihydroxyflavan, brosimines A & B, brosimacutins A-M and acutifolins A-F; the lignans mururins A-C; and syringaldehyde, coniferaldehyde, sitosterol & stigmasterol (Takashima & Ohsaki 2001; Takashima et al. 2005; Torres et al. 2000).

Crude aqueous ethanol extracts from the Helicostylis spp. produced CNS-depression, supposedly similar to that produced by **Cannabis**, in mice and rats. The LD50s of the extracts [given i.p.] were 2.5g/kg [H. tomentosa] and 3.1g/kg [H. pedunculata] (Buckley et al. 1973).

Brosimum acutifolium ssp. acutifolium is a dioecious tree to 35m tall, with latex; leafy twigs 2-5mm thick, white puberulous. Leaves (elliptic-)oblong-lanceolate, often markedly convex, 5-18cm long, 2.5-7cm wide, chartaceous, apex acuminate to mucronate, base acute to obtuse, margin entire, upper surface scabrous to scabridulous, underside usually slightly scabridulous, rather densely hairy, hairs minute to rather long and straight or curved, costa often with uncinate hairs, veins nearly plane above, prominent beneath, 8-15 pairs of secondary veins, without parallel tertiary veins; petioles 3-6mm long, often with uncinate hairs; stipules free, not fully amplexicaul, 2-8mm long, white appressed-pubescent. Inflorescence geminate or solitary in leaf axils. Staminate inflorescences globose, 4-8mm diam.; peduncle 5-8mm long, white puberulous; receptacle white puberulous; flowers many; perianth lacking; stamens 1-3, filaments 0.2-0.5mm long; anthers 0.15-0.2mm long and wide, connective rather broad; bracts many, white puberulous. Pistillate inflorescences (sub)globose, 8-12mm diam.; peduncle c.1cm long, white puberulous; receptacle white puberulous; flowers 1-5, embedded in receptacle; bracts many, white puberulous; ovary adnate to embedded perianth; stigmas vittiform to filiform. Fruit adnate to enlarged receptacle; fruiting receptacle subglobose to subdiscoid, to c.2.5cm diam., yellow to orange at maturity; seeds c.1cm long, without endosperm.

In forests and savanna; Surinam to Pará, Brazil.

B. acutifolium ssp. interjectum is found in w. Pará and e. Amazonas; ssp. obovatum is found in Guyana, Peru and Brazil [Amazon Basin, w. from Manaus] (Lanjouw & Stoffers ed. 1975).

Helicostylis pedunculata is a dioecious or monoecious tree to 25m tall, with pale yellow latex; leafy twigs 2-7mm thick, pale yellow, tomentose to sublanate. Leaves distichous, pinnatinervate, elliptic to lanceolate, 10-28 x 5-12cm, sometimes widest above middle, slightly inequilateral, coriaceous to chartaceous, acuminate to mucronate, obtuse at base, above tomentose on the costa, otherwise puberulous, glabrescent to scabridulous, beneath tomentose; margin often denticulate to dentate, mostly towards apex; veins almost plane above, prominent beneath, 10-17 pairs of secondary veins, most tertiary veins parallel; petioles 6-18mm long; stipules 5-9mm long, subsericeous to tomentose. Inflorescences on short axillary shoots, unisexual, involucrate. Staminate flowers up to 6 together, 8-9mm diam., with discoid receptacle; peduncles 5-15mm long, tomentellous; involucre with 5-6 series of ovate, acute, tomentellous bracts; perianth 1-1.3mm high, 4-lobed; filaments c.1-1.5mm long; anthers 0.6-0.7 x c.2mm. Pistillate flowers solitary or usually accompanied by 1-2 staminate flowers, discoid, 8-11mm diam.; peduncle 6-25mm long, tomentellous, often bracteate; flowers c.15-30; perianth 1.5-2mm high, 4(-6)-parted, tomentellous, inner tepals cohering by weak entangled thin hairs on inner surface. Ovary hairy at apex; style subterminal, 0.2-2.1mm long, hairy; stigmas vittiform, 2-3mm long, not or somewhat twisted. Infrutescences convexly discoid to hemispherical, 2-3cm diam.; fruiting perianth pale yellow, tomentellous; fruit ellipsoid, 7-8mm long; seed c.6mm long.

From Surinam to Para, Brazil; in Surinam in forests of the interior and the savannah, confined to the east part of the country (Pulle ed. 1966).

HERACLEUM

(Umbelliferae/Apiaceae)

Heracleum dulce *Fisch* – sladkaya trava, uchkui, inchkou, sweet grass

Heracleum lanatum *Michx.* **(H. elegans** *(Crantz) Jacq.***; H. intermedium** *Gaudin***; H. maximum** *Bartr.***; H. montanum** *Schleicher***; H. sphondylium ssp. elegans** *(Crantz) Schübl. et Mart.***; H. sphondylium ssp. montanum** *(Schleicher ex Gaudin) Briq.***; Pastinaca lanata** *(Michx.) Koso-Pol.***; Sphondylium lanatum** *(Michx.) Greene***)**

Heracleum lehmannianum *Bunge*

Heracleum pyrenaicum *Lam.* **(H. alpinum** *L.* **ssp. pyrenaicum** *(Lam.) Rouy et Cam.***; H. sphondylium** *L.* **ssp. pyrenaicum** *(Lam.) Bonnier et Layens.***)**

Heracleum sphondylium *Cham. et Schlecht non L.* – hogweed, hexenkohl

Heracleum spp. – cow parsnip

The Kamchadals of Siberia have been known to eat the fresh stems and petioles of H. dulce, to provide an 'alcohol-like' intoxication. The herb was also sometimes made into a wine, and in the past, vodka was distilled from the stem. Many other Heracleum spp. are eaten fresh or marinated when young (Brekhman & Sam 1967; Shishkin ed. 1986b). In Ladakh, India, excessive consumption of H. thomsoni leaves and fruits by goats has been known to result in blindness (Bhattacharyya 1991).

In China, H. lanatum tubers are considered "an excitant of the nerve centres, an anodyne to treat headache, influenza, dizziness, toothache, pain in the nerves of the face" (Perry & Metzger 1980). The tuber of H. lanatum was used by many Native American groups to treat colds, flu, cough, headache, sore throat and cramps; it has also been applied as a poultice on swellings, bruises, boils and rheumatic pains. The Winnebago also used it in their sweat-lodges. The roots, young leaves and shoots of H. sphondylium are sometimes brewed into a beer [see *Methods of Ingestion*]. In herbal medicine, a plant tincture is given for general debility. The leaves are used in homoeopathy as a digestive and sedative, and its fruits are said to be aphrodisiac (Bremness 1994; Kindscher & Hurlburt 1998). In some areas of Europe the plant is made into a vaginal douche cream [also containing Chelidonium majus (see *Endnotes*) and Satureja montana] "to increase sexual desire in frigid women" (Islam et al. 1991). In Germany, H. sphondylium has been known as 'hexenkohl', hinting at a past relationship with witches (De Vries 1991).

Air-dried leaves of some unspecified Heracleum spp. contained c.1.25% essential oil; fruits yielded 0.23-1.75% essential oil (Shishkin ed. 1986b). Antoside, rutin, epi-rutin, kaempferol [MAOI (Sloley et al. 2000)], quercetin, *scopoletin*, (R)-heraclenol and bergapten have also been found in the genus (Basargin 1976; Buckingham et al. ed. 1994; Svendsen et al. 1959).

H. candicum contains 3-phenylpropanal and 3-phenyl-1-propanol (Buckingham et al. ed. 1994).

H. lanatum has yielded angelicotoxin, angelicin, angelic acid, lanatin, sphondin, phellandrene and hydrocarotin; as well as psoralen from the roots [under investigation for treatment of AIDS, leukaemia and psoriasis] (Buckingham et al. ed. 1994; Perry & Metzger 1980).

H. lehmannianum contains an essential oil with c.80% *anethole* (Vuishenskii 1936).

H. pyrenaicum has yielded *apiole* (Buckingham et al. ed. 1994).

H. sphondylium root has yielded the coumarins pimpinellin, isopimpinellin, isobergapten, phondin, sphondylin and umbelliferone (Svendsen et al. 1959).

H. wallichii roots yielded the alkaloids cycleanine and isochondrodendrine, as well as columbianetin, marmesin, vaginidiol and stigmasterol (Gupta et al. 1976).

Heracleum dulce is a biennial or perennial herb 1.5-2m tall; stem thick, deeply furrowed with sparse hairs mainly at nodes. Leaves ternate, rarely pinnate-compound (2 pairs); petiolules of first pair of lateral segments 3-4cm long, other segments sessile, all broadly ovate, ternately or pinnately cut into ovate, pointed, largely and irregularly toothed lobes, terminal segment surrounded, deeply lobed, lobes broadly ovate, pointed, sometimes slightly overlapping; leaves glabrous above, with fine hairs mainly along nerves beneath; upper leaves usually ternate, with expanded sheath. Umbels many-rayed, all rays with finely spreading hairs; involucre lacking; stem under umbel densely covered with long hairs; leaflets of involucels many, linear-lanceolate, as long as or longer than flowering umbellets; flowers white; calyx 5-toothed, teeth small, triangular; petals obovate, +- deeply notched or 2-lobed, peripheral petals enlarged. Ovary spreading-hairy; stylopodium broadly conical; styles twice as long as stylopodium. Fruit 6-8mm long, 7-8mm wide, glabrous or sparsely hairy; dorsal canals usually ½ length of fruit, rarely slightly longer, commisural canals broader, ½ length of fruit.

Subalpine meadows, forest edges, very frequent in riparian valleys; Kamchatka, Siberia (Shishkin ed. 1986b).

HETEROPTERYS [Heteropteris]

(Malpighiaceae)

Heteropterys aphrodisiaca *O. Mach.* – nó de cocherro, nó de porco, guaco, tintureiro, resedá amarelo, jasmin-amarelo
Heteropterys chrysophylla *(Lam.) H.B.K.* **(Banisteria chrysophylla** *Lam.***)** – Brazilian gold leaf

In Mato Grosso, Brazil, some Heteropterys spp., known as 'nó de cocherro', are used as aphrodisiacs (Mors & Rizzini 1966). The vernacular name [meaning 'dog-knot'] refers to the appearance of the root, which looks like a dog's penis. The Amazonian H. aphrodisiaca is one of these plants, and its roots are saved for special occasions, when the women serve an infusion or decoction of it to their husbands. It is also used in folk medicine to "produce physical and mental well-being". Recent research has confirmed that the leaf and root improve sexual function, as well as enhancing memory and learning, and acting as an antioxidant and general tonic or rejuvenator (Baill pers. comm.; Biosintética 2000; Carvalho 2000). H. macrostachya and H. riparia are considered toxic, and the latter is known as 'dog-killer' in the Amazon. Seeds of H. macrostachya and H. suberosa are also used there to make a tea to treat diarrhoea (Schultes 1950; Schultes & Raffauf 1990).

A specimen of H. chrysophylla growing ornamentally in Brisbane [Queensland, Australia; harv. Mar.] was found to contain alkaloids in the leaf, which were not identified (Webb 1949), though presumed by Ott (1993) to be β-carboline alkaloids. Due to the close relationship of the plant to **Banisteriopsis**, it would not be surprising if this is so.

Plants of the genus Heteropterys have been reported to have yielded saponins, phenolic acids and tannins (Schultes 1950).

Heteropterys chrysophylla is a liana. Leaves opposite, ovate to oblong-ovate or lanceolate, 5-10cm long, acute or short acuminate, glabrous, shining, prominently reticulate above, lustrous-pubescent and veiny beneath, thick-membranous or leathery, rounded or subcordate at base, short-petioled. Flowers in panicled, often leafy-bracted cymes; calyx with 8 glands, or glandless; sepals 5, ovate, 3-4mm long, the glands fully ½ the length of the sepal body, sepals often recurved at tip, persistent; corolla yellow, orange or purple; petals 5, entire, undulate or erose-denticulate, larger petals somewhat longer than sepals; stamens 10; filaments subulate; anthers very thick. Ovary 3-lobed; styles 3, distinct, unequal. Samaras 2-3 together or solitary, wing conspicuous, thickened along dorsal side, 4.5-5.5cm long, the wing red-sericeous, dilated at apex, auricled at base on ventral side, body crownless.

Puerto Rico, Brazil (Fridericus & De Martius ed. 1965-1975; Small 1910 [for genus detail]).

Banisteria chrysophylla *Bello* represents a different plant, now known as Heteropterys wydlerana *Adr. Jussieu fide Niedenzu* (Gates 1982).

HIERACIUM

(Compositae/Asteraceae)

Hieracium pilosella *L.* **(H. canum** *Vuk.***; H. leucophyllum** *Schur***; Pilosella officinarum** *(Vaill.) F. Schultz et Schultz-Bip.***; P. communis** *A.-T. Mon.***)** – hawkweed, mouse-ear hawkweed, devil's weed, haret hogeurt

This common European herb has occasionally been used in the Danish 'underground' as an agent to expand consciousness. A dose of 1-2 cigarettes smoked is said to produce the desired effects (Ott 1993), which are very mild (Montgomery pers. comm.). An ethanol extract of the commercially-available dried herb was found to be more effective, but still mild (theobromus pers. comm.). One bioassay [by 2 people] of the smoked herb resulted in a perceived widening of peripheral vision (Wise pers. comm.).

Shepherds in rural southern Europe sometimes use the plant to apply to small wounds, to aid in healing. The herb is also used to treat brucellosis ['Malta fever'], a chronic bacterial disease of farm animals that is easily transmitted to humans. The fresh plant is antibiotic and diuretic; the dried plant is astringent (Chiej 1984; Martin et al. ed. 1996). The related 'rabbit's ear hawkweed', H. venosum, is used by the Cherokee [in combination with **Mitchella** repens] in the form of a root tea, to treat bowel complaints (Hamel & Chiltoskey 1975). In southern Africa, H. polydon is an ingredient in a compound medicine used by the Southern Sotho to treat sterility (Watt & Breyer-Brandwijk 1962).

H. pilosella has yielded pilosellin, hieracin, oxy-coumarin, umbelliferone, luteolin, tannin and a bitter substance (Bate-Smith et al. 1968; Buckingham et al. ed. 1994; Chiej 1984).

Hieracium pilosella is an abundantly stoloniferous perennial herb with milky juice, generally with a slender elongate rhizome, 3-25(-40)cm tall, throwing out stolons which root at the nodes; stem leafless or with a single much reduced leaf, viscid-puberulent or subtomentose, sparsely or moderately spreading-hispid with gland-tipped, usually blackish hairs, often also long-setose. Leaves basally clustered in a rosette, recumbent, spatulate or oblanceolate or a little broader, entire, 2-13 x 0.6-2cm, tawny-tomentose with stellate hairs beneath, and with some long glandless setae as well, greenish-grey and glabrous above except for the very long setae, those of the stolons similar but smaller, underside hoary; stolons bearing alternate leaves, becoming smaller towards apex. Flower heads solitary (rarely 2-3), then long-pedunculate, ligulate, yellow, often tinged with dark red beneath; involucre cylindric to hemispheric, 7-11mm high, stellate, shortly hispid with black, sometimes gland-tipped hairs, occasionally long-setose also; involucre bracts imbricate, lanceolate, closely packed. Achenes c.1.5-2mm long, terete or prismatic, mostly narrowed towards base, apex truncate, +- strongly ribbed and sulcate; pappus of numerous grey, slightly sordid capillary bristles. Fl. May-Sep.

On high ground and in dry, upland pastures and fields; native to Europe and Britain, widely established in N. America [Newfoundland to N. Carolina to Minnesota, also in Oregon]. Many subspecies, hybrids, and varieties exist (Chiej 1984; Gleason 1952).

HOMALOMENA

(Araceae)

Homalomena belgraveana *Sprague*
Homalomena cordata *Schott* **(H. alba** *Hassk.***; H. aromatica** *(Roxb.) Schott***; H. cordata** *Zoll.***)** – koktaar, kuschu-gundubi
Homalomena cf. ereriba – kuumang, ereriba, 'dream man'
Homalomena lauterbachii *Engler*
Homalomena versteegii *Engler*

In parts of the Fore region of Papua New Guinea's eastern highlands, leaves of a Homalomena sp. ['ereriba'] are decocted to be drunk with the leaf and bark preparation made from **Galbulimima** belgraveana ['agara']. This results in a kind of agitated delirium, ending in sleep. Alternately, for the same effects, several leaves [and sometimes also a portion of rhizome] may be eaten along with 7-8 "penny-sized" pieces of agara bark [probably referring to the old British or Australian pennies, roughly 31mm diam.]. It is also said that either plant can be eaten alone for the same effect. The plant is often used by men in order to achieve the eventual sleep-state, in which they divine from their dreams. The species used, sometimes referred to as H. cf. ereriba, is thought to possibly be equivalent to H. belgraveana (Emboden 1979a; Hamilton 1960; Ott 1993; Schultes & Hofmann 1980). Schultes & Hofmann (1992) depicted H. lauterbachii to represent this plant, though it was not clear whether or not they were suggesting it as a possible species identity.

The Bimin Kuskusmin of PNG consume Homalomena spp. [along with many other plants – see also **Boletus** and *Endnotes*] in the 10th and 11th stages of their initiation. In the 10th stage, H. cordata [which causes "visually vivid dream-like states"] is eaten with a **Boletus** sp., **Pandanus** julianettii, galangal [see **Kaempferia**, **Alpinia**], agara, **Polygala** sp. flower, Lithocarpus sp. nuts [see *Endnotes*], Colocasia esculenta ['taro leaf'] and Medinilla sp. sap. In the 11th stage, H. cf. ereriba [which "enhances the blurred vision of trance"] is eaten with a **Heimiella** sp. and a **Russula** sp. [see **Boletus**], P. julianettii, **Castanopsis** acuminatissima, galangal, agara, **Musa** sp., taro leaf, Baccaurea sp. fruit, and skin of the frog Litoria angiana [see *Endnotes*] (Poole 1987). In PNG, H. cordata is also used in some areas for rain magic, and similarly H. versteegii is used for love magic (Ott 1993).

In India, the rhizomes of H. cordata have been used as an 'aromatic and stimulant' herb (Nadkarni 1976). In Vietnamese folk medicine, the roots are used in the form of an infusion or alcoholic tincture, as a general tonic, antiinflammatory, and to strengthen the skeleton and 'cure stomach diseases' (Todorova et al. 1988). Malays use the aromatic H. rubescens in the preparation of a fish poison called 'ipoh' (Chopra et al. 1965; Nadkarni 1976). In TCM, H. occulta rhizome ['qian nian jian' ('thousand years of health')] is used in doses of 4.5-9g to strengthen sinew and bones, and to relieve pain and swelling from traumatic injuries, particularly in the elderly (Bensky & Gamble 1993).

H. cordata rhizomes have yielded [w/w] 0.8-1.1% essential oil, containing 71.2-80% linalool, and smaller amounts of many other compounds; rhizomes have also yielded the sesquiterpenes homalomenol A [0.03%], homalomenol B [0.006%], homalomenol C [0.005%], homalomenol D [0.011%], 1β,4β,7α-trihydroxyeudesmane [0.028%], (-)-α-cadinol [0.007%], (-)-T-muurolol [0.006%], oplopanone [0.01%], oplodiol [0.03%] and bullatantriol [0.023%] (Sung et al. 1992a, 1992b; Todorova et al. 1988).

H. rubescens rhizome contains an essential oil rich in linalool (Todorova et al. 1988).

Homalomena cordata is an erect herb, stem ascending, robust, strongly fibrous, 2-4.5cm diam., to 22cm or more tall. Leaves crowded near apex of stem, herbaceous, broadly- to elongate-cordate, with usually inwardly directed basal lobes; basal lobes c.2.5-3(-5) times shorter than anterior lobe, +- broadly triangular, apex rounded, 5-8cm long, 7-13cm wide, short-acuminate, with 7-8(-10) thin to rather broad primary nerves

and very numerous, densely placed, parallel, much thinner secondary and tertiary nerves; all nerves arcuating into leaf-margin, green or sordid-purple, 19-40 x 16-32cm; petiole slender to rather stout, in lower half widened into a robust sheath (or not so), suffused with green or red, 20-76cm long, sheath conspicuous, flabellate, pinnately nerved. Inflorescence an elongated spadix at or near apex, usually several together, lower portion female mixed with staminodes, upper portion male; peduncle thin, gradually widened towards apex, suffused with green or red, 6-22cm; flowers many, unisexual, naked; spathe when still inrolled oblong, straight or slightly narrowed, not constricted, mucronate, herbaceous, 3.25-8.5cm long, c.1.25-1.75cm diam., when expanded 2.25-2.75cm broad; stalk of spadix thin, 3-6mm; female portion of spadix cylindric, whether or not widened towards apex, 1.25-2cm long, 4-8mm diam.; male portion cylindric, whether or not tapering towards ends, 1.5-3cm x 4-10mm; stamens free, 2-4(-6) in fertile flowers, 0.5-0.66mm high; staminodes few, 1.5-1.75mm, at base of female flower; connective very narrow, linear, not concealing anther-cells; thecae oval, much longer than the broad filament; anthers ellipsoid or clavate, slightly shorter than filaments, dehiscing by a split; ovary oblong, sometimes narrowing into the minute style, 3-celled; ovules numerous, on a central placenta; pistil c.1.75mm high; stigma c.1mm across, discoid or lobed. Fruit a berry, oblong to ovoid, yellow, 1.5-4mm; seeds 1-5, on a long funicle, longitudinally striate.

In mixed- and teak-forest, swampy places, watersides; south-east Asia (Backer & Bakhuizen van den Brink 1968).

HORSFIELDIA

(Myristicaceae)

Horsfieldia superba *Warb.* **(Myristica superba** *Hook. fil.***)** – pendarah

Trees from this genus are sometimes used medicinally in s.e. Asia. For example, in India, H. mystax roots are bruised and applied as a poultice "in reducing inflammatory tumours and as an antidote to snake-bites." The powdered root is taken as an anthelmintic and febrifuge, and root bark is used as an antidote to poisons (Nadkarni 1976).

H. superba contains indole alkaloids – leaves yielded 0.0007% *5-methoxy-DMT*, 0.008% 6-MeO-2-methyl-THβC [2-methyl-*pinoline*] and 0.037% horsfiline [5-MeO-2'-methylspiro[3H-indole-5,5'-pyrrolidin]-2(1H)-one,1] (Jossang et al. 1991).

Horsfieldia superba is a large tree 30m or more tall, young parts red-tomentose; branches stout; branches, leaves beneath and panicles scurfily rusty-tomentose. Leaves stiffly coriaceous, bright red-brown, 30-46 x 10-20.3cm, densely tomentose when young, glabrous when adult, elliptic-lanceolate or oblanceolate, loosely stellate-tomentose beneath; midrib very stout; nerves 15-30 pairs sunk above, strongly raised beneath, firm, nearly straight; petiole thick, 6-19mm long. Flowers usually very small, yellow, globose, fragrant, rarely sessile. Male flowers in lax panicles or sub-umbellate clusters, c.15cm long and wide, in axils of fallen leaves, tomentose; perianth coriaceous, glabrous, obovoid-elliptic, obtuse, yellow, 3-4-toothed, 42-51mm long; pedicel as long as perianth, very stout; staminal column subsessile, solid, ovoid, obtuse; anthers 10-20, closely confluent to their tips in a subsessile column, not apiculate. Female flowers on stout woody racemes, tomentose; perianth glabrous, tubular, 2-3-toothed; stigmas very small, sessile. Fruit ovoid-globose, rough, yellow, very fleshy, 7.6cm long, nearly 5.1cm across, pericarp thick; seed testa thin, aril scarcely laciniate.

In forests; Singapore, Malacca, Selangor, Kuala Lumpur, Perak, Penang (Hooker 1954-1961; Ridley 1923).

HUGONIA

(Linaceae)

Hugonia oreogena *Schlechter*

This New Caledonian shrub has been shown to contain trace amounts of an important indole alkaloid. I am not aware of any traditional or modern uses for this plant.

H. oreogena root bark yielded 0.42% alkaloids, mostly of the pyrrolizidine type – absouline, isoabsouline, absouline N-oxide and isoabsouline N-oxide, as well as 0.00036% *5-methoxy-DMT*. Trunk bark yielded 0.41% alkaloids of similar constituency, although *5-methoxy-DMT* was not noted. All of these, except for *5-methoxy-DMT*, were found in H. penicillanthemum trunk bark, which yielded 0.54% alkaloids (Ikhiri et al. 1987b).

Hugonia oreogena is an unarmed shrub, sometimes climbing. Leaves alternate, stipulate, petiolate, obtuse, 2.3-2.6cm wide. Inflorescence paniculate; flowers hermaphroditic; sepals 5; petals 5, twisted; no disc; stamens 10, some from base of tube, tube and stamens glabrous, stamens shorter than styles; anthers dehiscing by 2 longitudinal slits. Ovary free, 5-locular; styles 5; ovules anatropous, pendant, from the interior angle of the locule, 2 in each locule, raphe internal. Fruit a drupe with several locules (Guillaumin 1948).

HUMULUS

(Cannabaceae)

Humulus japonicus *Sieb. et Zucc.* **(H. scandens** *(Lour.) Merr.***; Antidesmia scandens** *Lour.***)** – lu cao, Japanese hop

Humulus lupulus *L.* – hops, hop vine, hops vine, common hop, European hop, beer flower, hopfen, lupolo, hymel, pi jiu hua

In 1AD, Pliny named hops as the 'willow wolf', after its habit of twining around willow trees [Salix spp.], and from this Latin name 'lupulus' was derived. The 'hop vine' [H. lupulus] has been a popular garden plant and vegetable – in spring, young shoots were sold in markets, and eaten like asparagus spears. By the 8th century, brewers throughout much of Europe had begun using hops [as the freshly dried flowers] in beer-making, for their clearing, flavouring and preservative actions. The British resisted the use of hops until the 17th century, believing it to be a "wicked weed that would spoil the taste of the drink and endanger the people". For centuries, they had used instead plants such as 'ivy' [Hedera helix – may actually refer to other plants that are ivy-like in appearance] and 'costmary' [**Tanacetum** balsamita] to brew their ale. Still, hops were also believed to 'purge excess anger', and German-style hops-beer ['bier'] was seen as a more "physical drink to keep the body in health", preferable to English ale. Eventually legislation effectively banned the addition of herbs other than hops to beer; largely, it seems, because hops are not as intoxicating as some of the preferred additives [see also *Methods of Ingestion*] (Bremness 1988; Buhner 1998; Mabey et al. ed. 1990; Ody 1993).

Medicinally, hops have been used for far longer than in brewing. They have been used as a pillow-stuffing or infused tea for their sedative, anxiolytic and soporific effect; the tea is very bitter. Excessive use can cause dizziness, stupor and mild jaundice in some people. Hops flowers relax the smooth muscle of the digestive tract, easing gastrointestinal pain or irritation; they are also antispasmodic, diuretic and oestrogenic [causing anaphrodisia in men; galactagogue in women, may interfere with menstruation]. Skin contact with flower pollen may cause dermatitis (Hobbs 1993; Mabey et al. ed. 1990; Siegel 1976). In TCM, the dried flower strobiles are used [as 'pi jiu hua'] to treat tuberculosis, and are also recognised as being an anticonvulsant, as well as causing a "sexual-stimulating effect on females". H. japonicus aerial parts are also used to treat tuberculosis, cystitis, dysentery and other infections (Huang 1993).

Hops flower strobiles may be smoked for mild psychoactive effects, though the smoke is harsh, and can result in headache. The strobiles can also be made into a strong bitter tea for similar effects (Gottlieb 1992; Haesler pers. comm.; Siegel 1976).

In the 1940's, it was claimed by two researchers that experimental grafts of hops to **Cannabis** roots resulted in hops vines bearing "as much drug as leaves from intact hemp plants". It was theorised that cannabinoids were produced in the **Cannabis** rootstock, and transported into the grafted hops vine (Clarke 1981). Later experiments showed that this had no basis in fact. Although the two species cross-grafted very well, there was no translocation of cannabinoids to the hops vine (Crombie & Crombie 1975).

H. lupulus flower strobiles may yield 0.3-1% essential oil, which varies in composition across different strains of the plant; 0.2-0.6% prenylflavonoids; 3-18% bitter resinous constituents, which are collectively referred to as 'lupuline'; and c.3.5% tannins. Common constituents of the essential oil include 2-methyl-3-butene-2-ol [sedative hypnotic], 8-prenylnaringenin [a potent phytoestrogen; see also naringenin in **Citrus**], humulene, humulene epoxide, luparone, luparol, luparenol, lumulone, lupulone [has caused nausea, vomiting, loose stools and dizziness in some people], xanthohumol, xanthohumol B, valeric acid, isovaleric acid [see **Valeriana**], myrcene, farnesene, selinine, linalool, limonene, geraniol, *citral*, caryophyllene and α- & β-*pinene*. The compound 2-methyl-3-butene-2-ol is present only in traces in fresh hops, but after 2 years storage at room temperature the level has been shown to increase to c.0.15% (Chapman 1928; Hänsel et al. 1982; Harborne & Baxter ed. 1993; Hobbs 1993; Huang 1993; Mabey et al. ed. 1990; Ramic et al. 1986; Tabata et al. 1997; Tekel et al. 1999). The tendrils have been shown to contain neochlorogenic and *chlorogenic acid*s, rhamnoglucoside, kaempferol 3-monoglucoside, isoquercitrin, rutin, and ferulic acid- and p-coumaric acid-derivatives; tendrils twined around a support also contained an aesculetin-derivative [less so in aged tendrils; see **Aesculus**] and a gentisic acid-derivative (Tronchet & Bas 1964).

H. japonicus aerial parts have been reported to contain humulone, lupulone, asparagine, *choline* and luteolin (Huang 1993).

Humulus lupulus is a perennial, twining vine to 10m long; rootstock stout, branched; stems tall, scabrid or prickly with reversed bristles. Leaves opposite, petioled, cordate, toothed, palmatinerved; principal leaves as wide as long, 7.5-10cm diam., heart-shaped at base, 3-5 lobed to below middle, lateral lobes obliquely ovate-oblong, terminal lobes ovate-lanceolate, constricted at base; upper leaves commonly broadly-ovate, un-

lobed; stipules lateral, persistent. Flowers dioecious. Male flower panicles 5-15cm long, 7.5-12.5cm across; flowers c.6mm diam.; sepals 5, imbricate; stamens 5, adnate to sepals, erect in bud; no pistillode. Female flowers in pairs in axils of broad bracts of catkin-like ovoid spikes (strobiles) c.1(-3-6)cm long, 13mm diam., cylindric, straw-yellow, bracteate and 2-bracteolate; bracts entire, mostly blunt, scarious, very glandular at base; sepal a membranous scale; ovary sessile, compressed; ovule pendulous, campylotropous; styles 2, subulate; stigmas conspicuous, slender. Fruiting flowers c.3.8cm diam., scales orbicular; fruit an ovoid spike of imbricate bracts; achenes enclosed in sepal, 2 in each axil; albumen scanty or none; embryo a flat helix. Yellow glands secreting 'lupuline' occur on most of plant, but mostly on strobiles (Gleason 1952; Kirtikar & Basu 1980).

Most commercially-grown hops are seedless hybrids. Seeds can be very difficult to obtain, and require their natural dormancy to be broken prior to germination. Plants are often cultivated from rootstock division. Cultivate in well-drained, humus-rich soil, in full sun with protection from wind. Requires climbing supports. Usually grown from cuttings or suckers; seed-grown plants will have a higher incidence of undesirable males. Strobiles should be harvested when ripe in summer to mid-autumn, and dried quickly – they rapidly lose potency with exposure to air once cut (Grubber 1973; Ody 1993; Whitten 1999).

HYGROCYBE including HYGROPHORUS

(Agaricaceae/Hygrophoraceae)

Hygrocybe conica *(Scop. ex Fr.) Kummer* **(Hygrophorus conicus** *(Scop. ex Fr.) Fr.***)** – conical wax cap, witch's cap, witch's hat, conical slimy cap

Hygrocybe psittanica *(Schaeff. ex Fr.) Raith.* **(H. psittanica** *(Schaeff. ex Fr.) Wünsche***; Hygrophorus psittanicus** *(Schaeff. ex Fr.) Fr.***)** – parrot wax cap, parrot toadstool

Hygrophorus erubescens *(Pers. ex Fr.) Fr.* **(Limacium erubescens** *(Pers. ex Fr.) Wünsch***)**

Hygrophorus hypothejus *(Fr.) Fr.* **(Limacium hypothejus** *(Fr.) Kumm.***)** – pine-wood waxy cap, late fall waxy cap, olive-brown waxy cap, herald of winter

Hygrophorus marginatus *Peck.* – orange-gilled waxy cap

H. conica is known to cause 'intoxications' and to be 'poisonous'. Although also considered by many to be edible, it is apparently not recommended (Bresinsky & Besl 1989; Connor 1977; Ford 1910/1911b; Phillips 1981). There are reports of death attributed to consumption of this species, which is considered a doubtful identification (Ford 1910/1911b; Heim 1963b). Heim listed it as a toxic mushroom, along with **Amanita** phalloides and Pholiota [Galerina] autumnalis, under the category "mycétisme choléríforme" (Heim 1963b). H. psittanica is regarded in Europe as being "edible but not good due to its sliminess" (Phillips 1981).

I have heard of several reports of people ingesting H. conica in the US. One individual consumed "too much" of the fungus [amount unspecified], and experienced a "narcotic/drunk/stupor-like" effect which he experienced dysphorically, because of the high dose (pers. comm.). Some have described "an odd sensation of lightheadedness and numbness" (Toro 2004, quoting Arora). Others have described effects lasting 4-5hrs, comparable qualitatively to a mild dose of *psilocybin*, yet "repeatedly fading on and off". One individual who ingested 1g [dry] of Japanese specimens experienced these effects, but also "awoke in the middle of the night with severe diarrhoea that lasted 45 minutes". H. conica specimens from California and Montana have also been rumoured to be similarly psychoactive (Hoodoo pers. comm.). Hygrophorus erubescens and H. marginatus have been claimed to exert CNS effects (Norland 1976), though no further data was provided to support the assertion. H. marginatus is considered edible, though an injected extract [route not given] was toxic to a guinea pig [it was also non-toxic to a larger guinea pig, and to other animals] (Ford 1910/1911b).

See also the closely related Hygrophoropsis spp. in the *Endnotes*.

The pigments of Hygrocybe spp. are called hygro-aurins, and technically are betalain-like compounds of muscaflavin with various amino acids; the pigments of **Amanita** muscaria have a similar structure. The blackening reaction in H. conica and H. ovina results from the oxidation of L-*DOPA* which is found in these fungi (Bresinsky & Besl 1989). It is worth investigating whether a psychotropic *adrenochrome* or dopachrome analogue is formed as an intermediate in this process [eg. see **Solanum**].

Hygrocybe nigrescens has been shown to contain small amounts of muscarine [see **Amanita**, *Neurochemistry*], of which 65% was present as the inactive epi-muscarine (Stadelmann et al. 1976).

H. psittanica has a greenish-tinge under its whitish-yellow flesh colour, and sometimes shows slight bluing (Phillips 1981). Specimens from Germany were shown to contain *psilocybin* [estimated at c.0.05%], as well as traces of *psilocin* and *tryptophan* (Gartz 1986b). Other tests, using 5 samples from the US and Switzerland [H. psittanica var. psittanica], failed to detect these alkaloids; they were also absent in a sample of H. psittanica var. californica (Stijve & Kuyper 1988).

Hygrophorus hypothejus has been claimed to contain *tryptamine*-derivatives (Norland 1976), though no further data was provided to support this assertion. This species has yielded a lectin, HHL, which agglutinates type A & B blood-group erythrocytes (Veau et al. 1999). It is considered edible, though an injected extract [route not given] was lethal to a guinea pig; it had no effect on other animals (Ford 1910/1911b).

Caution should be exercised, as these genera have been little studied chemically.

Hygrocybe conica has a cap 2-5(-6)cm across, at first sharply conico-convex to conical, then applanate with a broad umbo, becoming distorted and often cracked with age, yellow to orange-reddish, centre sometimes darker, becoming black when bruised or with age; margin decurved, often irregular, when old also straight and sometimes pellucid-striate; surface at first somewhat glutinous, later dry, slightly shiny to matt. Stem 20-60(-120) x 8-10mm, bright yellow and blackening, terete or slightly flattened, equal or somewhat clavate, longitudinally striate and mostly intertwined to some extent, hollow; at first moist to somewhat glutinous, later dry; base whitish, becoming black. Flesh watery/juicy, of mild taste, smell occasionally fruit-like. Gills sinuate, pale yellow with white raised margin when young, later olive-yellow to greenish-olive, soon becoming flecked with grey and finally black, free to narrowly adnate, with intercalated lamellulae, fairly crowded when young, later somewhat distant. Spore print white; spores broadly ellipsoid, sometimes a few constricted in the middle, 7-9(-12) x 4-5(-8)µ; basidia 4-spored, sometimes mixed with a few 2-spored ones. Fr. summer-late autumn.

Common in grass in fields, lawns, roadsides in Europe, in forests in North America; also found in Japan (Bresinsky & Besl 1989; Phillips 1981).

HYOSCYAMUS

(Solanaceae)

Hyoscyamus albus *L.* – white henbane

Hyoscyamus aureus *L.*

Hyoscyamus boveanus *Asch. et Schweinf.*

Hyoscyamus desertorum *Täckh.*

Hyoscyamus faleslez *Coss.*

Hyoscyamus muticus *L.* – Egyptian henbane, Indian henbane, sakaran ['drunken'], koh i bhang ['mountain hemp']

Hyoscyamus niger *L.* – henbane, foetid nightshade, poison tobacco, hog's bean, insane root, infidel's opium, pilsener kraut, bilsenkraut, hexenkraut, appolinaris, beleno, lang-tang, tian xian zi, koh i bhang, bhang, vajrabhang, khursani ajavan, ajwaina-kurasam, laliwah, parasikava

Hyoscyamus physaloides *L.* **(Physochlaina physaloides** *(L.) G. Don.***; P. pseudophysaloides** *Pascher***; Scopolia physaloides** *(L.) Dunal***)**

Hyoscyamus reticulatus *L.* – bhang, koh i bhang

Hyoscyamus spp. – henbane

Henbane has long been known for its intoxicating properties, and was mentioned by the early Egyptians, Greeks and Romans (Schultes 1969c; Schultes & Hofmann 1980). The Greeks held it sacred to Apollo, and H. albus has been claimed to have been an ingredient of the incense thought by some to have been used by Apollo's Oracle at Delphi [see **Laurus**]. For the Romans, it was sacred to Jupiter, and they used it in love potions. The Greeks probably added it to their legendary wines, and the Gauls used the juice of the plant to tip their arrows. In mediaeval times, Germanic peoples added H. niger to their 'pilsener' beer, and witches reportedly used it in their flying ointments [see *Methods of Ingestion*]. Many bath-houses used the seeds on the heating plates, to 'incite pleasure'. It has been said that the mere smell of the fresh plant can inebriate. At one time, pieces of henbane root were strung around infant's necks to prevent fits and relieve the pain of teething [presumably the child would suck on its necklace for the effects to become manifest, or the alkaloids would be absorbed through the skin] (De Vries 1991; Morton 1977; Ott 1993; Rätsch 1992; Schultes & Hofmann 1980; Wasson et al. 1978).

In ancient China, henbane was referred to as 'lang-tang', and the seeds as 'tian xian zi'. The herb was steeped in wine to be used as a tonic, treating mania, malaria, dysentery and parasitic skin diseases. The seeds had a reputation for producing a 'violent delirium', causing one to see spirits, if crushed before consumption (Li 1978). The leaves and flowering tops are still sometimes used in TCM, with a dose of 130-320mg being given for ailments such as neuralgia and gastric spasms (Keys 1976). In Baluchistan, H. muticus and H. reticulatus are smoked as **Cannabis**-substitutes. Henbane is smoked with tobacco [see **Nicotiana**] or **Cannabis** in Kashmir, Hakims smoke the seeds, and some Hindu saddhus are known to smoke henbane with their **Cannabis**. In Nepal, it is used as a sedative. Nepalese shamans sometimes smoke it with tobacco when holding a serious healing ceremony, and as an antidepressant; the seeds are also sometimes smoked with **Cannabis**. Kirati women commonly brew the seeds in with their 'chhang' beer [see *Methods of Ingestion*], using 5-6 seeds per litre. Oddly, in India H. niger is used to treat "hysteria, mental and maniacal

excitement, epileptic mania, chronic dementia with insomnia, and neuralgia" (Chopra et al. 1965; Müller-Ebeling et al. 2002; Nadkarni 1976). Of course the narcotic effect of the herb partly accounts for some of these applications, though prescription against mental disorders seems counter-intuitive, given the known effects of the plant in larger doses. However, Nadkarni (1976) states that the effects as a "deliriant are milder than those of belladonna [see **Atropa**], but greater as hypnotic, and more reliable and rapid." It is also worth mentioning his caution that "In over-doses, **Hyoscyamus** is a narcotic poison, producing delirium, coma and death, and its operation is generally very rapid" (Nadkarni 1976).

In Iran, smoke from the burning seeds of H. muticus is inhaled to relieve toothache. The dried, powdered plant, mixed with dates or milk, has been reported to sometimes be used by Arabs 'for criminal purposes'. An antidote to the hallucinogenic effects of the drug, if taken early enough, was said to be a mixture of water, butter, pulverised dates and pepper [see **Piper 1**], which causes profuse sweating (Morton 1977). Some Arabian peoples regard henbane as a narcotic and aphrodisiac, burning it to ward off demons, as well as adding H. faleslez to their spiced coffee [see **Coffea**]. The Tungus of s. Siberia likewise use roasted H. physaloides seeds as a coffee-substitute (Rätsch 1992), reported earlier as being instead H. niger (Von Bibra 1855). In the Shetul Valley of Afghanistan, H. niger is sometimes mixed with **Amanita** muscaria and an Impatiens sp., to make a psychotropic remedial ointment for external application (Mochtar & Geerken 1979). H. reticulatus is also used as an intoxicant in Afghanistan. Bedouins of the Egyptian desert smoke H. boveanus flowers for their inebriating properties (Ott 1993). In Israel, traditional healers use H. aureus to treat toothache, rheumatism, and eye infections (Palevitch et al. 1986).

Since the post-conquest introduction of H. niger to N. America, many indigenous tribes have taken up use of the plant, in manners similar to **Datura**. The Seri, for example, of the Gulf of California and Shark Island, add the leaves or seeds to their 'chicha' or 'pulqué' [see *Methods of Ingestion*], or simply infuse them in water and drink, for the analgesic and soporific properties of the herb (Rätsch 1992).

Henbane is little used today in herbal medicine, though it has been used to control urinary spasms, as well as spasms related to asthma and digestive disorders, and as an analgesic, mydriatic and sedative. It may also help ease travel sickness, and some symptoms of Parkinson's Disease (Bremness 1994).

Occasionally H. niger [and probably other species] have been used by western experimenters for psychotropic effects, though this is not common. In Australia, where this species grows as an occasional weed, there is one literature report regarding a 20-year-old who chewed on 4 flowers at the suggestion of his friends, who had heard that the plant was psychoactive when chewed. He was shortly after "brought to hospital by police, having been found lying on the footpath and behaving in a bizarre manner [...] he was found to be experiencing gross visual hallucinations, and was too excitable and restless to account for himself, although he complained of thirst and difficulty in seeing [...] Twenty-four hours later he complained only of inability to read, but he remained excitable. Fourty-eight hours after his admission to hospital, accommodation was normal, and he was discharged." No mention was made of what became of this man's friends. Accidental intoxications have been far more common, when children or adults have mistaken the plant for an edible one. In 1910, 25 people ate the roots, mistaking them for horseradish; they "all suffered strange hallucinations, but had recovered in 12 hours." In Turkey, intoxications from Hyoscyamus spp. are relatively common. Considering some of the colloquial names for the plants in Turkey, two of which translate to 'insane root' and 'infidel's opium' (Sands & Sands 1976), one must wonder if all of these ingestions have been accidental.

All Hyoscyamus spp. contain similar mixes of anticholinergic tropane alkaloids, predominantly *hyoscyamine* and *hyoscine*, and thus share similar psychotropic properties. The roots are often the most potent part of the plant. *Hyoscyamine* is usually the dominant alkaloid, though young plants contain higher levels of *hyoscine*.

H. albus leaves yielded 0.21-0.56% alkaloids, roots 0.1-0.14% and seeds 0.16%, consisting of *hyoscyamine* and *hyoscine* (Henry 1939); leaves have also been found to contain 5 calystegines (Bekkouche et al. 2001).

H. aureus flowers have yielded 0.9% *hyoscine* and 0.2% tetramethylputrescine [tetramethyldiaminobutane; possibly an artefact of the extraction process], but no *hyoscyamine* (Paris & Saint-Firmin 1967).

H. desertorum contains *hyoscine* and *hyoscyamine* as the major alkaloids. Leaves yielded 0.195% [harv. 1.5-3 months old] to 0.23% alkaloids [3.5-5.5 months old]. Total alkaloids in flowering plants [at the stage of unopened flowers, 1 wk after flowers opening, 2 wks, 3 wks, 4wks, respectively] were measured in various organs – leaves [0.058%; 0.11%; 0.02%; 0.029%; 0.014%], stems [0.28%; 0.193%; 0.15%; 0.304%; 0.055%], roots [0.475%; 0.36%; 0.498%; 0.08%; 0.157%], and flowers [-; 0.166%; 0.094%; 0.37%; 0.071%]. Seeds from ripe fruits yielded 0.063% alkaloids. Of the two major alkaloids, *hyoscyamine* is the predominant one in stems, roots, and radical leaves 3.5-5.5 months old; *hyoscine* predominates in radical leaves 1.5-3 months old, flowers, ripe fruits, seeds, and leaves just before flowers open (Sabri et al. 1973).

H. muticus, grown in Sudan, yielded 0.63% alkaloids in summer, 0.34% in winter, from leaves and stems; alkaloid yields from the roots remained +- constant from seedling stage until flowering – 0.57-0.58% in summer, and 0.54% in winter. Alkaloid yields were measured through 3 stages of flowering [onset of flowering; flowering and fruiting; first fully ripe fruit] in various organs [each given as summer, winter] – leaves [0.69%, 0.75%; 1.33%, 1.07%; 1.64%, 2.15%], stems [0.38%, 0.33%; 0.4%, 0.5%; 0.34%, 0.47%], roots [0.41%, 0.56%; 0.61%, 0.53%; 0.58%, 0.71%], and flowering and fruiting tops [1.76%, 0.95%; 1.14%, 0.67%; 1.28%, 0.94%]. *Hyoscyamine* was the major alkaloid in all parts, with smaller amounts of *hyoscine*, especially in roots (El Sheikh et al. 1982). Seeds have yielded 0.87-1.34% alkaloids, mostly *hyoscyamine* (Henry 1939). Indian plants yielded 0.1% alkaloids from leaf [w/w], mostly *hyoscyamine*, as well as 0.02% *hyoscine*, and tetramethylputrescine (Chopra et al. 1965). Specimens from S. Africa [presumably whole plant] yielded 0.77% *hyoscyamine* (Anon. 1916a). Flowers alone have yielded 0.75% *hyoscyamine*, 0.25% *hyoscine*, and 0.1% tetramethylputrescine (Paris & Saint-Firmin 1967). A commercial sample of Indian henbane, impossible to identify confidently [probably H. muticus], yielded 0.016% *hyoscine*, 0.01% *hyoscyamine*, and 0.0015% *tropine* (Evans & Partridge 1949).

H. niger roots yielded 0.15-0.17% alkaloids; flowering tops and leaves have yielded 0.045-0.1% alkaloids; seeds have yielded 0.06-0.1% alkaloids. *Hyoscyamine* is the dominant alkaloid, with lesser amounts of *hyoscine*, and possibly *atropine* (Henry 1939). Whole plant yielded 0.04% *hyoscyamine*, 0.028% *hyoscine*, and 0.0025% tropine (Evans & Partridge 1949). Seeds also yielded traces of three withanolides [see **Withania**] – daturalactone-4, hyoscyamilactol and 16α-acetoxyhyoscyamilactol (Ma et al. 1999); calystegine N1 has also been found in the plant (Bekkouche et al. 2001).

H. pusillus contained only traces of alkaloids (Ott 1993).

H. reticulatus [whole plant] yielded 0.116-0.24% alkaloids, and seeds yielded 0.082%, consisting of *hyoscyamine* and unidentified alkaloids. Tetramethylputrescine has also been found in the plant (Henry 1939).

Hyoscyamus spp. have also yielded apo-*hyoscine*, nor-*hyoscine*, belladonnine, ψ-tropine, cuscohygrine, littorine [in 2 species], and possibly tigloidine and tigloyloxytropane (Buckingham et al. ed. 1994; Evans 1979).

Hyoscyamus niger is a biennial herb; stems erect, up to 1m tall, very leafy, stout, viscid-hairy. Leaves grey-green, 7.5-20(-30)cm long, oblong to oblong-ovate with conspicuous veins, nearly entire or coarsely and irregularly toothed, or sometimes deeply lobed, slightly downy, with long, glandular, black-tipped hairs beneath the midrib and veins, lower leaves narrowed to a short petiole, upper leaves partly clasping the stem. Flowers large, sessile or short-stalked opposite the upper axils, forming a leafy, secund, spike-like inflorescence; calyx campanulate, persistent and reticulately veined in fruit; corolla c.3cm wide and long, narrowly campanulate or almost funnelform, slightly zygomorphic, the limb somewhat oblique and lobes slightly unequal, throat purple, limb dingy yellow with purple veins; stamens 5, separate, all fertile; anthers opening by longitudinal clefts, 3 longer than other 2. Fruiting calyx 2-2.5cm long, much surpassing the subglobose capsule; capsule enclosed by the calyx, circumsessile near summit; seeds reniform, papillate.

Sunny coastal areas; native to Europe, naturalised as a weed in some temperate zones (Gleason 1952; Morton 1977).

Plant seed in spring, thinly 60-90cm apart; keep moist until germination. Will grow in a wide variety of soils (Grubber 1973). Light may be necessary for germination, as the plant often grows in newly disturbed ground (theobromus pers. comm.).

HYPERICUM

(Guttiferae/Clusiaceae)

Hypericum macgregorii *Chun.* – soam gaman

Hypericum patulum *Thunb.* **(Komana patula** *(Thunb.) Y. Kimura ex Hondra***; Norysia patula** *(Thunb.) J. Voigt***)** – goldencup St. John's wort, thumbhul, kinshibai

Hypericum perforatum *L.* **(H. nachitschevanicum** *Grossh.***; H. officinarum** *Crantz***; H. perforatum var. confertiflora** *Debeaux***; H. perforatum var. microphyllum** *H. Lév.***)** – hypericum, St John's wort, goatweed, Klamath weed, Tipton weed, amber, scare-devil, solterrestris, herba John, hexenkraut, hexenblume

Hypericum spp.

In Papua New Guinea, the Nkopo use H. macgregorii in rain magic (Schmid 1991). The Indian H. patulum is used for its seeds, which are an aromatic stimulant (Nadkarni 1976).

The common name of H. perforatum, 'St John's wort', apparently stems from several symbolic observations. Its petals turn blood-red when crushed, and it flowers around June 24, anniversary of the decapitation of John the Baptist (Parsons & Cuthbertson 1992; Polunin & Robbins 1992). Also, the knights of St. John of Jerusalem used the plant during the Crusades to aid in the healing of sword-wounds. The related H. andro-

saemum ['tutsan' – 'all-heal'] has also been used to treat wounds and inflammation. In Scandinavia, H. perforatum has been associated with the Nordic god Baldur. The plant also has an age-old reputation for dispelling evil spirits, for which it was sometimes burned. The insane were often given infusions of the herb for its antidepressant properties. Two of its German names, 'hexenkraut' ['witch herb'] and 'hexenblume' ['witch flower'], obviously suggest a past usage by witches. It is sometimes used in TCM to treat hepatitis, appendicitis, abscesses and snakebite. The herb is sedative, antidepressant, antiseptic, antiinflammatory, antibacterial, antiviral, diuretic, expectorant, emmollient and astringent. The oil may soothe burns, improve blood flow, and relieve gastritis and stomach ulcers. The plant has been implicated in stock-poisonings, causing contact dermatitis and photosensitisation. Greg Whitten, an organic herb farmer, has noted that prolonged contact with the fresh herb when harvesting [3-4hrs, through both skin contact and inhalation of vapours] can result in a strong inebriation. If the contact lasted over several days, the inebriation was described as more of a "melancholic depression" (Bremness 1994; Cunningham 1994; De Vries 1991; Keeler 1975; Ody 1993; Polunin & Robbins 1992; Watt & Breyer-Brandwijk 1962; Whitten 1999).

Previously used in western herbalism mainly as a safe sedative for hyperactive children, H. perforatum preparations are now widely popular as a herbal antidepressant, with few or no side-effects [photosensitisation reactions have occurred in some people]. These products are now competing well with Prozac™, for treatment of minor depression (De Smet & Nolen 1996; Katzenstein 1998; Linde et al. 1996; Raffa 1998; pers. obs.). Commercially-available H. perforatum preparations are usually 'standardised' for content of *hypericin*, a quinone pigment that is a major component of the herb, and was previously thought to be the 'main active ingredient' (pers. obs.), or for hypericins in general, including *hypericin*, pseudohypericin [the 2 major hypericins], protohypericin, protopseudohypericin and cyclopseudohypericin. Protohypericin and protopseudohypericin rapidly convert to *hypericin* and pseudohypericin on exposure to light. Hypericins are found primarily in glands which cover the plant, but are most concentrated on leaf margins and flowers. It is now thought that the phloroglucinol derivative hyperforin is responsible for much [but not all] of the antidepressant activity of H. perforatum (Sirvent et al. 2002).

H. perforatum herb has shown some very weak MAO- and COMT-inhibiting properties [see *Neurochemistry*], as well as weakly inhibiting *serotonin* and *norepinephrine* re-uptake, but the full mechanism of action is yet to be shown, and is clearly a synergistic one between the various compounds present. It has been suggested that the MAOI effect would be due to an unidentified xanthone component (Bruneton 1995; Perovic & Muller 1995; Raffa 1998; Suzuki et al. 1984). The herb also induces cytochrome P450 3A4 and 3A5 activity [see *Neurochemistry*], and has been shown to potently inhibit cytochrome P450 isoenzymes other than the types mentioned above, with extended use (Coxeter et al. 2003; Fugh-Berman 2000; http://www.dml.georgetown.edu/depts/pharmacology/clinlist.html). This herb usually must be taken daily for several weeks to become fully effective (Katzenstein 1998; pers. comm.), and should not be combined with MAOIs or *serotonin* re-uptake inhibitors, as symptoms of *serotonin* syndrome may result (Fugh-Berman 2000). Antidepressants which have shown interactions with St. John's wort include sertraline, nefazodone, fluoxetine, paroxetine and amitriptyline. Some studies suggest that St. John's wort may interfere with the activities of some antiarrhythmic [digoxin], antiretroviral [indinavir], immunosuppressant [cyclosporin, tacrolimus], oral contraceptive and anticoagulant drugs. However, more evidence is needed to determine the extent of these interactions in humans (Coxeter et al. 2003).

H. crispum has been shown to contain *hypericin* (Schindler 1954).

H. hirsutum has been shown to contain *hypericin* and pseudohypericin, though a later study found only 0.043% *hypericin* (Kitanov 2001; Schindler 1954).

H. kalmianum inhibits human plasma AChE (Orgell 1963b).

H. maculatum has been shown to contain 0.058% *hypericin* and pseudohypericin, combined (Kitanov 2001).

H. maculatum var. genuinum was shown to contain 0.01% *hypericin* in stems, 0.08% in leaves, and 0.306% in flowers; H. maculatum var. punctatum was shown to contain 0.009% *hypericin* in stems, 0.078% in leaves, 0.542% in flowers, and 1.42% in the stamens (Schindler 1954).

H. perforatum has yielded 0.0095-0.466% *hypericin*, pseudohypericin, protohypericin, protopseudohypericin, hyperforin [inhibits uptake of *serotonin*, *dopamine*, *norepinephrine*, *GABA* and *glutamine*], adhyperforin, hyperin, epicatechin, *chlorogenic acid*, emodinanthranol, pseudohypericodihydrodianthrone, hypericodihydrodianthrone, 2-methyloctane, flavonoids [including luteolin, rutin, isoquercitrin, quercitrin, quercetin, amentoflavone (BZ-receptor agonist), *apigenin* derivatives, hyperoside], and 0.065-0.113% of a volatile oil, containing caryophyllene, *pinene*, limonene and myrcene (Bruneton 1995; Buckingham et al. ed. 1994; Chaterjee et al. 1998; Constantine & Karchesy 1998; Kartnig et al. 1996; Nielsen et al. 1988; Polunin & Robbins 1992; Raffa 1998; Schindler 1954; Singer et al. 1999; Watt & Breyer-Brandwijk 1962). One study of the dried herb found c.5% flavonoids, c.80% of which was a mixture of hyperoside and rutin (Borkowski 1960). *Melatonin* has also been found in the leaf [0.000175%] and flower [0.000439%] (Murch et al. 1997).

Different parts of two varieties were tested for *hypericin* content. H. perforatum var. angustifolium was shown to contain 0.011% in stems, 0.062% in leaves, 0.308% in flowers, and 1.414% in the stamens; H. perforatum var. vulgare was shown to contain 0.136% in the 'whole drug', 0.305% in the 'whole drug' minus stems, 0.01% in stems, 0.122% in leaves, 0.431% in flowers, and 1.565% in stamens. In the flowers, higher levels of *hypericin* are also found in petals, compared to the whole flower (Schindler 1954). Flowers of Swiss plants yielded 0.2-0.5% *hypericin* and 0.5-1% pseudohypericin. Flowers, sepals and capsules of plants from the Pacific n.w. US yielded 0.01-0.08% *hypericin* and 0.08-0.62% pseudohypericin. Limited data suggests that plants growing in sites with strong sunlight may contain greater levels of hypericins; this also seems to be the case for plants exposed to heavy grazing from herbivores, and plants exposed to insect pests (Sirvent et al. 2002). In early stages of growth, H. perforatum yielded 3.67-5.27% flavonoids; highest yields were obtained later, during the flowering period, which was followed by a decline in flavonoid content. Leaves and sepals, particularly of young growth, were the organs with the greatest flavonoid yields. Plants grown in humid regions gave higher flavonoid yields, but the variety of flavonoids present was small, whereas plants from arid regions gave lower yields, but with greater variety (Alyukina & Klyshev 1969).

Commercial preparations of H. perforatum, which are usually 'standardised' to *hypericin* content, have been shown to contain levels of *hypericin* ranging from 47-165% of labelled concentrations (Constantine & Karchesy 1998).

Many other Hypericum spp. have been shown to contain *hypericin* and/or pseudohypericin [as % combined, unless stated otherwise] – H. annulatum [H. degenii; 0.066%], H. attenuatum [0.072%], H. aucheri [0.031%], H. barbatum [0.306%; *hypericin* not found in earlier studies], H. bithynicum [0.056%], H. boissieri [0.512%], H. cerastoides [0.029%], H. elegans [0.104%], H. empetrifolium [0.009% *hypericin*], H. formosissimum [0.054% pseudohypericin], H. linarioides [0.019%], H. montanum [0.04%], H. montbretii [0.174%], H. olympicum [0.015%], H. origanifolium [0.064%], H. perfoliatum [0.056%], H. polyphyllum [0.012%; not found by earlier studies], H. richeri [0.134%], H. rochelii [0.232%], H. rumeliacum [0.263%], H. tetrapterum [0.052%], H. thasium [0.124%], H. triquetrifolium [0.09%] and H. umbellatum [0.063%]. An earlier study found *hypericin* in H. scabrum, though neither *hypericin* or pseudohypericin were found in the most recent analysis (Kitanov 2001).

Hypericum perforatum is an erect perennial herb to 1.2m tall, usually less; stems often reddish, glabrous, with 2 opposite longitudinal ridges bearing dark glands; several stems arise from a woody crown or rootstock, woody at base, branched mostly in upper ½, branches opposite and paired. 2 opposite, sessile leaves under the fork of each pair of branches; leaves green, lighter on lower surface, in opposite pairs, 1.5-3cm long, ovate to linear, sessile, glabrous, entire, covered with small oil glands which are seen as translucent dots. Flowers golden yellow, c.2cm diam., numerous in terminal clusters, often in groups of 3; sepals 5, green, sepals of young buds often with reddish markings, especially at tips; petals 5, rounded-lanceolate, often with glands that appear as black dots along margins; stamens yellow, numerous in 3 bundles. Fruit a sticky, many-seeded 3-celled capsule, 5-10mm long, with 3 persistent styles as long as fruit; seeds dark brown or black, cylindrical with rounded ends, c.1mm long, densely pitted.

Humid and subhumid temperate regions, 500-1000m; Great Britain, Europe to Central China, n. Africa, Australia [every state except NT]; a widespread weed.

Plants do not flower in first year, and may lie decumbent early in life (Chiej 1984; Parsons & Cuthbertson 1992). Due to its status as a noxious invasive weed in some countries [such as Australia], it is not advisable to cultivate this herb unless it can be contained within a controlled area. If you can locate unsprayed wild patches of the plant, there will be no need to cultivate it, anyway! Harvest the tops when the first flowers are opening, and dry without heat. Stems and flowers often take longer to dry than the leaves (Whitten 1999).

HYPOMYCES

(Hypocreaceae/Clavicipitaceae)

Hypomyces aurantius *(Pers. ex Fr.) Tulasne* **(H. cesatii** *(Mont.) Tulasne et Tulasne***; H. subaurantius** *Heinrichson***; Bonordenia aurantia** *(Pers. ex Fr.) Schulzer***; Nectria aurantia** *(Pers. ex Fr.) Fr.***; N. cesatii** *Montagne***; Sphaeria aurantia** *Pers.***)** – golden Hypomyces

This mould fungus is known to grow on other fungi, particularly species of the family Polyporaceae [see **Lycoperdon/Scleroderma**], and has been recorded growing on some Agaricaceae [eg. Coriolus pubescens in Ukraine – see *Endnotes*] (Rogerson & Samuels 1993). In Hueyapan, Mexico, H. lactifluorum and H. macrosporus, growing on what is probably a Lactarius sp., are eaten as food – the former is said to cause puckering in the mouth (De Avila & Welden 1980).

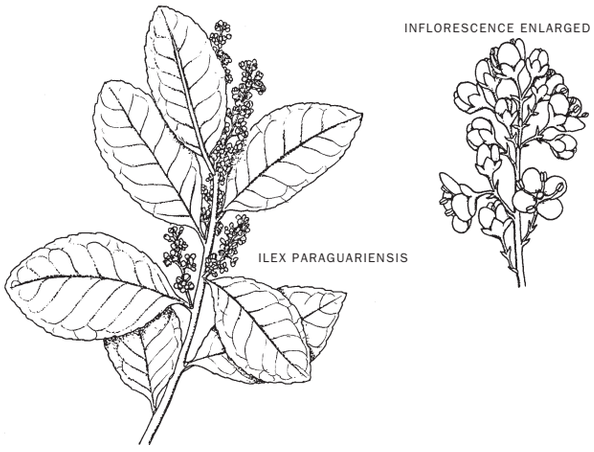
H. aurantius in liquid culture has yielded the ergot alkaloids [see **Claviceps**] *elymoclavine*, *agroclavine*, *chanoclavine*, ergokryptine and ergokryptinine (Yamatodani & Yamamoto 1983).

Hypomyces aurantius has subiculum typically yellowish-orange, orange, red to rusty-red, varying from almost white to buff, through many shades of orange and red, floccose and effuse, often covering the entire host, occasionally spreading over a large portion of surrounding substrate, turning violet to purplish-red in KOH; hyphae 4-6µm wide, much branched and often at right angles, septate, smooth, thin-walled, cells often becoming enlarged and thick-walled, up to 10-12µm wide with wall 1-1.5µm thick, loosely interwoven; perithecia globose to ovate or obpyriform, 250-575 x 200-375µm, gregarious, pale to golden yellow, orange or red; papillate; asci cylindrical to clavate, 100-140 x 6-7µm, apex thickened with a pore; ascospores fusiform to lanceolate, 2-celled, verrucose, apiculate; conidiophores arising in aerial mycelium, indefinite in length, verticillately branched with 3 or more branches arising from one point, branches sparingly septate or aseptate, each terminating in a single conidiogenous cell, its base tapering slightly to the tip, its apex proliferating retrogressively and percurrently; conidia at first globose to subglobose, becoming ellipsoidal or obovoidal, (8.5-)10-16(-21) x 5-7.5(-10)µm, 0-1-septate, with a basal hilum and often with refractive material at apex, conidia produced singly and held end to end in dry chains; chlamydospores oblong-oval, 18-48 x 12-18µm, 1-4-celled, constricted at septa, pale brown to reddish-brown, wall 1-3µm thick.

Common in north and south temperate zones, rare in tropical regions (Rogerson & Samuels 1993).

ILEX

(Aquifoliaceae)



Ilex amara *(Vell.) Loes.* – caa-una, caachira
Ilex ambigua *(Michaux) Chapman* – holly
Ilex aquifolium *L.* – European holly, English holly, holy tree, Christ's thorn, bat's wings, holm chaste, hulm, hulver bush, tinne
Ilex argentina *Lillo* **(I. tucumanensis** *Speg.***)**
Ilex brevicuspis *Reissek* **(I. caaguazuensis** *Loes.***; I. theezans var. acrodonta** *auct. non. (Reiss.) Loes.***)**
Ilex caroliniana *(Lam.) Loes.* **(I. cassine** *Walt. non L.***)**
Ilex cassine *L.* – cassina holly, cassena, yaupon
Ilex crenata *Thunb.* – Japanese holly
Ilex crepitans *Bonpland* – caa-una, caachira
Ilex dahoon *Walter* – dahoon holly, yaupon
Ilex dumosa *Reissek*
Ilex gigantea *Bonpland* **(I. theezans var. fertilis** *(Reiss.) Loes.***)** – caa-una, caachira
Ilex guayusa *Loes.* – guayusa, huayusa, guanusa, wayusa, wais, weisa, kopiniak
Ilex humboldtiana *Bonpland* – caa-unina, caa-una, caachira
Ilex integerrima *Reissek*
Ilex microdonta *Reissek*
Ilex mitis *(L.) Radlk.* **(I. capensis** *Sond. et Harv.***; I. monticola** *Tul.***; Sideroxylon mite** *L.***)**
Ilex opaca *Aiton* – American holly
Ilex ovalifolia *Bonpland*
Ilex paraguariensis *Saint-Hilaire* **(I. curitibensis** *Miers***; I. domestica** *Reiss.* **var. glabra** *Reiss.***; I. mate** *St.-Hil.***; I. paraguayensis** *Hook.***; I. paraguensis** *D. Don.***; I. sorbilis** *Reiss.***; I. theaezans** *Bonpl. ex Miers***; Cassine gongonha** *Raben.***; C. gouguba** *Guibourt***; Chomelia amara** *Vell.***)** – maté, yerba maté, yerba de palos, Paraguay tea
Ilex perado *Soland.*
Ilex pseudobuxus *Reissek*
Ilex tarapotina *Loes.* – té o maté
Ilex taubertiana *Loes.*
Ilex theezans *Mart. ex Reissek*
Ilex vomitoria *Soland.* – yaupon, black drink
Ilex yunnanensis *Franch.* **var. eciliata** *var. nov.* – shui-cha-tze ['tea growing by the water']

These trees and shrubs, all related to the 'true European holly' [I. aquifolium] are known for their content of purine alkaloids and for their ceremonial uses. Magically, holly is said to be an excellent protective herb (Cunningham 1994). One of the best known of these would be 'yerba maté' [or simply 'maté' – the name for both the beverage and the vessel it is consumed from], I. paraguariensis, which is widely consumed in parts of S. America [Bolivia, Brazil, Chile, Paraguay, Peru, Argentina] as a daily beverage which stimulates the CNS and suppresses hunger. It is also available commercially. Leaves of the tree are harvested with their twigs attached, and quickly roasted in a pan or dried over a fire. The leaves are then beaten free from the twigs, before being powdered and packaged. Sometimes the leaves are cured in a specially constructed oven, to retain more of the aroma of the herb. Yerba maté is drunk from a special tin gourd, which is also called maté. This consists of a gourd with a tube ['bombilla'] entering from the top like a straw, and the bottom of the tube holds a fine spherical strainer. The herb is put into the gourd, a little cold water poured in to moisten it, and near-boiling water is poured in. The drink is sucked up in quick sips through the tube, whilst the liquid is still very hot. It may be passed around the group, or kept to one's self. The herb may have further boiling water added 3-4 times, until the residue is exhausted. Western users may wish to let the herb infuse and cool for longer, as native users seem less sensitive to the scalding heat of the drink. In higher doses, maté is known to have slightly stupefying properties (Hume 1953; Peckolt 1883; Von Bibra 1855; pers. obs.). Guarani shamans make a strong decoction of it to enter a trance (Rätsch 1992).

I. amara, I. argentina, I. brevicuspis, I. crepitans, I. dumosa var. dumosa, I. gigantea, I. humboldtiana, I. integerrima, I. microdonta, I. ovalifolia, I. pseudobuxus, I. taubertiana, and I. theezans have been used as substitutes or adulterants of I. paraguariensis where it is not available or is in short supply, though I. paraguariensis is the only such species in cultivation (Filip et al. 1998, 2001; Peckolt 1883). I. tarapotina from n. Peru is said to be the source of a maté derivative called 'té o maté', of unknown effects. Similarly, a tea substitute [see **Camellia**] is made from leaves of I. yunnanensis var. eciliata, along the border of China and Tibet (Hu 1949; Hume 1953).

I. guayusa [usually known as 'guayusa'] is also similarly used, though it is considered more potent. It is mostly employed in the Peruvian/Ecuadorian region, by the Jivaro [including the Achuar Shuar], Pintsche, Zaparo, Canelo, Kokama and others. It was probably once used in Bolivia, based on findings of the leaves in the 5th century tomb of a Bolivian highland shaman. The leaves are collected in the lowlands, strung together, and carried to the village, where they are dried for use. Unlike many magical plants, guayusa was used and even sold by the missionaries of the area, for whom it was an important source of revenue. Some tribes cultivate it near their huts. Guayusa leaves are boiled whole in water for an hour to be drunk every morning [the decoctions being called 'wayus'], sometimes also throughout the day. Large amounts are consumed in a sitting – one dose may consist of a 2.2 litre decoction containing an extract of c.18g I. guayusa leaves. To avoid excessive stimulation and side effects from *caffeine* overdose, users cause themselves to vomit shortly after consumption, eliminating roughly half of the *caffeine* consumed. The beverage itself does not appear to act as an emetic. Ritual cleansing of the body in such a way is considered very important to these indigenous groups, and they learn how to induce emesis from an early age. Although it makes more sense to simply drink less of the beverage [as do women], men seem to enjoy drinking large quantities of the beverage and participation in the male bonding of the daily ritual including emesis. The drink is said to help bad nerves, stomach troubles, chills, venereal infections, female sterility, faulty menstruation, malarial fevers and liver pains. Even without emesis, guayusa is said to remove impurities through sweat and phlegm. It is usually prepared exclusively by men, though it may be consumed by all, and is often consumed at social occasions or given to dogs before hunting trips. It is considered a good omen to have a dream in which one sees a pot of guayusa boiling. Fittingly, the drink itself in sufficient dose is said to impart 'little dreams' on the drinker, which are used to aid in divining the success of a hunt. Strong decoctions are known to sometimes cause visual disturbances [as well as other symptoms of *caffeine* overdose], such as sticks on the forest floor seeming to move like snakes, though these effects are often seen as undesirable, and overly potent strains of I. guayusa are usually avoided. Guayusa may also be drunk before taking ayahuasca [see **Banisteriopsis**] to cleanse the system, or it may be taken with ayahuasca [or added to the brew] to 'kill the taste, prevent hangover' and 'give strength to deal with ayahuasca'. It has been used as a headache remedy by the Quicha (Bennett 1992; Lewis et al. 1991; Ott 1993; Patiño 1968; Rätsch 1992; Schultes 1967a; Schultes & Raffauf 1990).

I. cassine, I. dahoon and I. vomitoria are said to be used to make a stimulating drink by the Choctaw, Cherokee, Creek, Seminole, Alabama,

Karankawa and Natchez of the south-eastern US. It seems, however, that only I. vomitoria is actually used, early writers confusing these species. The 'black drink' or 'yaupon' is prepared from the leaves, which are roasted to dryness in a clay pot over fire, before water is added to make a strong decoction. It acts as a stimulant, strengthening tonic, emetic and purgative, and is taken at the opening of tribal councils and other important occasions. Sometimes, drinking sessions would continue for several days. James Adair wrote that "no one is allowed to drink it in council unless he has proved himself a brave warrior". Tobacco [see **Nicotiana**] may sometimes be added to the drink, which is consumed from conch shells. It also causes sweating [said to purify physically and morally], and is said to evoke 'ecstasies'. It is used in the training of shamans amongst the Seminole. Sometimes, the leaves are smoked as a tobacco substitute. I. cassine and I. vomitoria were also used as tea substitutes [see **Camellia**] by southern rebel forces during the American Civil War (Alikaridis 1987; Cooke 1860; Hamel & Chiltoskey 1975; Hume 1953; Power & Chesnut 1919b; Rätsch 1992).

Dried leaves of I. aquifolium are infused to make a beverage in the Black Forest, as well as having been employed in folk medicine as an antipyretic, antirheumatic, diuretic and astringent. In Corsica, the roasted fruits have been used as a coffee substitute [see **Coffea**]. Both parts are known to be purgative and emetic, and to produce a 'mild narcosis' (Alikaridis 1987; Chiej 1984; Ott 1995a; Von Bibra 1855). Early European pagans have been said to have offered holly twigs to forest faeries (Alikaridis 1987). I. opaca produces very similar symptoms – vomiting, diarrhoea and stupor (Foster & Caras 1994), though the Cherokee use the berries for indigestion and colic (Hamel & Chiltoskey 1975). The leaves have also been used as a tonic, cardiac stimulant, diuretic and purgative (Alikaridis 1987). In southern Africa, Sotho shamans use I. mitis and divinatory dice to prevent bewitchment of sick patients. Small pieces of the bark are chewed by the Kgatla as a purgative (Watt & Breyer-Brandwijk 1962). In Malaya, small amounts of I. cymosa bark ['kayu kelingat kuali'] are used in the manufacture of dart-poisons (Bisset & Woods 1966).

I. ambigua leaves were found to contain *caffeine* and *theobromine* (Bohinc et al. 1978).

I. aquifolium fruits have yielded neoxanthin, mutachrome, lutein, phytofluene, carotenes, pelargonidin-3-bioside, pelargonidin-3-glucoside, pelargonidin-3-xylosylglucoside, cyanidin-3-xylosylglucoside, α-amyrin, uvaol, 2-trichloromethylpropan-2-ol, 27-p-coumaroxyursolic acid, p-OH-benzoic acid, vanillic acid and fatty acids; leaf has yielded *theobromine*, rutin, quercetin, kaempferol [MAOI (Sloley et al. 2000)], sitosterol, baurenol, uvaol, erythrodiol, α-amyrin, β-amyrin, oleanolic acid, *chlorogenic acids*, fatty acids, amino acids and sugars (Alikaridis 1987).

I. argentina has yielded more than 0.5% *theobromine* (Suzuki et al. 1992); another analysis found only traces, and extreme traces of *caffeine*.

I. brevicuspis was not found to contain any detectable xanthines (Filip et al. 1998).

I. caroliniana contains *theobromine* (Alikaridis 1987).

I. cassine leaf yielded 0.27-0.32% *caffeine*, though species identification may have been in error (Power & Chesnut 1919b); *theobromine* has also been found (Alikaridis 1987).

I. crenata contains *theobromine* (Bohinc et al. 1975).

I. dumosa was found to contain traces of *caffeine* and *theophylline* (Filip et al. 1998).

I. guayusa leaf has yielded 1.69-7.69% *caffeine* [this high value was from a wild plant], traces-0.12% *theobromine*, *theophylline* [traces or none] (Lewis et al. 1991), *chlorogenic acid*, and an essential oil with traces of vanillin, fatty oil, tannins and resins (Rätsch 1992). A cold water infusion of the leaves [for 24hrs] was more effective in extracting the alkaloids of the leaf than was boiling in water for 10mins, though boiling in water for 1hr [the traditional method] was most effective (Lewis et al. 1991).

I. microdonta was found to contain traces of *caffeine* and *theobromine* (Filip et al. 1998).

I. opaca leaves have not yielded any purines, though they have been shown to contain nonacosane, *choline* and *acetylcholine* (Alikaridis 1987).

I. paraguariensis leaf has yielded 0.13-2.2% *caffeine* [only 0.02-0.03% in young leaves, dried 'without special care'; in one analysis, roasted maté from Parana (Brazil) yielded 0.55% *caffeine*, whereas unroasted maté from the same place yielded 1.67%] (Filip et al. 1998; Hume 1953; Lewis et al. 1991; Lindner 1956; Nagata & Sakai 1985; Ott 1995a; Peckolt 1883; Power & Chesnut 1919a), 0.15-0.9% *theobromine*, *theophylline* [none or traces], adenine, 5-10% *chlorogenic acids* [caffeic acid, 5-O-caffeoylquinic acid, 3-caffeoylquinic acid, *chlorogenic acid*, neochlorogenic acid, monocaffeoylquinic acid, dicaffeoylquinic acid, 3,4-, 4,5-, and 3,5-dicaffeoylquinic acids, feruloylquinic acid, p-coumarylquinic acid and others], flavonoids [rutin, kaempferol, kaempferol-3-O-rutinoside, quercetin, quercetin-3-O-glucoside], triterpenes [mostly ursolic acid, possibly also α-amyrin], ascorbic acid [vitamin C], thiamine [vitamin B1], riboflavin [vitamin B2], carotene, nicotinic acid, matesaponin 1 [c.1.23%], trigonelline, *choline*, amino acids, sugars, resins, fatty oil, and c.0.55% essential oil containing traces of vanillin. Unroasted leaves from Parana have yielded 0.25% of an aromatic substance different to the essential oil [which was extracted with ether]. The leaf contains no true tannins, but the 'pseudotannin' cafe-tannic acid or caffetannin [which is identical with *chlorogenic acids*, which give caffeic acid on hydrolysis]; some early research found mate-tannic acid [1.68% in roasted leaves, 4.5% in unroasted], reported to be similar but different to caffe-tannic acid. Small twigs have yielded [w/w] 0.26% *caffeine*. Fruits have also yielded *caffeine*, *theobromine* and *theophylline*, as well as fatty acids (Alikaridis 1987; Bruneton 1995; Buckingham et al. ed. 1994; Filip et al. 1998, 2001; Gosmann et al. 1989; Lewis et al. 1991; Lindner 1956; Ohem & Hölzl 1988; Peckolt 1883; Rastogi & Mehrotra ed. 1990-1993). Tea made from the leaves [using tea bags containing 1.8g leaf, or loose leaf (8.52g)] yielded 1.05-15.83mg *caffeine* per cup (De Camargo & Toledo 1999). Leaf extract showed some degree of BZ-receptor agonist activity (Medina et al. 1989). Tea made from the leaves has also shown antioxidant, hepatoprotective, choleretic, and hypocholesteremic properties; these activities are thought to be due to phenols, particularly the flavonoids and caffeoyl-derivatives [*chlorogenic acids*] present (Filip et al. 2001).

I. perado leaves have yielded *theobromine* (Bohinc et al. 1975).

I. pseudobuxus was found to contain c.0.0006% *theophylline* and traces of *caffeine* (Filip et al. 1998).

I. pubescens leaves have yielded *scopoletin*, aesculetin, 6-methyl-7-OH-coumarin, glaberide I, oleanolic acid and ursolic acid (Alikaridis 1987).

I. theezans was found to contain traces of *caffeine* and *theophylline* (Filip et al. 1998).

I. vomitoria leaf has yielded 0.09-1.67% *caffeine* and 0.04% *theobromine* (Lewis et al. 1991; Power & Chesnut 1919b).

Ilex paraguariensis is an evergreen shrub or small tree 4-7m tall. Leaves simple, persistent, alternate or rarely opposite, dark green, coriaceous, elliptic to obovate, 2.5-13(-25)cm long, 2-6.4cm wide, margins undulate and coarsely crenate in the upper 2/3, upper surface usually shiny, petiolate; stipules minute and caducous. Flowers unisexual, rarely some appearing perfect, in numerous small cymes along the current year's growth, usually 1-2cm long, peduncles 0.5-0.8cm long; sepals usually 4, 0.4-0.6mm long, persistent, imbricate and usually connate at base; petals usually as many as sepals, 1.5-2mm long, connate at base, white or greenish, rotate, caducous; stamens as many as petals, inserted at base of corolla, staminodia in pistillate flowers similar to fertile stamens but usually smaller; anthers usually dithecal, opening by longitudinal slits. Ovary superior, angled or lobed, (2-)4-6(-24)-carpellate, carpels connate, ovary 4-celled, rudimentary in staminate flowers; ovules 1(-2) per cell, pendulous on axile placentas, usually anatropous; style terminal, usually absent; stigmas 4, distinct or connate. Fruit a drupe, with as many 1-seeded pyrenes as carpels, dark red to brownish, c.6mm diam.

Native to Paraguay and adjacent Argentina and Brazil; cultivated and sparingly naturalised in Hawaii (Wagner et al. 1990).

Cultivate from seed, after freeing them from the flesh of the fruit; germinate with heat and/or in a humidity tent. Transplant to final site when c.15cm tall, planting 4-5m apart; likes a shaded position [young plants are easily killed by hot sun] and damp soil, and may benefit from a trench dug around the base to hold water. When 1-2m tall, trees can do with less shade, and harvesting may take place some 4 years after this point. Harvest may take place at various times – in Argentina and some areas of Brazil, Feb. to late Jul. is the preferred time, in Paraguay Dec. to Aug., and in some other areas of Brazil, Mar. to late Sep. However, harvesting young leaves in August may be damaging to the plant as this is when it puts out new shoots. Leaves are most aromatic when fruits are nearly ripe. Three grades of yerba maté have been encountered. These are 'caá-cuy' [new leaves of barely developed shoots, delicate texture, pleasant flavour, yellowish colour – rarely found for sale], 'caá-mirim' or 'herba mansa' [leaves only, with midribs removed] and 'caá-guacu', 'caá-una' or 'yerba de palos' [large and old leaves, plus twigs and wood fragments, strong bitter flavour, inferior quality – most commonly encountered]. In some areas such as Rio de Janeiro the leaves are sold either whole or powdered. With powdered maté, quality is tested by taking a small amount in the palm of the hand and blowing on it; if most of it blows away, it has probably been heated too much in the drying process (Peckolt 1883).

ILLICIUM

(Magnoliaceae/Illiciaceae)

Illicium parviflorum *Michx. ex Vent.* **(Badianifera parviflora** *(Michx. ex Vent.) Kuntze***)** – yellow anise, yellow anise tree of Florida, small-flowered anise shrub, small anise tree

Illicium religiosum *Sieb. et Zucc.* **(I. anisatum** *L.***; I. japonicum** *Sieb.***)** – Japanese star anise, sacred anise tree, hana noki, shikimi noki, hana shimiki [possibly derived from ashikimi, 'evil fruit'], dai ui kio, iririshi ya mu, koshiba, anasphal, anashuppu, badian, moso, mang-tsao ['mad herb']

Illicium verum *Hook. f.* **(I anisatum** *Lour.***; I. san-ki** *Perr.***; Clausena sanki** *(Perr.) J.F. Molina***)** – star anise, Chinese star anise, hwai hiang, bajiao hui xiang, ta hui xiang, kai-ko, dai uikio, hakkaku uikio, anasphal, anasuppan, anasapurvem, badian, badian-i-khatai, raziyanje-khatai, ewas

'Star anise' [I. verum], not to be confused with 'anise' or 'aniseed' [see **Pimpinella**], has been known to the Chinese since at least 100BC. It is commonly used as a cooking spice, and is an ingredient of Chinese five-spice. Its generic name comes from the Latin 'illicere' ['to attract'], referring to the alluring smell of the fruit and foliage. The dried fruits are believed to bring luck, and are burned as an incense to 'increase psychic powers'. Medicinally, the fruits stimulate appetite and digestion, relieve flatulence, rheumatism, chest complaints and pain. They are sedative and considered to be warming and to restore the normal flow of ch'i. The related I. religiosum is planted around Japanese Buddhist temples and near graves; it is considered sacred, and was introduced to Japan from China [and perhaps Korea] by Buddhists. When in flower, it is used to adorn consecrated vessels, altars and tombs. Powdered bark and leaves are also made into incense sticks, which are burnt in Buddhist temples and during religious rites. Unlike I. verum [with which it has been confused in the past], the fruit does not have a very agreeable aroma or taste, though the seed kernel does have a sweetish taste. All parts of the plant, especially the fruits, are considered poisonous in Japan. In China, it is reputed to cause "paroxysms of frenzy" if consumed by humans (Anon. 1881b; Bremness 1994; Cunningham 1994; Eykman 1881; Huang 1993; Müller-Ebeling et al. 2002; Simonetti 1990).

The essential oils of some Illicium spp. are known for their content of useful phenylpropenes [see also **Myristica**, **Sassafras**].

I. floridanum ['poison bay'] leaves and branches yielded an essential oil rich in linalool [20.23-24.86%] and linalyl acetate [12.32-15.54%], and also containing traces of (E)-*methylisoeugenol* [c.0.04%] and many other compounds (Tucker & Maciarello 1999). In Alabama, the leaves are considered posionous (Anon. 1881b).

I. majus fruits have a taste similar to that of 'mace' [see **Myristica**] (Anon. 1881b), and thus may have similar chemistry (pers. obs.).

I. parviflorum leaves and branches yielded an essential oil rich in *safrole* [67.26-69.04%], *methyleugenol* [11.02-12.76%], and linalool [12.15-14.17%], and also containing traces of *eugenol* [2.04-2.28%], *elemicin* [0.59-0.73%], (E)-*isosafrole* [c.0.02%] and many other compounds (Tucker & Maciarello 1999).

I. religiosum seed essential oil has yielded *safrole*, *eugenol*, cineol, *borneol*, and possibly *anethole* or *estragole* (Tardy 1905a).

I. verum fruit and seeds have yielded 2.5-9% essential oil, of which 71-90% may be trans-*anethole* and 5% *estragole*, as well as *safrole*, anisaldehyde, limonene, linalool, cinnamyl acetate, cis-ocimene, chavicol methyl ether, p-MeO-phenylacetone, p-propenylphenol, *pinene*, phellandrene, dipentene, terpineol, p-cymene, bisabolene, feniculin, farnesol, trans-α-farnesene, β-caryophyllene, nerolidol, salicylic acid and many other trace compounds (Anon. 1911a; Battaglia 1995; Bruneton 1995; Morton 1977; Schermerhorn et al. ed. 1957-1974).

Illicium verum is a glabrous, evergreen, slow-growing tree to 18m or more tall. Leaves mostly alternate, thick, leathery, sometimes clustered or seemingly whorled, petioled, without stipules, usually obovate to oblong-elliptic, to 15.5cm long. Peduncles quite short, nearly or quite bractless. Flowers solitary or 2-3 together, rarely in clusters on trunks and old branches, axillary, bisexual; flowers globose, perianth segments 7-12 in several series, to c.1cm long, the largest often as broad as long, not spreading, at first whitish but changing to pink and then to purple; stamens 11-20, with short filaments and basifixed anthers; carpels many, separate in a circle, with superior 1-celled ovary. Fruit star-shaped, of many separate 1-seeded follicles.

S.e. China and n.e. Vietnam.

Propagate by seed or by cuttings of half-ripened wood (Bailey & Bailey 1976). Trees are productive only after 15 years, giving 3 harvests a year. Fruits are gathered just before they are ripe, and dried quickly in the sun (Simonetti 1990).

INOCYBE

(Agaricaceae/Cortinariaceae)

Inocybe aeruginescens *Babos* – fibrehead mushroom
Inocybe calamistrata *(Fr.) Gill.*
Inocybe coelestium *Kuyp.*
Inocybe corydalina *Quél* **var. cordyalina**
Inocybe corydalina *Quél* **var. erinaceomorpha** *(Stangl et Vesel.) Kuyp.*
Inocybe haemacta *(B. et Cooke) Sacc.*
Inocybe tricolor *Kühner*

I. aeruginescens first attracted attention in e. Germany, from 1977-1986, due to a series of [perhaps not all] unintentional intoxications deriving from confusion with the 'fairy ring mushroom' Marasmius oreades, which is edible. Symptoms were typical of *psilocybin*-type activity, and the species was later confirmed to contain this class of tryptamines (Gartz 1995, 1996). I. haemacta has likewise been shown to be psychoactive [see below for details] (Stijve & Glutzenbaum 1999). Some researchers have not been able to find *psilocybin* in some of the species discussed here – while others have [see below]. The active species so far found exhibit bluing [or greening] when bruised, as a possible indicator of usefulness, but caution should still be exercised due to the known presence of toxins within the genus.

Human poisonings have resulted from the consumption of I. infida [from New York], with symptoms including "nausea, vomiting, diarrhoea, pain and a general feeling of unrest, all the affected individuals being restored to normal health within a few hours". I. rimosa is also claimed to be "very poisonous". I. infelix was found to be highly toxic to rabbits and guinea pigs, having a 'narcotic' effect, which was frequently followed by death in the guinea pigs (Clark & Smith 1914; Ford 1910/1911b). I. decipiens was found to be similarly toxic to animals (Ford et al. 1913).

I. aeruginescens has yielded 0.03-0.5% *psilocybin*, and 0.15-0.52% *baeocystin*; only traces of *psilocin* [0.02%] or none were detected. Also found, in similar yield to *psilocybin* and *baeocystin*, was a new 4-substituted *tryptamine* of unknown structure [c.0.35%], named aeruginascin by Gartz. He believed it may contribute to consistent euphoric effects in the inebriation. Lower alkaloid concentrations have also been reported, but these were from old specimens. *Psilocybin* was also found in the mycelial culture [0.01-0.1%], which bruises bluish-green (Gartz 1986c, 1988, 1990d; Gurevich 1995; Semerdzieva et al. 1986; Stijve et al. 1985; Wurst et al. 1992). In one bioassay, 2.4g of dried specimens was sufficient for moderately strong psychedelic effects (Gartz 1995).

I. calamistrata from Germany was shown to contain *psilocybin*, *psilocin*, *baeocystin* and *tryptophan* (Gartz 1986b), though 6-year old samples did not contain detectable tryptamines. It has a blue-green stem, though this is the natural colour rather than a bruising reaction (Stijve et al. 1985).

I. coelestium specimens from Germany [3yrs old] yielded 0.035% *psilocybin* and 0.025% *baeocystin* (Stijve et al. 1985).

I. corydalina var. corydalina specimens from France [8yrs old] yielded 0.011% *psilocybin*, 0.007% *baeocystin*, and no *psilocin*; Austrian specimens [3yrs old] yielded 0.032% *psilocybin*, 0.092% *baeocystin*, and no *psilocin* (Stijve et al. 1985); specimens from Sardinia [Italy] yielded 0.021% *psilocybin* and 0.72% *psilocin* (Ballero & Contu 1998); Swiss specimens yielded 0.023-0.03% *psilocybin*, 0.025-0.06% *baeocystin* and no *psilocin* (Stijve & de Meijer 1993); Russian specimens [some 8yrs old] yielded 0.008% *tryptophan*, 0.002% *psilocybin* and traces of *baeocystin*; a different Russian collection [5yrs old] yielded 0.004% *psilocybin* from both caps and stems, though only the caps yielded *baeocystin* [0.006%] (Gurevich 1995); *psilocybin* and *baeocystin* were also detected in German specimens (Gartz 1986b). One study found muscarine, but no *psilocybin*, but this finding has not been duplicated (Stamets 1996). This species, usually found in N. America and Europe, has also been found in India (Allen & Gartz 1997).

I. corydalina var. erinaceomorpha specimens from Germany [3yrs old] yielded 0.1% *psilocybin* and 0.04% *baeocystin* (Stijve et al. 1985).

I. haemacta specimens from Austria [3yrs old] yielded 0.17% *psilocybin*, 0.02% *psilocin* and 0.034% *baeocystin* (Stijve et al. 1985), which were also detected in German specimens (Gartz 1986b). Stijve & Kuyper (1985) reported the same yields as Stijve et al. (1985) but with the absence of *psilocin*; Swiss specimens yielded 0.02-0.042% *psilocybin* and 0.003-0.008% *baeocystin*, but no *psilocin* (Stijve & de Meijer 1993). Czech Republic specimens were found to contain *psilocybin* and *psilocin* (Stríbrný et al. 2003). The species has a pinkish-red bruising reaction, as well as bluing (Stamets 1996). Bioassays in four people using freeze-dried fruiting bodies [containing on average 0.1% *psilocybin*, 0.02% *baeocystin* and traces of *psilocin*] from Switzerland [harv. Sep./Oct.] showed 7g to be a moderately psychedelic dose (Stijve & Glutzenbaum 1999).

I. hirsuta var. maxima has been shown to contain *tryptamine*, and no muscarine (Robbers et al. 1964).

I. tricolor has been shown to contain *psilocybin* and *baeocystin* (Gartz 1996).

Many species of Inocybe, often red-staining ones, contain the toxic cholinergic muscarine [see **Amanita**, *Neurochemistry*], in amounts up to 0.8%, and fatalities have occurred (Bresinsky & Besl 1989); as an example, muscarine has been found in I. flocculosa [0.19%], I. griseolilacina [0.063%], I. pudica [0.027%], I. napipes [0.55-0.71%] and I. trechispora [0.25%], as well as at least 19 other species. I. patouillardi has caused poisonings in Europe (Hatfield & Brady 1975; Robbers et al. 1964; Stijve et al. 1985), and has yielded *phenethylamine* (Lundstrom 1989).

Inocybe aeruginescens has a cap (1-)2-3(-5) cm across, conic at first, expanding with age to convex and eventually plane with obtuse umbo; margin incurved when young, soon straightening; surface adorned with radial fibrils, more floccose towards disc; colour sordid buff to sordid ochraceous-brown, often with greenish tinges, darker olive-greenish at umbo – umbo dry, silky, usually smooth. Stem 22-50 x (2-)3-7mm, equal to swelling at base, solid, whitish to pallid at first, becoming bluish-green from base upwards; surface pruinose near apex, longitudinally fibrillose below; partial veil cortinate, soon disappearing. Gills adnate to nearly free, crowded, pale greyish-brown to clay-brown with greenish tones or bruising greenish where injured, up to 3mm deep. Bluish-green staining mostly disappears after picking. Spores clay-brown, smooth, ellipsoid, inaequilateral, 7-10 x 4-5μ; basidia 20-23 x 6-8μ, clavate, 4-spored; pleurocystidia

31-71 x 12-24µ, narrow to broadly fusiform, subclavate, with clear to yellowish tinged walls; cheilocystidia scattered, similar to pleurocystidia, 18-31 x 8-14µ. Odour 'soapy'. Fr. May-Jun.[-Oct.].

In sandy soils, and beneath poplars [Populus spp.], linden [**Tilia** spp.], oak [Quercus spp.], birch [Betula spp.] and willows [Salix spp.]; central Europe and n.w. North America – widely distributed across temperate zones. Inocybe spp. can be very difficult to identify, even for mycologists, and thus severe caution is advised with this genus (Gartz 1995, 1996; Stamets 1996).

IOCHROMA

(Solanaceae)

Iochroma fuchsioides *(Humb., Bonp. et Kunth) Miers* **(Chaenesthes fuchsioides** *Nob.***; I. puniceum** *Werderm.***; I. sodiroi** *Dammer***; I. umbrosa** *(HBK.) Miers***; Lycium fuchsioides** *HBK.***)** – guatillo, paguando, borrachero, borrachero andake, arbol de campanilla, totubjansush, nacadero, flor de quinde ['hummingbird flower'], quatillo

Iochroma grandiflorum *Benth.* – contrahechizo

I. fuchsioides is used as a shamanic hallucinogen by the Kamsá and Ingano of the Sibundoy Valley, in the southern Colombian Andes. It is usually only used in cases of difficult divination, due to its great strength and unpleasant side-effects. A handful of fresh bark is rasped from the stems, and an equal amount of fresh leaves is picked; these are decocted in water and drunk. Between 1-3 cupfuls of a strong decoction is consumed over about 3 hours, and the effects may last for at least a day. In past times when it was more frequently used, a tea made from **Hedyosmum** translucidum ['granicillo'] would be administered to aid in recovery from the intoxication. The trunk and root barks have also been used as a purgative in cases of internal bleeding, and to treat colic, stomach ache and digestive difficulties; a root infusion is given in cases of difficult childbirth (Schultes 1977b; Schultes & Raffauf 1990). In Peru, I. grandiflorum is sometimes added to **Trichocereus** pachanoi brews (Rätsch 1998).

Unidentified alkaloids have been detected in I. fuchsioides, which are thought to probably be tropanes [eg. *hyoscine*] (Schultes 1977b). Obscure withanolides [see **Withania**] have been isolated – withanolide D, 18-acetoxywithanolide D, 18-acetoxy-4-deoxy-5,6-deoxy-5-withanolide D and 18-acetoxy-5,6-deoxy-5-withanolide D (Raffauf et al. 1991).

I. coccineum has also yielded withanolides – withaferine A, withacnistine and iochromolide (Alfonso & Kapetanidis 1991).

I. cyaneum leaves and stems have yielded three hydroxycinnamic amides – N,N-di-dihydrocaffeoylspermidine, caffeoylputrescine [paucine] and feruloylputrescine [subaphylline] (Sattar et al. 1990).

Iochroma fuchsioides is a shrub or small tree 3-4.5(-6)m tall, densely branched; branches red-brown, tomentellous. Leaves oblong-obovate, slenderly attenuate to petiole, obtuse, 10-15 x 5.5-9cm, subfasciculate, +-glabrous above, white-tomentellous beneath, brown-tomentellous along veins; petiole brown-tomentellous, 20-30mm long. Flowers 25-35mm long, in umbellate clusters, axillary and terminal; pedicels ashy-tomentellous, elongate, cernuous; calyx c.5mm long, subglabrous, brown-tomentellous, bilobed, margin unequal, shortly 5-dentate, with intervening teeth in the plicature of each sinus; corolla tubular-campanulate, flaring at mouth, 8-9(-11)mm wide at mouth, deep red, externally tomentellous or rarely subglabrous, puberulent within; stamens included or sometimes slightly exserted, filaments thickened and densely tomentose at base; stigma greenish. Fruit a red berry, ovate-oblong to pyriform, acute to acuminate, 15-25mm long, 6-15mm wide, with enlarged persistent calyx, splitting on one side to the base.

At 2000-3000m altitude; Colombia, Ecuador (Miers 1848; Schultes 1977b).

May be grown outdoors in warm climates, from seed or cuttings taken in early spring; cuttings may take several weeks to root (Grubber 1973).

IPOMOEA

(Convolvulaceae)

Ipomoea amnicola *Morong* **(I. nuda** *N.E. Br.***; I. nuda** *Peter***)**

Ipomoea aquatica *Forsk.* **(I. reptans** *Poir.***)** – potato-vine, kalmishak, kangkung

Ipomoea argillicola *R.W. Johnson*

Ipomoea argyrophylla *Vatke*

Ipomoea asarifolia *(Desr.) Roem. et Schult.* **(I. beladamboe** *Roem. et Schult.***; I. crassifolia** *Cav.***; I. grisebachii** *Prain***; I. nymphaeifolia** *Griseb.***; I. pes-caprae var. heterosepala** *Chodat et Hassl.***; I. repens** *Lam.***; I. urbica** *(Salzm.) Choisy***; Amphione asarifolia** *(Desr.) Raf.***; Convolvulus asarifolius** *Desr.***; C. rugosus** *Rottler***)** – salsa brava, batatarana

Ipomoea cairica *(L.) Sweet* **(I. cavanillesii** *Roem. et Schult.***; I. funaria** *Larrañaga***; I. palmata** *Forssk.***; I. pentaphylla** *Cav.***; I. senegalensis** *Lam.***; I. stipulacea** *Jacq.***; I. tuberculata** *(Desr.) Roem. et Schult.***; I. vesiculosa** *P. Beauv.***; Batatas cavanillesii** *(Roem. et Schult.) G. Don***; B. senegalensis** *G. Don***; Convolvulus cairicus** *L.***; C. cavanillesii** *(Roem. et Schult.) Spreng.***; C. limphaticus** *Vell.***; C. tuberculatus** *Desr.***)** – Cairo morning glory, mile-a-minute, wasovivi

Ipomoea sp. aff. calobra *Hill et Muell.* **(not=I. calobra** *Hill et Muell.***)** – weir vine

Ipomoea carnea *Jacquin* – borrachero ['intoxicant'], matacabra ['goat killer'], toé

Ipomoea carnea ssp. fistulosa *(Mart. ex Choisy) D.F. Austin* **(I. fistulosa** *Mart. ex Choisy***; I. nicaraguensis** *(Donn. Sm.) House***)** – amapola, algodão-bravo

Ipomoea coccinea *L.* **(Convolvulus coccineus** *L.***; Quamoclit coccinea** *(L.) Moench.***)** – red morning glory, star Ipomoea

Ipomoea costata *F. Muell. ex Benth.*

Ipomoea diamantinensis *J.M. Black ex Eardley*

Ipomoea digitata *L.* **(I. paniculata** *(L.) R. Br.***; Convolvulus paniculatus** *(Burm. f.) Kuntze***; C. paniculatus** *L.***; Quamoclit digitata** *(L.) G. Don***)** – bidarikand, vidari, vrashavalli, payasvini, phalmodika

Ipomoea hederacea *Jacquin* **(I. desertorum** *House***; Convolvulus hederaceus** *L.***; Pharbitis githaginea** *Hochst.***; P. hederacea** *(L.) Choisy***; P. hispida** *A. Rich.***)** – pharbitis, mirchai, bildi

Ipomoea hederifolia *L.* **(I. angulata** *Lamk.***; Quamoclit angulata** *Boj.***; Q. hederifolia** *(L.) G. Don.***)** – Texas red morning glory

Ipomoea hildebrandtii *Vatke*

Ipomoea hybrida 'Darling' *Hort.* **(I. nil 'Darling'** *Hort.***)**

Ipomoea involucrata *P. Beauv.* **(I. pileata** *Roxb.***; Convolvulus perfoliatus** *Schumach. et Thonn.***)** – nguenga

Ipomoea lacunosa *L.*

Ipomoea leptophylla *Torr.* – bush morning glory, big-root morning glory, man-root, bush moonflower, wild potato vine, kahts-tuwiriki ['whirlwind medicine'], pezuta nige tanka ['big-stomach medicine']

Ipomoea muelleri *Benth.*

Ipomoea nil *(L.) Roth* **(I. cuspidata** *Ruiz et Pavon***; I. githagenia** *A. Rich.***; I. hederacea** *Auct. non Jacq.***; Convolvulus nil** *L.***; C. tomentosus** *Lour.***; Pharbitis nil** *(L.) Choisy***)** – qian niu zi [seed in TCM], kaladana ['black seed'], nil, nil-kalmi ['blue-leaf']

Ipomoea oblongata *E. Mey. ex Choisy* **(Turbina oblongata** *(E. Mey. ex Choisy) A. Meeuse***)** – mothokho

Ipomoea orizabensis *(Pelletan) Ledeb. ex Steudl.* **(I. longipedunculata** *(M. Martens et Galeotti) Hemsl.***; I. superba** *(Kunth) G. Don***; I. tyrianthina** *Lindl.***; Convolvulus orizabensis** *Pelletan***; C. sanguineus** *Willd. ex Roem. et Schult.***; C. serotinus** *DC.***; C. superbus** *Kunth***; Pharbitis longipedunculata** *M. Ipomoea parasitica *(Kunth) G. Don* **(I. perlonga** *B.L. Rob.***; Convolvulus circinnatus** *Willd. ex Roem. et Schult.***; C. parasiticus** *Kunth***)**

Ipomoea pes-caprae *(L.) R. Brown* **(I. biloba** *Forssk.***; I. brasiliensis** *(L.) G. Mey.***; I. brasiliensis** *(L.) Sweet***; I. maritima** *(Desr.) R. Br.***; Convolvulus bilobatus** *Roxb.***; C. brasiliensis** *L.***; C. maritimus** *Desr.***; C. pes-caprae** *L.***)** – goatsfoot convolvulus, purple beach convolvulus, coast morning glory, endabari, waljno-jo, ale, aliali, lauwere, lavere, dopatilata

Ipomoea pes-tigridis *L.* **(I. capitellata** *Choisy***; I. hepaticifolia** *L.***; Convolvulus pes-tigridis** *(L.) Spreng.***)**

Ipomoea petaloidea *Choisy* **(I. bufalina** *Choisy***; I. nymphaefolia** *Blume***; I. peltata** *(L.) Choisy***; Convolvulus bufalinus** *Lour.***; C. crispatulus** *Wall.***; C. peltatus** *L.***; Merremia borneensis** *Merr.***; M. bufalina** *Merr. et Rendle***; M. distillatoria** *(Blanco) Merr.***; M. elmeri** *Merr.***; M. peltata** *(L.) Merr.***; Operculina bufalina** *Hall. f.***; O. petaloidea** *Ooststr.***; Spiranthera peltata** *(L.) Bojer***)**

Ipomoea piurensis *O'Donnell*

Ipomoea purpurea *(L.) Roth* **(Convolvulus purpureus** *L.***; Pharbitis purpurea** *(L.) Voigt***)** – purple-flowered morning glory, purple-flowered bell vine, jalambu, jalapha

Ipomoea quamoclit *L.* **(I. cyamoclita** *St.-Lag.***; Convolvulus pennatifolius** *Salisb.***; C. pennatus** *Desr.***; C. pinnatus** *Desr.***; C. quamoclit** *(L.) Spreng.***; Quamoclit pennata** *(Desr.) Bojer***; Q. pinnata** *(Desr.) Bojer***; Q. quamoclit** *(L.) Britton***; Q. vulgaris** *Choisy***)** – cypress vine morning glory

Ipomoea rubrocaerulea *Hook.* **(Convolvulus rubrocaeruleus** *(Hook.) Dietrich***; Pharbitis rubrocaeruleus** *(Hook.) Planch.***)**

Ipomoea sinensis *(Desr.) Choisy* **(I. biflora** *(L.) Pers.***; Convolvulus sinensis** *Desr.***)**

Ipomoea stans *Cav.* **(I. jaliscana** *House***; Convolvulus firmus** *Spreng.***; C. sinuatus** *Sessé et Moc.***; C. stans** *(Cav.) Kunth***)** – tumbavaqueros

Ipomoea trichocarpa *Elliott*

Ipomoea verbascoidea *Choisy*

Ipomoea violacea *L.* **(I. glaberrima** *Bojer ex Bouton***; I. grandiflora** *(Jacq.) Hallier f.***; I. longiflora** *R. Br.***; I. macrantha** *Roem. et Schult.***; I. punticulata** *Benth.***; I. tricolor** *Cav.***; I. tuba** *(Schltdl.) G. Don.***; Calonyction grandiflorum** *(Jacq.) Choisy***; C. jacquinii** *G. Don.***; C. tuba** *(Schltdl.) Colla***; Convolvulus grandiflorus** *Jacq.***; C. tuba** *Schltdl.***)** – badoh negro, tlitliltzin, badúngas, piH pu'ucte-sh ['broken-plate flower'], la'aja shnash ['seed of the Virgin'], gui réh

Ipomoea wrightii *Gray* **(I. gracilipes** *Hassl.***; I. pulchella** *Roth.***; I. spiralis** *House***)** – palm-leaf morning glory

Once used by the Aztecs as an alternative psychotrope to 'ololiuqui' [**Turbina** corymbosa], the black, angular seeds of the morning glory I. violacea [proposed to be the Aztec 'tlitliltzin'] are still used in Mexico, mostly in the Zapotec and Chatin area of Oaxaca. In some villages, the seeds from either vine are used; in this case, the I. violacea seeds ['macho'] are taken by males, and the **Turbina** corymbosa seeds ['hembra'] are taken by females. I. violacea is chemically more potent than T. corymbosa, but they contain the same essential components, and are both used for the same means of divination or consultation. The seeds are taken at night in relative seclusion; the dose is usually 7 seeds or a multiple of 7; or 13 seeds or a multiple of 13; or a thimble-full, which are ground to a powder and soaked in cold water for ½ an hour or more, before being finely strained, and the liquid consumed (Lipp 1990; Schultes & Hofmann 1980, 1992; Wasson 1961, 1963). I. violacea seeds are reportedly chewed [a dose of 200-500] in Zimbabwe as a 'hallucinogen' (De Smet 1998).

I. orizabensis is known as 'yerba de las ánimas' ['herb of souls'] in Mexico (Diaz 1979); though this species is not known to currently be used in any way, the seeds have been shown to contain ergoline alkaloids [see below] (Amor-Prats & Harborne 1993). I. stans rhizome is used in Mexico to treat epilepsy and hysteria, and as a choleretic – stems and roots had a CNS-depressant action in rats. Very large doses are said to be intoxicating in humans, lasting about 10hrs. I. murucoides ['palo bobo', 'banú'] is known to be poisonous, and may cause paralysis (Heffern 1974; Jiu 1966). The leaves of I. murucoides and I. arborescens have similar medicinal properties to those of I. violacea and ololiuqui, but it is not known whether they are psychoactive (Fields 1969). The Maya and other ancient Mesoamerican cultures once used the latex from I. alba, mixed with the latex from Castilla elastica, to make the rubber from which many items were fashioned, notably including the rubber balls used in the infamous ball-game of the Maya. The latex of I. alba served to strengthen the rubber, as latex of C. elastica alone becomes brittle when dry and does not keep its form well (Hosler et al. 1999).

I. carnea is known to have intoxicating properties in Ecuador (Schultes & Hofmann 1980); it has been claimed to sometimes be added to ayahuasca in the Amazon (Rätsch 1998) [see **Banisteriopsis**] but it might not be particularly safe or recommended for human use [see its chemistry discussed below]. In Brazil, I. carnea ssp. fistulosa is known to cause stock intoxications which manifest gradually, symptoms including lassitude and disequilibrium. The lethal dose of the fresh plant in cattle was 9kg/100kg. I. asarifolia also causes stock intoxications in Brazil, with symptoms including tremor, rocking of the head, and disequilibrium; affected animals frequently recover (Pott & Alfonso 2000). In Paraíba, n.e. Brazil, I. riedelii and I. sericophylla have intoxicated goats, sometimes fatally (Barbosa et al. 2006). In Dominica, I. denticulata and I. tiliacea are known as 'caapi' [see **Banisteriopsis**] (Trout ed. 1998).

The Fang of Central Africa use a maceration of the whole plant of I. involucrata as a stimulant, and in shamanic healing (Akendengué 1992). Root juice from I. verbascoidea has been claimed to be 'narcotic'. In southern Africa, I. oblongata has been reported as an ingredient of a compound drug ['sehoere' – see *Methods of Ingestion*] consumed by the Basuto in intoxicating ritual feasts (Laydevant 1932). The Southern Sotho snuff the powdered leaf of I. oblongata var. hirsuta mixed with tobacco [see **Nicotiana**]; the plant is also used to 'drive away lightning'. I. purpurea is used by the Zulu as a purgative, as which it is very effective (Watt & Breyer-Brandwijk 1932). Interchangeably with I. nil, the seeds are used in TCM as a purgative, in a dose of 3-6g. Nausea and vomiting result from overdosage, and the seed should not be used during pregnancy (Huang 1993). I. nil seeds are also used as a purgative in India, under the name 'kaladana' or 'nil', names which may also apply to seeds from a variety of related and unrelated plants [**Calonyction** muricatum, Clitoria terneata, Indigofera tinctoria, Nigella sativa (see *Endnotes*), **Piper** nigrum] (Austin 2000).

I. aquatica is given to treat "nervous and general debility" in w. Bengal, and is applied as a poultice to treat febrile delirium in Cambodia. In Burma, the juice of the plant is used as an emetic to treat poisoning from opium [see **Papaver**] or arsenic (Datta & Banerjee 1979). Its leaf sap is mixed with a root decoction of water lily [**Nymphaea** spp.] and given as a sedative to treat insanity in Tanganyika (Burkill 1985-1997). In Vietnam, the leaf is given to treat mushroom-induced 'intoxication' (Heim 1963b; Morgan 1995). In Australia, the plant was suspected of poisoning horses – "animals developed shivers and stiffness, and died soon after being ridden" (Webb 1948). However, I. aquatica leaves are commonly eaten as a vegetable in some parts of s.e. Asia (Nadkarni 1976; Perry & Metzger 1980).

I. sp. aff. calobra [earlier reported incorrectly as I. calobra] has caused stock intoxications ['staggers'] in s. Queensland [Australia], and is suspected of containing lysergic acid-type alkaloids. Also suspected of causing stock intoxications in Australia are I. muelleri (Der Marderosian et al. 1974; Everist 1974; Parsons & Cuthbertson 1992), I. coccinea, I. hederacea, I. heterophylla, I. learii and I. cairica [as I. palmata]. In the case of I. sp. aff. calobra, some symptoms of the intoxication in sheep were described – "it staggers badly when walking, the hind legs being straddled, apparently in an efort to maintain balance, and the sheep seems no longer able to judge the kind of obstacle it encounters". Death sometimes results, either from misadventure, or possibly from the direct effects of the plant itself (Webb 1948).

I. pes-caprae ssp. brasiliensis leaves are used as a poultice around the north coast of Australia to treat painful wounds and sores; it has a mild anti-*histamine* action (Aboriginal Communities 1988). I. pes-caprae roots and leaves have tonic and purgative actions (Nadkarni 1976). Roots and stems are reputed to cause vertigo if eaten over an extended period. The leaves are decocted in Fiji and consumed to treat menstrual disorders and as a female tonic following childbirth. The shoots reputedly have some anti-cancer activities. Also in Fiji, crushed leaves of I. petaloidea are infused to relieve headache and earache, sometimes combined with **Macropiper** vitiense. The roots are sometimes taken with **Evodia** hortensis bark to relieve chills and attacks of rigor (Cambie & Ash 1994). I. quamoclit has apparently been used in Australia as a snuff, and to treat snakebite; it has a purgative action (Webb 1948).

The tuber of I. digitata is taken in India as an aphrodisiac with ghee [clarified butter] and honey. It is also part of a compound aphrodisiac, fried in butter with equal parts of **Syzygium** aromaticum, 'cardamom' [Elettaria cardamomum], **Myristica** fragrans, **Mucuna** pruriens, 'almonds' [see **Prunus**], Asparagus racemosus, 'quince' [Cydonia oblonga] seeds and Hygrophila spinosa seeds (Nadkarni 1976). In n. Ghana, the root is sometimes pulverised and added to a composite intoxicating snuff for shamanic initiation [see **Piper 1**] amongst the Kusasi (De Smet 1998).

I. leptophylla roots are burned by the Pawnee of N. America; the smoke treats nervousness and bad dreams. The pulverised, dried root is dusted on the body as an analgesic, or to revive a fainted person. It is eaten raw by the Lakota for stomach trouble (Kindscher 1992). The Nkopo of Papua New Guinea use I. batatas ['yawot', 'sweet potato'] in rituals to promote hunting success (Schmid 1991). The Siona of the Amazon know this species as 'yahi', a Tukano name meaning 'sorcerer's plant' (Trout ed. 1998). When eaten in large amounts, the tubers can reputedly act as an aphrodisiac in women (Rätsch 1990).

Seeds of commercial morning glories [usually I. violacea cultivars, though I. purpurea has been used by Italian psychonauts] have been used by adventurous westerners as a psychotropic drug since their native usage and chemical content became apparent in the early 1960's, and even earlier in isolated experiments. Such use was most noted amongst students, and reactions were varied – people consuming the seeds whole usually experiencing no effects, and those who had ground them experiencing the expected effects to varying degrees depending on dosage. Many users have been disappointed, expecting an LSD-like experience, which is generally not to be found when *ergine* is the predominant alkaloid [see below]. Sometimes psychonauts have admitted themselves to hospitals due to the unexpected nature of the effects, such as in one case where a 20-year old woman ingested 250 commercial I. violacea seeds (Cohen 1964; Festi & Samorini 1999b; Ingram 1964; pers. comm.). See **Turbina** for further discussion.

It is estimated that 5g of morning glory seeds containing 0.04% ergot alkaloids should be sufficient for psychedelic effects (Wilkinson et al. 1986); one 'underground' source suggests 5-10g of seeds; many modern experimenters report using 100-300 seeds or more to produce effects (Gottlieb 1992; Ingram 1964; pers. comms.). These upper reaches are no doubt due to the fact that commercial cultivars of the wild species seem to often be much less potent in terms of alkaloid levels (Ott 1993). Seeds of active Ipomoea spp. can be smoked for a mild "**Cannabis**-like euphoria" lasting c.1 hour; for this purpose, they should be packed in a clean tobacco-pipe with a large bowl, and the ground seeds will need to be re-lit for each inhalation (Trout & Friends 1999). As the alkaloids would not be active by combustion, it is most likely that other compounds found in the seeds are responsible for this activity; gibberellins have been suggested as possible candidates (theobromus pers. comm.).

Commercial morning glory seeds are usually from a cultivar or mix of cultivars of I. violacea; they may be coated with poisonous fungicides [such as N-trichlorete] or other chemicals to discourage ingestion – thus, they should be washed thoroughly with warm, soapy water and dried fully before use. The infusion made from morning glory seeds is soapy-tasting; the resinous material responsible for this seems to cause nausea and purging, and is found in the seed pulp. There are chemicals in the seed husk that are only slightly water soluble, and these seem to counteract the psychedelic effects, as well as causing headache and blurred vision. A more effective extraction process should help one to get the best experi-

ence from these seeds [see *Producing Plant Drugs*]. Other side effects reported are vomiting, diarrhoea, drowsiness, numbness of extremities, and muscle tightness (Chao & Der Marderosian 1973a; Cohen 1964; Ingram 1964; pers. comm.).

The psychedelic components of the morning glories are ergot alkaloids [see **Claviceps**] – ergoline and clavine alkaloids, some very closely related to LSD [lysergic acid diethylamide; a semisynthetic compound], concentrated in the seeds, and often found in traces in the vegetation. *Ergine* [LA-111; lysergic acid amide] is usually considered the main active chemical, but as its activity is reportedly soporific and 'foggy', with little true psychedelic activity, the other chemicals present no doubt play a role in developing the full psychoactivity of the seeds [such as *agroclavine*, *elymoclavine*, lysergene (partial 5-HT2a-agonist, also affects α1-adrenoceptors in rat), *lysergol*, *festuclavine* and *penniclavine*] (Pertz 1996; Yui & Takeo 1958a, 1958b). *Ergine* and isoergine are partly present in the seeds as lysergic acid N-(1-OH-ethyl)amide and the iso-derivative; under hydrolysis in isolation, they easily convert to *ergine*, isoergine and acetaldehyde. Lysergic acid N-(1-OH-ethyl)amide might also be responsible for some of the more psychedelic effects (Schultes & Hofmann 1980), which seems to be supported by the observation that freshly harvested seeds are the most effective (theobromus pers. comm.). Seeds high in alkaloids have high lipid levels, mainly consisting of linoleic acid and palmitic acid (Genest & Sahasrabudhe 1965).

I. alba seeds have yielded indolizine-type alkaloids – ipalbine, ipalbidine, ipomine, isoipomine, methoxy-ipomine, dimethoxy-ipomine and ipalbidinium (Ikhiri et al. 1987a).

I. amnicola seed [fresh] yielded 2 ergoline alkaloids [0.039%] (Amor-Prats & Harborne 1993).

I. aquatica mature seeds [as I. reptans] have been shown to contain gibberellins (Matsuo et al. 1984); fresh seed was also reported to have yielded 0.006% ergoline alkaloids, though subsequent tests detected none (Amor-Prats & Harborne 1993). It should be mentioned that these authors refer erroneously to Nair et al. 1986 [misquoted as Geetha et al. 1996] for the positive test, though this latter paper contains no reference to alkaloids, or yields thereof. Nair et al. (1986) did, however, find quercetin derivatives, napthoquinones, gentisic acid, protocatechuic acid, vanillic acid, syringic acid, and saponins in the leaves. Aerial parts have shown hypoglycaemic effects in rats (Malalavidhane et al. 2000), and potently inhibit prostaglandin synthesis in vitro. Stems have yielded 0.006% N-trans-feruloyl-*tyramine*, 0.0016% N-cis-feruloyl-*tyramine*, 0.014% *scopoletin* and 0.012% umbelliferone (Tseng et al. 1992).

I. argillicola seed [fresh] yielded 3 ergoline alkaloids [0.084%] (Amor-Prats & Harborne 1993).

I. argyrophylla seed yielded 0.27% alkaloids, including *agroclavine* [0.04%], ergosine [0.05%] and ergosinine [0.07%] (Stauffacher et al. 1965).

I. asarifolia growing in Thailand was found to contain indole alkaloids in leaves and seeds, with higher levels in seeds (Jirawongse et al. 1979). Another analysis found ergolines in leaves, stems and seeds, but not fruit; seeds were shown to contain mainly *chanoclavine*, as well as ergometrine, ergometrinine and 3 unidentified alkaloids (Nunes et al. 1982b).

I. batatas mature seeds have been shown to contain numerous gibberellins (Matsuo et al. 1984).

I. cairica seed [fresh] yielded 0.009-0.02% ergoline alkaloids, but subsequent tests revealed none (Amor-Prats & Harborne 1993). The lower value is quoted erroneously from Nair et al. 1986 [see above]. Seeds also contain glycosidal resins known as glykoretins. Aerial parts have yielded the lignanolides arctigenin and trachelogenin [which exhibited cytostatic activity, as well as inhibiting replication of the HIV-1 virus], and traces of the coumarins *scopoletin* and umbelliferone (Eich et al. 1990; Trumm & Eich 1989). Traces of HCN were detected in the leaf and root (Watt & Breyer-Brandwijk 1962).

I. calobra leaf [from St. George, Queensland, Australia; harv. Feb.] tested weakly positive for alkaloids. Stem and root gave weak and inconclusive reactions (Webb 1949).

I. sp. aff. calobra has yielded calystegine B2 and swainsonine [see **Swainsonia**] (Griffin & Lin 2000).

I. cardiophylla seed yielded unidentified ergoline alkaloids (Chao & Der Marderosian 1973a).

I. carnea seeds were found to contain at least 3 alkaloids, 2 of which were tentatively identified as *ergine* and isoergine (Lascano et al. 1969); leaves, flowers and seeds have yielded [w/w] swainsonine [0.0029% in leaves, 0.0028% in flowers, c.10 times higher in seeds; see **Swainsonia**], 2-epi-lentiginosine [α-mannosidase and glycosidase inhibitor], N-methyl-trans-4-OH-l-proline and calystegines B1, B2, B3 [mannosidase-inhibitor] and C1 [B1, B2 & C1 inhibited rat lyosomal β-glucosidase] (Haraguchi et al. 2003; Ikeda et al. 2003). Latex yielded carnein, a serine protease enzyme (Patel et al. 2007).

I. carnea ssp. fistulosa leaf yielded 0.006% ergoline and clavine alkaloids [including *agroclavine* and α-dihydro-*lysergol*]; the non-alkaloidal fraction from the leaf extract was sedative, hypnotic, CNS-depressant and muscle-relaxant in rats and mice (Rastogi & Mehrotra ed. 1990-1993; Umar et al. 1980).

I. coccinea seed has yielded 0.04% alkaloids, consisting solely of *elymoclavine* (Gröger 1963); a later analysis found 0.003-0.0043% alkaloids, consisting mostly of *elymoclavine*, followed by ergonovinine, ergosine, *agroclavine*, *chanoclavine*, and traces of *ergonovine* and ergosinine (Wilkinson et al. 1987). I. coccinea var. hederifolia seed [fresh] yielded traces of *elymoclavine*, and 11.7% lipids (Genest & Sahasrabudhe 1966).

I. costata seed [fresh] yielded 3 ergoline alkaloids [0.046%].

I. diamantinensis seed [fresh] yielded 2 ergoline alkaloids [0.018%] (Amor-Prats & Harborne 1993).

I. digitata tubers have yielded 0.02% paniculatin, a glycoside, which showed oxytocic, hypertensive, respiratory stimulant, vasoconstrictor and bronchoconstrictor activity (Matin et al. 1969).

I. hederacea seed yielded 0.003% alkaloids [28% ergonovinine, 23% *elymoclavine*, 16% *agroclavine*, 16% *chanoclavine*, 16% *ergonovine*, trace *penniclavine*] (Wilkinson et al. 1986); as well as *lysergol* (Chao & Der Marderosian 1973a) and pharbitisin. The seeds are a drastic purgative, cathartic and anthelmintic (Nadkarni 1976). Other studies failed to detect any ergoline alkaloids (Abou-Chaar & Digenis 1966; Gröger 1963), and there may have been contamination with I. violacea seed in the positive tests.

I. hederifolia seed [fresh] yielded 0.004-0.016% ergoline alkaloids (Amor-Prats & Harborne 1993), though the higher value is quoted erroneously from Nair et al. 1986 [see above] and others have found none (Gröger 1963); another analysis found 0.0031-0.0044% alkaloids, consisting mostly of ergosine and *chanoclavine*, with lesser amounts of *elymoclavine*, and traces of *ergonovine*, ergonovinine and ergosinine (Wilkinson et al. 1987). The seed has also yielded pyrrolizidine alkaloids – 0.02% ipanguline A and 0.025% isoipanguline A. Roots yielded ipanguline B and isoipanguline B; aerial parts without seed yielded all four compounds, as well as 34 other ipangulines – total ipanguline content in shoots and young leaves was measured at 0.45% (Jenett-Siems et al. 1993, 1998).

I. hildebrandtii seed yielded 0.03% *festuclavine* and 0.2% cycloclavine (Stauffacher et al. 1969).

I. hybrida 'Darling' seed [fresh] yielded 0-0.016% alkaloids and 9.7-11.3% lipids (Genest 1965; Genest & Sahasrabudhe 1966; Taber et al. 1963a).

I. lacunosa seed yielded 0.001% alkaloids [62% *chanoclavine*, 38% ergosinine, trace *elymoclavine* and *agroclavine*]; interestingly, seeds that had been penetrated by the larvae of an unknown insect gave yields nearly double those of 'normal' seeds (Wilkinson et al. 1986). The plant has also yielded quamoclitic acid (Buckingham et al. ed. 1994).

I. leptophylla seed yielded 0.02% alkaloids [*chanoclavine*, *ergine*, isoergine, *ergonovine*, and unidentified ergolines] (Chao & Der Marderosian 1973a; Der Marderosian 1967).

I. muelleri seed [fresh] yielded 0.005-0.011% alkaloids [13.2% *ergine*, 11.5% isoergine, 6.4% *elymoclavine*, 4.8% *ergonovine*, 3.5% lysergic acid α-OH-ethylamide, 2.6% *penniclavine*, 2.4% ergometrinine, 2.1% *lysergol*, 2% isolysergic acid α-OH-ethylamide, 2% molliclavine, 1.8% *chanoclavine*-II, α-dihydrolysergol, and isochanoclavine, as well as other unidentified alkaloids]; 121-day old leaves yielded 0.0015% alkaloids, and similarly aged stems yielded 0.001% alkaloids (Amor-Prats & Harborne 1993; Chao & Der Marderosian 1973a; Everist 1974).

I. nil 'Scarlet O'Hara' seed [fresh] yielded 0-0.014% alkaloids, and 11.2-14.3% lipids. I. nil 'Royal marine' seed yielded 0.001% alkaloids. It is thought that these are non-ergoline alkaloids (Genest 1965; Genest & Sahasrabudhe 1966; Genest et al. 1965; Rice & Genest 1965; Taber et al. 1963a). Japanese strains ['Chiyo no okina', 'Matzukaze', and 'Yuki'] yielded 0.007-0.011% alkaloids (Staba & Laursen 1966); many contain none, including the 'Tall mixed', 'Candy pink' and 'Double rose marie' varieties (Friedman et al. 1989; Genest et al. 1965). Some of the positive results may have arisen from I. violacea seed contamination. Up to 0.07% alkaloids have been found in some strains of I. nil seed. The plant is known as a strong irritant purgative; a dose of 50 seeds can cause purging (Der Marderosian & Youngken 1966; Festi & Samorini 1999b; Genest & Sahasrabudhe 1966). This is most likely due to the purgative glycoside pharbitin, found at c.2% in seeds (Huang 1993). I. nil seeds also contain gibberellins (Matsuo et al. 1984) and the growth hormone muristerone A (Austin 2000).

I. obscura seed has yielded ipobscurine A [N-(p-coumaroyl)-*serotonin*] and ipobscurine B, an unusual *melatonin*-conjugate (Eich et al. 1989).

I. orizabensis seed [fresh] yielded 4 ergoline alkaloids [0.163%].

I. parasitica seed [fresh] yielded 13 ergoline alkaloids [0.16%]; foliage also bears significant quantities of the alkaloids (Amor-Prats & Harborne 1993).

I. pes-caprae mature seeds have been shown to contain gibberellins (Matsuo et al. 1984); fresh seed has also yielded 0.004-0.009% ergoline alkaloids (Amor-Prats & Harborne 1993; Rastogi & Mehrotra ed. 1990-1993), which were also found in the foliage (Tofern et al. 1999). The plant has also yielded 6"-O-acetylhirsutin (Buckingham et al. ed. 1994), pescapriside E, glycoretin (Cambie & Ash 1994), quercetin, 3',4'-dimethoxyquercetin, ferulic acid, vanillic acid, syringic acid and p-coumaric acid (Nair et al. 1986). Leaves contain citric, fumaric, maleic, malic, succinic and tartaric acids (Cambie & Ash 1994). The aerial parts showed anal-

gesic effects in mice, and were shown to contain alkaloids, steroids, terpenoids, and flavonoids (De Souzaa et al. 2000a). Leaves of ssp. brasiliensis contain triterpenes, steroids and small amounts of saponins (Aboriginal Communities 1988); indole alkaloids have been found in leaves and seeds of plants growing in Thailand, with higher levels in seeds (Jirawongse et al. 1979).

I. pes-tigridis seed [fresh] yielded 0.0025% ergoline alkaloids (Rastogi & Mehrotra ed. 1990-1993), though subsequent tests detected none (Amor-Prats & Harborne 1993).

I. petaloidea seed yielded 0.5-0.678% ergoline alkaloids, mostly *lysergol*, as well as *chanoclavine* and other ergoline alkaloids; the phytoecdisones [polyhydroxylated steroids] muristerone, ecdisone, crustecdisone and makysterone A were also obtained (Ferrari 1979, 1980). Leaves have yielded the alkaloid convolamine (Perry & Metzger 1980).

I. piurensis seed yielded 0.0024% *chanoclavine*, 0.0005% each of *ergine* and lysergic acid α-OH-ethylamide, and 0.0002% ergobalansinine; these are also found in the stems and leaves (Jenett-Siems et al. 1994; Tofern et al. 1999).

I. plebeia leaf, stem and fruit [combined] from Brisbane, Australia [harv. Apr.] gave weak-positive reactions for alkaloids in some tests (Webb 1949).

I. purpurea seed [fresh] yielded 0-0.0816% alkaloids [*chanoclavine*, *elymoclavine*, *agroclavine*, *ergonovine*, ergonovinine and ergosine in similar amounts; trace ergosinine], though the positive results may be due to confusion with I. violacea, as others have found no indole alkaloids (Amor-Prats & Harborne 1993; Der Marderosian & Youngken 1966; Hahn 1990; Taber et al. 1963a; Wilkinson et al. 1986); gibberellins have been reported from mature seeds (Matsuo et al. 1984). The plant has also yielded 4.8% of a purgative resin (Watt & Breyer-Brandwijk 1932) and 3,11-dihydroxytetradecanoic acid (Buckingham et al. ed. 1994). A dose of 100-150 seeds was deemed similar to 75-150mcg LSD, but lasting only 4 hours; higher doses produced pronounced side-effects, including narcosis, nausea, cold extremities and torpor (Festi & Samorini 1999b).

I. quamoclit seed [fresh] yielded 0.005-0.006% ergoline alkaloids, though subsequent tests found none (Amor-Prats & Harborne 1993); another analysis found 0.0043-0.0057% alkaloids, consisting mostly of *elymoclavine*, *chanoclavine* and ergonovinine, with smaller amounts of ergosinine and traces of *penniclavine* (Wilkinson et al. 1987).

I. riedelii has yielded 0.14% swainsonine, as well as calystegines B1, B2 & C1 (Barbosa et al. 2006).

I. rubra seed yielded unidentified ergoline alkaloids (Chao & Der Marderosian 1973a).

I. rubrocaerulea seeds have yielded 0.02-0.05% alkaloids – only *elymoclavine* was found in some samples; others contained up to 6 alkaloids [*chanoclavine*, *ergine*, isoergine, *ergonovine*, and lysergic acid α-OH-ethylamide]; others contained none. Similarly, aerial parts contained the previous 6 alkaloids [0.012%] in some samples (Gröger 1963). In feeding tests, detached leaves were shown to be capable of converting *elymoclavine* to *penniclavine* (Gröger 1964).

I. rubrocaerulea var. praecox seed [fresh] yielded 0.057% alkaloids (Taber et al. 1963a); others detected 0.01-0.04% alkaloids, including *ergine*, isoergine, *chanoclavine*, *elymoclavine* and other indoles (Beyerman 1964).

I. sericophylla has yielded 0.11% swainsonine (Barbosa et al. 2006).

I. sinensis seed [fresh] yielded 0.007% ergoline alkaloids, though subsequent tests found none (Amor-Prats & Harborne 1993), and the positive result was referenced erroneously from Nair et al. 1986 (see above).

I. tamnifera seed yielded unidentified ergoline alkaloids (Chao & Der Marderosian 1973a).

I. trichocarpa seed yielded 0.004% alkaloids [28% *chanoclavine*, 20% ergosinine, 19% *elymoclavine*, 16% *penniclavine*, 6% *agroclavine*, 5% *ergonovine*, 5% ergosine, trace ergonovinine and *festuclavine*] (Wilkinson et al. 1986).

I. violacea seed yielded 0.006-0.117% alkaloids [58.33% *ergine*, 8.33% isoergine, *agroclavine*, 8.33% *chanoclavine*, 8.33% *elymoclavine*, *festuclavine*, *lysergol*, isolysergol, *penniclavine*, 8.33% *ergonovine*, ergometrinine, lysergic acid α-OH-ethylamide, isolysergic acid α-OH-ethylamide, and 6 unidentified alkaloids] (Amor-Prats & Harborne 1993; Chao & Der Marderosian 1973a, 1973b; Der Marderosian & Youngken 1966; Hahn 1990; Hofmann 1961, 1963, 1995; Schultes & Hofmann 1980). Seeds were analysed for alkaloid content at different stages of maturity – alkaloid content was highest [c.0.1%] in early stages of development, though the major alkaloid at this stage was *chanoclavine*. The level of *ergonovine* decreased as maturation progressed, but its proportion of the total alkaloids increased. *Ergine* levels rose through maturation to become the dominant alkaloid at maturity. Second harvests of seed always yielded higher alkaloid levels (Genest 1966). Immature fruits from plants in Rockhampton, Queensland [Australia], harvested in December, tested weakly positive for alkaloids. The plants were identified as I. longiflora [a synonym of I. violacea], but the identification was uncertain (Webb 1949). Mature seeds have also been found to contain gibberellins (Matsuo et al. 1984). Aerial parts yielded a resinous glycoside, tricolorin A [0.4%] (Pereda-Miranda et al. 1993), and the stems have yielded calystegines [see **Convolvulus**] (Schimming et al. 1998).

I. violacea 'Blue star' fresh seed yielded 0.02-0.048% alkaloids and 16.4% lipids (Der Marderosian & Youngken 1966; Genest & Sahasrabudhe 1966).

I. violacea 'Flying saucers' fresh seed yielded 0-0.057% alkaloids [0.0025% *ergine*, 0.0053% isoergine, 0.0234% clavines], and 15.6% lipids; aerial parts [fresh] yielded traces-0.00035% alkaloids; roots [fresh] yielded 0-0.00033% alkaloids (Der Marderosian & Youngken 1966; Genest 1965; Genest & Sahasrabudhe 1966; Genest et al. 1965; Staba & Laursen 1966).

I. violacea 'Heavenly blue' fresh seed yielded 0.005-0.066% alkaloids [0.0077% *ergine*, 0.0042% isoergine and 0.0124% clavines; in another test (as % of total alkaloids) 30% *elymoclavine*, 40% *chanoclavine*, 9.7% each of *penniclavine*, ergosine and ergosinine, and traces of *agroclavine* and *ergonovine*], 0.31-0.84% *chlorogenic acid* and 15.2-22.1% lipids. Aerial parts [fresh] yielded 0.0025-0.0047% alkaloids; roots [fresh] yielded 0-0.0015% alkaloids (Der Marderosian & Youngken 1966; Friedman et al. 1989; Genest 1965; Genest & Sahasrabudhe 1966; Genest et al. 1965; Staba & Laursen 1966; Taber et al. 1963a; Wilkinson et al. 1986, 1987). As morning glory seeds are occasionally a contaminant of grain crops, such as soy, experiments were conducted with this cultivar to discover the relative degradation of the seed chemicals through the baking process, to simulate bread baked from contaminated grains. It was found that the ergoline alkaloids only experienced moderate loss, whilst *chlorogenic acid* content was almost totally destroyed (Friedman & Dao 1990).

I. violacea 'Major' fresh seed yielded 0.026% alkaloids and 16.3% lipids (Genest & Sahasrabudhe 1966).

I. violacea 'Pearly gates' fresh seed yielded 0.015-0.120% indoles [65.8% *tryptophan*, 10.7% *chanoclavine*, 1.1% *elymoclavine*, 2.7% *ergonovine*, 0.9% ergometrinine, 4.7% *ergine*, 0.23% isoergine and *penniclavine*], and 14.7-18.1% lipids. Aerial parts [fresh] yielded 0.0032-0.013% alkaloids; roots [fresh] yielded 0-0.0005% alkaloids (Beyerman 1964; Der Marderosian & Youngken 1966; Genest 1965; Genest & Sahasrabudhe 1966; Genest et al. 1965; Staba & Laursen 1966; Taber et al. 1963a).

I. violacea 'Summer skies' fresh seed yielded 0.053-0.079% alkaloids [*ergine*, isoergine, *ergonovine*, *elymoclavine*, *chanoclavine*, *penniclavine* and *tryptophan*] (Der Marderosian & Youngken 1966).

I. violacea 'Wedding bells' seed yielded 0.023-0.075% alkaloids [0.011% *ergine*, 0.0026% isoergine and 0.0147% clavines] and 15.2% lipids; the alkaloidal fraction produced an excited intoxication in mice, the excitation being more prevalent than in the mouse intoxication caused by the 'Pearly gates' variety (Der Marderosian & Youngken 1966; Genest 1965; Genest & Sahasrabudhe 1966; Genest et al. 1965; Rice & Genest 1965).

The human LD50 for the alkaloid extract of I. violacea horticultural varieties was estimated to possibly be 1-2g (Genest et al. 1965).

I. wrightii seed yielded 0.0023-0.0038% alkaloids, consisting mostly of ergosine, with lesser amounts of *chanoclavine*, ergosinine, *penniclavine*, *agroclavine* and *elymoclavine* (Wilkinson et al. 1987).

Ipomoea violacea is an annual/perennial vine, much branched, glabrous throughout. Leaves membranaceous, entire, ovate, 4-10cm x 3-8cm, deeply cordate, long acuminate, often soon caducous; petioles up to 1.5cm long. Inflorescence cymose, 3-4-flowered; peduncle thickened, hollow, wandlike, longer than petiole; bracts triangular-ovate, acute, up to 1.2mm long; bracteoles similar but minute. Flowers 5-7cm wide, solitary or clustered, axillary; sepals triangular-ovate, acute to obtuse, often mucronulate, 5-6mm long, subequal, exterior ones marginate, dorsally carinate; corolla infundibuliform, 5-7cm long, tube white, 5-8mm diameter, corolla limb white, red, purple, violet-blue or blue, often spotted or blotched, midpetaline bands well-defined by 2 distinct nerves; stamens 5, included. Ovary 2-4 celled; ovules 4(-6); style simple, filiform; stigma capitate. Fruit a dehiscent ovoid capsule, 13mm long, 4(-6)-valved; seeds 1-4(-6), glabrous, very dark brown to black, 3-angled, back rounded (like a c.¼ segment of a hemisphere) with a central, shallow groove, other sides concave, hilum pear-shaped, depressed, containing translucent trichomes. Size of seeds differs in cultivars, though wild plant seed is 5.5-6.5 x 3-3.5mm, 100 seeds weighing c.2.43g. Seeds of cultivars are generally larger and heavier.

From w. & s. Mexico to Guatemala, West Indies and tropical S. America (Bailey 1968; Der Marderosian et al. 1964; Schultes & Hofmann 1980; Wagner et al. 1990).

Gather seeds as pods become brown, papery and dry. Seeds should be nicked and soaked for 2hrs in warm water before sowing; plant about 1cm deep. Grows in strong, well-drained soil in a sunny site; hardy once established. Water moderately (pers. comms.; pers. obs.).

IRYANTHERA

(Myristicaceae)

Iryanthera longiflora *Ducke* **(I. paradoxa** *(Schwacke) Warb.***)** – cumala colorada

Iryanthera macrophylla *(Benth.) Warburg* **(I. dialyandra** *Ducke***; Myristica macrophylla** *Benth.***; Palala macrophylla** *(Benth.) Kuntze***)** – cumala

Iryanthera ulei *(Benth.) Warburg* **(I. congestiflora** *J.F. Macbr.***; I. hostmannii** *(Benth.) Warb.***; I. leptoclada** *Markgr.***)** – wiri-saka, chaw, ka-wee-a-ka-he, peé-wa-ree, te-roó-rai, ucuúba, cumala

The barks of these plants were reportedly once used by the Bora and Witoto of Amazonian Peru to prepare orally-ingested entheogenic pellets, in the same manner as with **Virola** spp. [probably taken sublingually – see **Virola**]. The aromatic bark of I. ulei is stripped and used by the Secoya to make perfumed arm-bands, and they also use the leaves as a perfume. I. ulei bark resin is also used in Peru for what may be oral thrush. The inner bark and sap of many species [such as I. cf. elliptica, I. juruensis and I. paraensis] are used to treat fungal infections. Leaves have been used as a poultice for wounds (Ott 1993; Schultes & Holmstedt 1971; Schultes & Raffauf 1990; Schultes et al. 1977a). In the Río Purús of Brazil, I. tricornis ['pucuna caspi', 'balo'] is frequently used to manufacture blowguns (Duke & Vasquez 1994; Schultes & Raffauf 1990).

I. coriacea and I. juruensis trunk woods yielded flavans [3',4-dihydroxy-5,7-dimethoxyflavan and 2'-OH-7-MeO-4',5'-methylenedioxyflavan] (Franca et al. 1974).

I. macrophylla bark was analysed and found to contain no detectable alkaloids (McKenna et al. 1984b), though material reported as I. ulei did contain alkaloids [see below] (Holmstedt et al. 1980; Schultes & Raffauf 1990). The plant has yielded juruenolide and 1-(2,4-dihydroxy-6-MeO-phenyl)-3-(3,4-dimethoxyphenyl)-1-propanone (Buckingham et al. ed. 1994).

I. ulei bark yielded 0.000013% *5-methoxy-DMT* in one analysis (Holmstedt et al. 1980), though a later analysis of this species found no alkaloids (McKenna et al. 1984b). Schultes & Raffauf (1990) report that the material analysed by Holmstedt et al. (1980) was actually I. macrophylla. I. ulei bark has yielded c.0.0035% dihydrochalcones, lignoflavonoids [iryantherins B (0.004%), D (0.0032%), E (0.0039%) & F (0.0009%; a ligno-bis-dihydrochalcone)], and neolignans [0.0018% trans-burchelin and 0.0012% cis-burchelin]; trunk wood has yielded 0.0006% dihydrochalcones, 0.025% diarylpropanes, 0.09% sitosterol and 0.036% juruenolide, a lactone (Conserva et al. 1990a, 1990b; Vieira et al. 1983).

I. crassifolia, I. juruensis and I. paraensis barks were analysed, and found to contain no detectable alkaloids (McKenna et al. 1984b). As I. macrophylla and I. ulei were also found to be alkaloid-negative by McKenna et al. [though not ignoring the positive report of Holmstedt et al. above], it would seem either that these plants are highly chemically-variable, and/or alkaloids may not actually be the psychoactive agents in preparations made from these plants. Perhaps knowledge of the location of specimens with desirable chemistry has diminished over time, as more powerful plant-teachers have since come into greater use [ie. **Virola**]. Perhaps the samples analysed were simply collected at times of low or nil alkaloid content, and samples collected at other times from particular patches would contain useful levels of alkaloids. Further studies are needed, which could be difficult as these plants might no longer be used as psychotropes, complicating attempts to obtain reliable information from native sources.

Iryanthera macrophylla is a monoecious tree, to 17m tall; inner bark frequently exuding reddish liquid; branches ferruginous-strigose when young. Leaves alternate, simple, entire, oblong to obovate-oblong, glabrous, thick-coriaceous, fragile when dry, often finely rugose or minutely papillose, 17-35(-40) x 5-12(-14)cm, subcordate, rounded, or obtuse at base, apex obtusely cuspidate or short-acuminate, costa very prominent, venation convolute, pinnate, secondary nerves 14-20 on each side, anastomosing toward margins; petioles 10-20mm long, robust, narrowly winged distally. Inflorescences minutely strigose externally, fasciculate-racemose or narrowly-paniculate, 1-3 in leaf axils, or on defoliate branches, female inflorescences often on old bark of trunk or branches; male inflorescences elongate, (2-)3-7(-11)cm long, rachis stout, swollen at fascicles; fascicles 6-13 per inflorescence, essentially sessile, flowers 4-12 per fascicle, apetalous; pedicels slender, to 5mm long, bracteolate at summit; bracteole cupuliform or cleft to base, 0.7-1.5mm long; perianth campanulate, 2-3mm long, flaring distally, 3-lobed about 1/3 of length, lobes valvate, thin-carnose and strigose; filament column 1.5-2.2mm long; anthers 3(-4), c.0.5mm long, free to base, 2-celled, dehiscing longitudinally. Ovary superior, sessile, usually ellipsoid, glabrous, 1-celled; ovule 1, +-basal; style short; stigma subsessile. Mature fruits usually 3-4 per inflorescence, transversely ellipsoid, coriaceous, carinate, 2-valved, 8-24mm long, 10-26mm broad, pericarp 1.5-6mm thick, usually woody, covered with an aril, aril inconspicuously laciniate distally; seeds transversely ellipsoid or subglobose, uniform in colour.

Amazonian Peru [Loreto – Rio Huallaga basin, 220m], Brazil, Guyana (Smith 1938).

ISLAYA

(Cactaceae)

Islaya minor *Backeberg* **(I. bicolor** *Akers et Buining***; I. brevicylindrica** *Rauh et Backeb.***; I. copiapoides** *Rauh et Backeb.***; I. divaricatiflora** *Ritter***; I. flavida** *Ritt.***; I. grandiflorens** *Rauh et Backeb.***; I. grandis** *Rauh et Backeb.***; I. islayensis** *(Först) Backeb.***; I. islayensis var. minor** *(Backeb.) Ritter***; I. krainziana** *Ritt.***; I. maritima** *Ritt.***; I. minuscula** *Ritt.***; I. mollendensis** *(Vaupel) Backeb.***; I. paucispina** *Rauh et Backeb.***; I. paucispinosa** *Rauh et Backeb.***; I. unguispina** *Ritt.***; Eriosyce islayensis** *(Först.) Kattermann***; Neoporteria bicolor** *Akers et Buin.***; N. islayensis** *(Först.) Donald et Rowley***; N. krainziana** *(Ritt.) Don. et Rowl.***; Parodia minor** *(Backeb.) Borg***)**

This small, slow-growing cactus from s. Peru is not known to be used in any way. It has yielded 0.0017% *mescaline*, as well as 0.0038% *DMPEA*, *phenethylamine*, *tyramine*, N-methyltyramine, 3-MeO-tyramine [homovanillylamine], *hordenine*, corypalline [7-OH-6-MeO-2-methyl-THIQ] and *pellotine* (Doetsch et al. 1980).

Islaya minor is a simple, short plant, +- spherical, to c.13cm tall, 7cm across; ribs to c.17, 1cm wide, 6mm high; areoles 3cm apart, initially bearing whitish-grey felt; radial spines 20-24, to 6mm long, thin; centrals 4, cruciform, to 18(-20)mm long, stouter, thicker below; all spines rigid, black at first, becoming grey. Flowers 2.2cm across, gold to light greenish-yellow, arising from felted area. Fruit hairy, carmine, to 6mm long, at first globular, ripening to elongate, with some persistent bristles and perianth at apex; seeds flat black.

Southern Peru [above Mollendo] (Backeberg 1959, 1976).

Prepare soil from 2 parts grit/1 part humus; requires good drainage, and less water than most cacti; withold all water in winter; min. temp. 8°C. Adapt to full sun when several years old; keep lightly shaded otherwise. Older plants often do not do well on their own roots, and grafting is recommended (Trout & Friends 1999).

ISOTOMA

(Campanulaceae/Lobeliaceae)

Isotoma anethifolia *Summerh.*

Isotoma longiflora *(L.) C. Presl.* **(Hippobroma longiflora** *(L.) G. Don.***; Laurentia longiflora** *(L.) E. Wimm.***; L. longiflora** *(L.) Endl.***; Lobelia longiflora** *L.***; Rapuntium longiflorum** *Mill.***)** – star of Bethlehem, cimora toro, misha veneno, estrella, lagrimas de San Diego, revienta caballos

Isotoma petraea *F. Muell.* – rock isotome, rock bluebell, euro fingers, wild tobacco, minekalpa, tundi-wari, pulbawari, anterlp, irranerratye, wanngati, multu, yarrampa, mara-kanyala

Isotoma spp.

I. longiflora is reportedly sometimes added to **Trichocereus** pachanoi brews in Peru, along with other plants (Davis 1983; Schultes 1967a). The Cuna of Panama also use the latex of I. longiflora medicinally (Ott 1993), and the herb has been decocted to treat asthma (Usher 1974).

An Australian species, I. petraea, is sometimes chewed [or occasional-

ly decocted and drunk] as a 'pituri' substitute [see **Duboisia**], or mixed in small quantities with pituri or wild tobacco [see **Nicotiana**] to add potency, in the Mt. Margaret region. For use, the leafy stalks are fire-dried and powdered, sometimes mixed with **Acacia** aneura ash. They are said to have 'narcotic and stimulating' effects, as well as causing analgesia and treating colds. It is considered by some to be very poisonous, and its juice can cause soreness or even temporary blindness if brought into contact with the eyes. The crushed foliage is also sometimes used as a poultice for headaches. This species is also suspected of having caused stock intoxications (Cribb & Cribb 1981; Lassak & McCarthy 1990; Latz 1995; Low 1990; Reid & Betts 1979).

The active chemicals in some Isotoma spp. are *lobeline* and related alkaloids, which have pharmacological activities comparable in some ways to *nicotine* [see **Lobelia**, *Chemical Index*].

I. anethifolia from Australia yielded 0.24% alkaloids, consisting of partially racemic *lobeline*, lobelanidine, and 1-[6'-(2"-OH-2"-phenylethyl)-1'-methyl-1',2',5',6-tetrahydroxypyridin-2'-yl]butan-2-one. The alkaloid fraction caused "neurological and respiratory deficits" in mice, emesis and convulsions in cats, and was cardioactive in cats and dogs (CSIRO 1990); however, the doses used were not specified. Herbage from Stanthorpe, Queensland [harv. Nov.] tested strongly positive for alkaloids (Webb 1949).

I. fluviatilis from Stanthorpe [harv. Nov.] gave negative tests for alkaloids (Webb 1949).

I. longiflora has yielded [w/w] 0.00066% *lobeline*, 0.0004% lobelanidine, lobelanine and 0.002% (-)-cis-8,10-diphenyllobelidiol (Arthur & Chan 1963). Root and leaf from Innisfail, Queensland [harv. Aug.] tested strongly positive for alkaloids (Webb 1949).

I. petraea has yielded 0.26% alkaloids with *lobeline*-like activity (CSIRO 1990), and probably contains *lobeline* itself (Lassak & McCarthy 1990).

Isotoma longiflora is an erect annual or biennial herb; stems coarse, fleshy, 15-50(-80)cm long, glabrous or pubescent. Leaves alternate, 6-25 x 1.5-8cm, glabrous or pubescent on veins, apex obtuse to acute, mucronulate. Flowers in racemes or solitary and axillary; peduncles long, with leaf-like bracts; pedicels erect at anthesis, but declined in fruit, 5-10mm long, pubescent; hypanthium 10-nerved, 8-11 x 3-5mm, sparsely pubescent; calyx shortly tubular, lobes 10-22mm long; corolla tubular, slightly zygomorphic, 7-15mm long, pubescent externally, glabrous within, +- notched on anterior, with lobes almost equal, spreading horizontally, very shortly and obliquely campanulate at base, lower 3 lobes often with markings; stamens 5, fused adnate to corolla tube; anthers fused around style, white, anterior anthers smaller, bearing a long bristle, upper 3 slightly longer and +- curved down at apex onto lower ones. Ovary inferior or semi-inferior, 2-locular; style 1, slender; stigma +- hairy, slightly swollen, scarcely 2-lobed. Capsule ellipsoid, 1.8-2.5 x 1-1.5cm, pendent, 2-valved, loculicidally dehiscent within calyx lobes; seeds 0.6-0.8mm long, numerous.

In low elevation areas with moderate rainfall, especially disturbed areas; originally endemic to West Indies, now naturalised as a weed throughout much of the tropics (Carolin & Tindale 1994; Harden ed. 1990-1993 [for genus detail]; Wagner et al. 1990).

JASMINUM

(Oleaceae)

Jasminum abyssinicum *R. Br.*
Jasminum floribundum *R. Br.* - hab el tsalim
Jasminum grandiflorum *L.* **(J. officinale var. grandiflora** *(L.) Stokes***)** – jasmine, jati
Jasminum officinale *L.* – common jasmine, white jasmine, queen of the night, chamba, jazminero, mallika
Jasminum spp. – jasmine

Jasmine, an oil normally obtained from J. officinale or J. grandiflorum, is well known as a perfume of love. The Indian god of love, Kama, is said to tip his arrow with jasmine flowers in order to pierce the heart through the senses. The flowers are said to make the mind receptive to the energies of mantras. Ayurvedists consider it to be useful for heart diseases, diabetes, biliousness, burning sensations, eye, tooth or mouth problems, skin and blood diseases, and thirst; it is also sedative, antispasmodic, tonic, uplifting, euphoric, inebriating, aphrodisiac, emmenagogic, haemostatic, emollient and antibacterial. The medical formulary of Al-Kindi advised that oil of jasmine and 'asafoetida' [see **Ferula**] be combined for a few days, before applying it to the penis before intercourse, for an effective aphrodisiac for both partners. The oil may also be mixed with sesame oil and rubbed onto the head as a nervine sedative. The leaves may be boiled in oil to yield a balsam which is applied to strengthen vision, and to treat insanity. The fruits of the plant are considered narcotic. Indians make an offering of 'yellow jasmine' [J. humile] to Shiva and Ganesh. The Chinese sometimes give balls of jasmine to drunk guests to 'clear the head', and they used it to clear the atmosphere around sick people. 'Arabian jasmine', J. sambuc, is added to jasmine tea [see **Camellia**] in China for its scent and flavour. It is apparently used in some Buddhist ceremonies (Bremness 1994; Chevallier 1996; Frawley & Lad 1986; Kirtikar & Basu 1980; Lawless 1995; Martinez-Lirola et al. 1996; Nadkarni 1976). Leaves of J. abyssinicum in Eritrea, and J. floribundum in Abyssinia, have been used as inebriants (Rätsch 1998).

J. grandiflorum flowers have yielded up to 0.38% essential oil, consisting of 54-65% benzyl acetate, 20% linalyl acetate, 15% linalool, 24% free alcohols, 3.5% primary alcohols, 2.5-3% cis-jasmone, 3% benzyl benzoate, vanillin, 10% geraniol, 2.5% indole, 0.5% methyl anthranilate, farnesol, nerolidol, phytol, *eugenol* and numerous other trace components. The best quality oil [and best yield] is obtained from flowers harvested in the early morning, or in the evening (Battaglia 1995; Kotlyarova 1959; Rastogi & Mehrotra ed. 1990-1993). Apparently jasmine oil stimulates *enkephalin* release in the brain [note – Lawless gave this as 'encephaline', which as far as I can tell, does not exist, leaving *enkephalin* as the only likely neurotransmitter this could refer to – Ed.] (Lawless 1994).

J. racemosum from Queensland [Australia] tested positive for alkaloids in leaf and root [leaf strongly so, in some tests]; bark gave both positive and negative results in different tests. Leaf of J. simplicifolium and herb of J. suavissimum also tested positive for alkaloids (Webb 1949).

Jasminum spp. have also yielded jasminine, syringin, cantleyine, γ-caryophyllene and octahydro-6-OH-7-methyl-1-oxocyclopenta[c]pyran-4-carboxylic acid (Buckingham et al. ed. 1994).

Jasminum officinale is a twining shrub, puberulous when young; branches striate. Leaves opposite, simple, imparripinnate, 5-10cm long; leaflets 3-7, the terminal one 2.5-7.5 x 1-2.5cm, usually distinctly larger than the rest, ovate or lanceolate, acuminate, the lateral leaflets shorter and relatively wider, acute, sessile or shortly petiolulate, the distal pair sometimes with wide connate bases; petiole and rachis narrowly margined. Flowers 1.7-2.5cm across, in terminal few-flowered cymes or corymbs and axillary pedunculate few-flowered cymes shorter than the leaves or the cymes often reduced to a single flower; pedicels of the cyme-flowers 7.5-18mm long, those of the solitary and corymb-flowers often much longer; bracts up to 1.3cm long, linear-subulate or narrow-linear; calyx 7.5-18mm long, puberulous, tube 2.5-3.8mm long, lobes 5, subulate, 2-4 times as long as tube; corolla hypocrateriform, usually white, tube narrow and 1.3-1.8cm long, with 5 ovate or elliptic spreading lobes, imbricate in bud; stamens 2, included in corolla tube; filaments very short; anthers attached at the back near base, connective usually mucronate. Ovary 2-celled; ovules usually 2 in each cell, attached near base; style cylindric; stigma at length usually 2-fid. Berry didymous or often by suppression simple; carpels 2, 7.5-10mm long, ellipsoid or subglobose, colourless, translucent; seed usually solitary in each carpel.

Himalaya from the Indus east, into the inner valleys of India, as well as in Afghanistan and Iran; often cultivated (Kirtikar & Basu 1980).

Jasmine oil is very delicate; the flowers are handled carefully after harvesting, and kept cool. One method of extracting the oil involves scattering the flowers over trays or glass plates smeared with purified odourless oil. After 1-4 days, the flowers have withered, and their scent has passed into the oil. The oil may be further enriched by adding more fresh flowers, anywhere up to 20 times. This procedure is known as 'enfleurage' extraction, and produces an oil known as an 'enfleurage pomade'; this may be made into 'enfleurage absolute' by washing the oil with alcohol. An oil of lower purity [but higher yield] is obtained by macerating the flowers in cold-pressed vegetable oil, in a sealed vessel, for 4-8 weeks [shaking once a day] before straining the oil (Battaglia 1995).

JATROPHA

(Euphorbiaceae)

Jatropha curcas *L.* **(J. moluccana** *Wall.***; Castiglionia lobata** *Ruiz et Pav.***; Curcas purgans** *Medic.***)** – physic nut, angular-leaved physic nut, purging nut, bhernda, jangli-erandi, dandenahri, kesugi
Jatropha dioica *Cerv.* **(Mozinna spathulata** *Ort.***)** – sangre de drago, drago, leather stem, rubber plant, tlapelex patli
Jatropha gossypiifolia *L.* **(Adenoropium gossypiifolium** *(L.) Pohl.***)** – piñón colorado, chuvanna kodala-vanakku
Jatropha grossidentata *Pax et Hoffm.* - purgative nut, canioja, maske engioatite
Jatropha macrantha *Arg.* - huanarpo macho
Jatropha moluccana *L.* **(Aleurites moluccana** *(L.) Willd.***; A. triloba** *Forst. et Forst.***)** – candlenut tree, Indian walnut, tarkal, nappalla, askhota, akhrot

J. dioica is thought to most likely be the herb 'drago' documented in the 19th century to have been used by Native Americans of s.e. Texas, who smoked the leaves and bulbs of the plant to induce 'ecstatic visions' (Lipp 1995). In n.e. Mexico, extracts of the plant are used to treat toothache, gum disease and skin cancer (Villarreal et al. 1988), and act as an astringent (Jiu 1966). The related J. gaumeri ['pomolche'] from Mexico is used to treat snakebite, in the form of a root decoction (Usher 1974). Resin

from Jatropha spp. may also be used as 'copal' incense [eg. see Bursera and Protium in *Endnotes*] (Case et al. 2003).

Seeds of the Indian J. gossypiifolia are emetic, and are said to cause insanity (Nadkarni 1976). In Peru, J. gossypiifolia leaves are used as a defense against sorcerers; only 5-lobed leaves are used for this purpose (Luna & Amaringo 1991). J. grossidentata is used in Paraguay, where Ayoré shamans smoke the dried root for shamanic initiation, and to communicate with animal spirits. However, one researcher who tried it under the supervision of an Ayoré shaman perceived no effects. The Lengua-Maskoy consider it to have magical and dangerous properties, causing sore eyes with conjunctivitis, and they do not touch it. J. macrantha is used in n. Peru as a popular male aphrodisiac. J. multifida is sometimes known as 'cabalonga' [see **Strychnos**, and Thevetia in *Endnotes*] and thus might be psychoactive (Rätsch 1998; Schmeda-Hirschmann et al. 1992). J. curcas has reportedly been used in Peru as an ayahuasca additive [see **Banisteriopsis**], also known as 'piñón colorado'; this might perhaps be a confusion with J. gossypiifolia. Two ayahuasqueros reportedly added the leaves [4-10] to their ayahuasca, which also consisted of **Banisteriopsis** caapi ['12 pieces'], **Diplopterys** caberana [200 leaves], and a Dieffenbachia sp. ['patiquina', 3 leaves; see *Methods of Ingestion*] in one case; B. caapi ['8-12 pieces'], **Psychotria** viridis [30 leaves], and **Brunfelsia** grandiflora [10 leaves] in the other (Gnostic Garden 2001). The seed of J. curcas yields an oil ['curcas oil'] that is used as a purgative, lubricant and lamp oil (Usher 1974). In India, the seeds are said to be 'acro-narcotic' (Nadkarni 1976); they have been used to poison rats (Bremness 1994), and as an ordeal poison in e. Africa (De Smet 1998). The roasted nuts of J. moluccana [a plant found from n.e. Australia to India] are taken as an aphrodisiac, yet raw they are a poisonous purgative (Lassak & McCarthy 1990; Nadkarni 1976).

J. curcas seeds contain curcin [jatrophin], a lectin (De Smet 1998) similar to ricin from Ricinus spp., as well as caseine and c.30% of a fixed oil contaning jatrophic acid (Nadkarni 1976).

J. dioica var. sessiflora roots have yielded the diterpenes riolozatrione, epoxytrione and citlalitrione, as well as β-sitosterol and jatropholone B (Villarreal et al. 1988).

J. gossypiifolia roots have yielded 2α-OH-jatrophone, 2β-OH-jatrophone and 2β-OH-5,6-isojatrophone; and a lignan, 2-piperonylidene-3-veratryl-3R-γ-butyrolactone [a GBL-derivative – see *GHB* in *Chemical Index*]. Seeds contain an oil rich in saturated acids [73.8% of oil], including mostly palmitic acid [31.4%] (Rastogi & Mehrotra ed. 1990-1993).

J. grossidentata root has yielded the diterpenoids caniojane, 1,11-bis-epi-caniojane, jatrogrossidione, 2-epi-jatrogrossidione, jatrogrossidion, 4E-jatrogrossidentadion, 4Z-jatrogrossidentadion, 15-epi-4E-jatrogrossidentadion, 15-epi-4Z-jatrogrossidentadion, isojatrogrossidion, 2-epi-isojatrogrossidion, 2-OH-isojatrogrossidion and 2-epi-OH-isojatrogrossidion; as well as a coumarino-lignan and another unnamed lignan (Jakupovic et al. 1988; Schmeda-Hirschmann et al. 1992)

J. moluccana seed [both mature and immature] tested strongly positive for alkaloids, from plants growing in Queensland, Australia. Bark harvested in February gave negative results (Webb 1949).

J. podagrica stems have yielded the alkaloid tetramethylpyrazine, which has been shown to be hypotensive, spasmolytic, and cardiac depressant, as well as blocking neuromuscular transmission, in animal experiments (Ojewole 1980).

J. capensis, J. curcas and J. multifida all tested positive for HCN (Watt & Breyer-Brandwijk 1962).

Jatropha dioica var. dioica is a perennial, scarcely woody shrub; rootstocks buried, orange, horizontal, to 1m or longer; stems thick, fleshy, terete, folded on drying, simple or sparingly branched, rising at intervals, wand-like, 20-60cm tall, usually arcuate, with short lateral spurs; sap clear, astringent, turning blood-reddish on exposure to air. Leaves fasciculate on the spurs, subsessile, deciduous, blades spatulate or linear, widest towards apex, rarely palmately 2-3-lobed with the middle lobe the longest, apex usually blunt, base narrowed, margin entire, mostly 6-10mm wide, (2-)5-6 times as long as wide; stipules subulate-lanceolate, c.2.5mm long, early deciduous. Male and female flowers on separate plants. Male flowers in greatly reduced cymes, appearing to be in dense terminal or axillary fascicles; bracts and sepals 5, +- scarious, usually entire and non-glandular; calyx 3-3.5mm long, silvery-puberulent throughout; corolla whitish, about ½ as long as calyx, cylindrico-urceolate with recurved lobes, the reddish tube usually longer than lobes and +- hirsute within at base; petals 5, alternate with sepals; glands 5, opposite sepals; stamens regularly 10, the filaments partially united; anthers ovate to linear, often 1mm long or less. Female flowers in reduced, often merely 1-flowered cymes; sepals 5, herbaceous; corolla cylindrico-urceolate with recurved lobes, the tube usually longer than lobes and more or less hirsute within at base; petals 5, alternate with sepals; locules of ovary and styles 1-2, with 1 ovule in each locule; styles (when 2) coherent to some extent, unequally or irregularly bilobed; stigmas thickened and fungoid. Capsules 1-2-locular, each locule 1-1.2cm thick, about 15mm long (thus, when 2-locular, fruit is wider than long); locules apiculate and loculicidal; seeds subglobose or somewhat flattened along ventral line, essentially smooth and brownish.

In scrub; s. & w. Texas [common in Rio Grande Plains, n.w. to Val Verde county, and n. to Bexar, Blanco and Uvalde counties], s. to Oaxaca, Mexico (Correll & Johnston 1970).

JUNIPERUS

(Cupressaceae)

Juniperus angosturana *R.P. Adams*

Juniperus communis *L.* – common juniper, ginevro, ginepro, zinevro, dhupi

Juniperus excelsa *M. Bieb.* **(J. foetida var. excelsa** *(M. Bieb.) Spach***)** – Greek juniper, spiny Greek juniper

Juniperus indica *Bertoloni* **(J. wallichiana** *Hook. f. et Thomson ex Parl.***; Sabina wallichiana** *(Hook. f. et Thomson ex Parl.) W.C. Cheng et L.K. Fu***)**

Juniperus macropoda *Boiss.* **(J. excelsa** *Wall.* **; J. excelsa var. farreana** *P.N. Mehra***; J. excelsa** *Marschall et Bieb.* **var. polycarpos** *(K. Koch) Takhtajan***; J. excelsa var. polycarpos** *(K. Koch) Silba***; J. polycarpos** *K. Koch.***; J. seravschanica** *Komarov***; J. turcomanica** *B.A. Feltsch.***)** – Himalayan juniper, Indian juniper, dhup

Juniperus oxycedrus *L.* **(J. rufescens** *Link***)** – Spanish cedar, prickly juniper, ginebró, ginebre, enebro de la miera, cade

Juniperus pseudosabina *Fisch. et C.A. Mey.* **(J. centrasiatica** *Komarov***; J. sabina** *Pall. non L.***; Sabina centrasiatica** *(Kom.) Cheng et Fu***; S. fischeri** *Antoine***; S. pseudosabina** *(Fisch. et C.A. Mey.) W.C. Cheng et W.T. Wang***)** – scrub juniper, xinjiang juniper, dwarf pine, shug-pa

Juniperus recurva *Buch.-Ham. ex D. Don* **(J. religiosa** *Royle ex Carrière***; Sabina recurva** *(Buch.-Ham. ex D. Don.) Antoine***)** – Himalayan juniper, drooping juniper, high-altitude juniper, dhupi

Juniperus scopulorum *Sarg.* **(J. occidentalis var. pleiosperma** *Engelm.***; J. virginiana var. montana** *Vasey***; J. virginiana var. scopulorum** *(Sarg.) Lemmon***; Sabina scopulorum** *(Sarg.) Rydb.***)** – mountain red cedar, Colorado red cedar, Rocky Mountain juniper, weeping juniper

Juniperus virginiana *L.* **(Sabina virginiana** *(L.) Antoine***)** – red cedar, eastern red cedar, southern red cedar, Virginia red cedar, juniper bush, cedar apple, maazi, tawatsaako, hante, hante sha, savin

Juniperus spp. – junipers, gin berry, ginepro, enebro

'Junipers' are a common group of trees worldwide, cultivated or wild, with a long history of medicinal and magical use. The ancient Egyptians made use of J. drupacea and J. phoenicea [as well as Cedrus libani] as sources of 'cedar oil', to be used for sacred incenses and in the mummification process. Ancient Germanic peoples had a reverence for the juniper as the 'tree of life', or 'world tree', and throughout Europe even now one might find sprigs of juniper hung over doorways as protection against evil – a reminder of mediaeval ages when juniper branches were burnt frequently to dispel evil beings. Germanic and Finnish peoples once added juniper berries to their beer [see *Methods of Ingestion*], and a simple decoction of the berries was said to bring the gift of prophecy. Juniper berries have been said to increase male potency when carried, a questionable proposition (Cunningham 1994; Lawless 1994; Rätsch 1992).

In the area around n.w. Pakistan live the Dards and the Kaffir, whose shamans have a mystical relationship with juniper. They, like the Hunza, use it by inhaling the smoke of the burning plant and dancing into a drumbeat-driven trance. The Hunza also sometimes drink warm goat's blood in this ritual, and add **Peganum** harmala seeds to the burning vegetation. Many Siberian shamans inhale juniper smoke to fall into a stuporous intoxication, as do Sherpa, Tibetan, Tamang and Nepali shamans in the Himalayas. Himalayan usage is usually centred on branch tips of J. macropoda, J. communis and J. recurva. In Tibet, J. pseudosabina ['shug-pa' – also a name applied to other valued incense junipers in Tibet] is burned as incense to treat delirium (Clifford 1984; Müller-Ebeling et al. 2002; Rätsch 1992); likewise, in India J. macropoda smoke is inhaled to treat delirium of fever (Nadkarni 1976). Tibetan Bon shamans offer juniper branches in ritual sacrifices, as well as using the berries "as a narcotic to induce ecstatic trances". In Tibet, juniper incense is also called 'tsang', and sacred juniper trees are believed to be home to spirits. The column of smoke from such incense is said to form a kind of magical ladder meeting the sky, which coaxes deities to descend. Women may smoke their genitals with juniper incense to entice spirits of recently deceased lamas to reincarnate in their wombs (Dunham et al. 1993).

Junipers and/or cedars are generally highly revered by native N. American tribes for their endurance and longevity, as well as for their medicinal and spiritual properties. Native American 'peyote' groups [see **Lophophora**], especially the Tarahumara, may burn J. virginiana during all peyote rituals as a purifying incense. The leaves and berries may also be smouldered in sweat lodges for their therapeutic properties. The Pawnee inhaled the smoke to relieve nervousness and nightmares, and the Cheyenne used it as a sedative tea to relieve coughs and hyperactivity (Kindscher 1992; Schultes 1937a; Rätsch 1992).

Following the reported Asian use of J. macropoda and similar species, they have been suggested for use as a 'legal hallucinogen' (Gottlieb

1992; Siegel 1976). Gottlieb (1992) gave directions for use – "Leaves and branches are spread upon embers of fire. Person places blanket over head while inhaling smoke" – though he probably had not tried this himself.

J. communis is the most commonly used species of juniper medicinally and commercially. Native Americans boiled the berries for colds, and they were later used to flavour gin. The berries yield an essential oil which is aphrodisiac, nervine, sudorific, antiseptic, diuretic, antirheumatic, antiinflammatory, digestive and detoxifying. Steam inhalations of the berries are excellent for coughs and colds. The oil may irritate the skin, and should not be used by pregnant women (Bremness 1994; Chiej 1984; Lawless 1994; Mabey et al ed. 1990). In Tuscany, Italy, branches of the wild plant are burned on Christmas eve to prevent the 'evil eye' and bring good omens (Pieroni & Giusti 2002).

Juniperus spp. have broadly similar effects, and apart from those listed under the species below, the following compounds have been found in the genus – silicolin [deoxypodophyllotoxin], dihydroanhydro-podorhizol, savinin, sugars and vitamin C (Harborne & Baxter ed. 1993; Mabey et al. ed. 1990). Some species not otherwise mentioned here have leaf essential oils very rich in *camphor*, such as J. ashei [64.9%], J. saltillensis [42.1%], J. osteosperma [33.4%], and J. pinchotii [31.4%] (Adams 2000b). Essential oil contents may vary considerably even within trees of the same species, though the least variation is encountered in winter (Tatro et al. 1973).

J. angosturana leaf essential oil was shown to contain α-*pinene* [23.1%], δ-3-carene [11.5%], elemol [8.5%], *elemicin* [10.2%], *camphor* [0.9%], *safrole* [0.1%], traces of *estragole*, and many other compounds (Adams 2000b).

J. communis var. nana essential oil has yielded 20% α-*pinene*, 1.1% β-*pinene*, 8.7% limonene, 8.5% myrcene, 8% *borneol*, 7.2% β-caryophyllene, 7% germacrene D, 3.9% α-humulene, 10.4% δ-cadinene, 1.3% α-cadinol, 1.7% sabinene, and traces of camphene, α-copaene, α-cubebene, p-cymene, β-phellandrene, α-terpineol, α-terpinene, γ-terpinene, terpinolene and terpinen-4-ol (Proenca da Cunha & Roque 1990).

J. excelsa leaves yielded an essential oil containing cedrol [28.1-30.8%], α-*pinene* [22.5-26.5%], limonene [5.5-22.6%], and smaller amounts of many other compounds, including *camphor* [0.2-0.5%] (Adams 2001); berries have yielded diterpenes, including isocommunic acid, (-)ent-transcommunic acid, isopimaric acid, sandracopimaric acid [antibacterial], and a new labdane diterpene 3α-acetoxy-labda-8(17),13(16),14-trien-19-oic acid; and a sesquiterpene, 4α-OH-cedrol. An extract of the plant has shown CNS-depressant activity in rats (Topçu et al. 1999).

J. indica [harv. Nepal] leaf essential oil was shown to consist mostly of sabinene [26.1%], as well as β-*thujone* [16%], α-*thujone* [2.3%], trans-sabinyl acetate [15.7%], terpinen-4-ol [7.2%] and many other compounds (Adams 2000a).

J. macropoda leaves have yielded an essential oil containing α-*pinene* [15.5-68.8%], myrcene [1.2-20.7%], cedrol [0-26.4%], limonene [1.2-9%], and smaller amounts of many other compounds, including β-*thujone* [0-0.2%], *camphor* [traces-1.7%] and *borneol* [0%-traces] (Adams 2001); as well as isoflavones [junipegenins A-C, irigenin, iridin and 5,7,3',5'tetrahydroxy-4'-methoxyisoflavone] and stilbenes [resveratrol and piceid (resveratrol-3-O-β-D-glucoside)] (Sethi et al. 1980, 1981); berries have yielded 0.007% hypolaetin 7-glucoside (Siddiqui & Sen 1971).

J. oxycedrus leaf and stem extracts have shown sedative, analgesic, and antiinflammatory effects in mice, and exhibited low toxicity. Extracts have also been found to partially antagonise *acetylcholine*, *histamine* and *serotonin* in vitro (Moreno et al. 1998).

J. pseudosabina [harv. Mongolia] leaf essential oil was shown to consist mostly of α-*pinene* [52%], as well as cedrol [10.7%], sabinene [5.8%], β-*pinene* [4.5%], myrcene [3.8%], 2-nonanone [3.4%], linalool [2.1%], germacrene D-4-ol [2%] and many other compounds (Adams 2000a).

J. recurva [harv. Nepal] leaf essential oil has been shown to consist mostly of δ-3-carene [23.7%], as well as limonene [18.4%], sabinene [13.4%], α-*pinene* [6.9%], elemol [3.9%], terpinen-4-ol [3.7%], and many other compounds (Adams 2000a).

J. scopulorum essential oil has been found to contain *safrole* (Harborne & Baxter ed. 1993).

J. virginiana leaves and twigs yielded podophyllotoxin, which has some tumour-inhibiting properties (Kupchan et al. 1965); this species has also yielded α-eudesmol, which was shown to inhibit neuronal Ca2+ channels sensitive to ω-agatoxin IVA [a peptide toxin isolated from the funnel web spider, Agelenopsis aperta] (Asakura et al. 1999).

Juniperus macropoda is a small to medium-sized tree with fibrous, vertically fissured reddish-brown bark, peeling in fibrous strips. Leaves on young plants and on lower branches of older ones are subulate and pungent; on most branches, the leaves are scale-like, closely adpressed, with a large oblong or elliptic gland in the centre of the back. Male flowers found at tips of branches; catkins small, cylindric, ovoid, axillary or terminal, and solitary; stamens decussate or in threes, connective enlarged, ovate or peltate at apex, bearing 2-6 globose pollen-sacs near base. Female flowers found terminating short side branches; cones composed of 2-6 opposite or ternate scales, the scale usually not all fertile; ovules 1-2 to each fertile scale, upright. Fruit a berry-like cone, 7.5mm diameter, globose, bluish-black, very resinous, tips of scales forming transverse ridges; seeds 2-5.

In the Himalayas from Nepal west up to 4270m, also in Baluchistan, Afghanistan, Iran and Saudi Arabia (Kirtikar & Basu 1980).

The taxonomy of Juniperus spp. is quite confused, with species synonymy constantly being revised based on new findings. The listing at the head of this chapter should be regarded as only one interpretation of the taxonomic relations of the species discussed.

JUSTICIA

(Acanthaceae)

JUSTICIA PECTORALIS VAR. STENOPHYLLA

Justicia caracasana *Jacquin* – curia

Justicia gendarussa *Burman f.* **(J. nigricans** *Lour.***; Gendarussa vulgaris** *Nees***)** – venco tudo Africano

Justicia ideogenes *Leonard*

Justicia pectoralis *Jacquin* **(Dianthera pectoralis** *(Jacq.) J.F. Gmel.***; D. pectoralis** *(Jacq.) Murray***; Ecbolium pectorale** *(Jacq.) Kuntze***; Psacadocalymma pectorale** *(Jacq.) Bremek.***; Rhytiglossa pectoralis** *(Jacq.) Nees***; Stethoma pectoralis** *(Jacq.) Raf.***)** – masha-hara-hanak, boo-hanak, yakayú, Jamaica garden balsam, herbe aux charpentieres, sèpantye

Justicia pectoralis *Jacquin* **var. stenophylla** *Leonard* – mashihiri, masha-hiri, masha-hari, ya-ko-yoo, shäri kä henakö

Justicia prostrata *Gamble*

In Venezuela and Brazil, J. pectoralis and J. pectoralis var. stenophylla [which is probably a growth form of J. pectoralis, rather than a distinct variety] are used in the preparation of entheogenic snuff made principally from **Virola** spp., usually V. theiodora. The leaves are toasted, powdered and mixed with the **Virola** resin, but there are reports of Justicia being used on its own to prepare an 'epéna' weaker than that made primarily from **Virola** spp. Snuff made from this Justicia is also called 'machohara', and is said to send the user into a trance. Usually, the plant is added mainly for its aroma and many tribes may consider it to have only negligible potency. It is prepared by sun-drying or fire-drying the leaves, which are then toasted on a heated piece of clay until crisp – the leaves are then crushed between the hands, and then ground with mortar and pestle to a fine powder. The snuff is so fine that it is often mixed with ashes of Elizabetha princeps bark to give bulk and help hold it together. J. pectoralis is also used as an aphrodisiac, and to treat pulmonary infection and pneumonia by the Puinave (Brewer-Carias & Steyermark 1976; Chagnon et al. 1971; Lizot 1985; Macrae & Towers 1984b; Prance 1972; Schultes 1990; Schultes & Raffauf 1990; Seitz 1967), and is also used to treat coughs and colds in the Caribbean (Ott 1993).

In Venezuela, J. caracasana is added to 'lickable' tobacco preparations [see **Nicotiana**] (Ott 1993). J. ideogenes is used by the Kofan of n.w. Amazonia, who rub a decoction of the plant over the lower limbs to treat 'palsy-like trembling'; the plant may have antidepressant properties (Schultes 1993). In Candomble, Brazil, living plants of J. gendarussa ['venco tudo Africano'] are believed to protect against a form of the 'evil eye' that targets financial affairs (Voeks 1997). In Madagascar, the Tanala use the plant in sorcery, in unspecified ways (Ott 1993). In the Malay Peninsula, it is used obscurely as a magic plant, as well as for medicine. The leaves are used externally to treat headache, rheumatism, lumbago and swellings, or internally as a diaphoretic, febrifuge, purgative and asthma treatment (Perry & Metzger 1980). In Nepal, J. adhotoda ['aatashu dhu', 'asura'] herbage is sometimes used an an incense material (Müller-Ebeling et al. 2002).

J. gendarussa leaves contain a 'slightly toxic, non-volatile alkaloid', and are rich in potassium; roots have yielded justicine, and essential oil (Perry & Metzger 1980); the plant has also yielded 2-aminobenzyl alcohol and 2-(2-aminobenzylamino)benzyl alcohol (Lorenz et al. 1999). A decoction or alcohol extract of the roots, taken in a dose of 1-2g/kg, produces slight paralysis; 10-20g/kg may act as an "antipyretic and depressant producing

violent diarrhoea and eventually death" (Perry & Metzger 1980).

J. ghiesbreghtiana has yielded 0.089% justiciamide [(-)-N-(2-OH-4,5-dimethoxyphenyl)-2S,4S)-γ-OH-*glutamic acid*], as well as racemic allantoin and an α-malamidic acid derivative (Lorenz et al. 1999).

J. pectoralis has yielded 2.4% betaine [anticonvulsant], 0.42-1.18% coumarin [sedative and hypnotic near toxic levels, analgesic, spasmolytic; highest in mature leaves], *scopoletin*, 0.3-0.58% umbelliferone [spasmolytic; highest in mature leaves], β-sitosterol and traces of vasicine [hypotensive, bronchodilator, respiratory stimulant, uterotonic; see **Peganum**] (Macrae & Towers 1984b; Schultes 1990). Whole plant from Guadeloupe yielded flavonoids – 0.0022% swertisin, 0.004% 2"-O-rhamnosylswertisin, 0.0019% swertiajaponin and 0.001% 2"-O-rhamnosylswertiajaponin (Joseph et al. 1988). 34g of the herb taken with 3g **Peganum** harmala seeds, in an aqueous extraction, proved to be psychoactive in a human bioassay (pers. comm.).

J. pectoralis var. stenophylla has been reported to contain trace amounts of tryptamines by two researchers, although others have found none (Schultes 1990). TLC analysis tentatively identified traces of *DMT* and *N-methyltryptamine* from August harvests; a November analysis showed the tentative presence of *5-methoxy-DMT* (Heffter 1996; Trout ed. 1997d).

A snuff sample ['mashahari'] believed to consist solely of J. pectoralis var. stenophylla yielded 0.052% *5-methoxy-DMT* and 0.009% *DMT* (McKenna et al. 1984b).

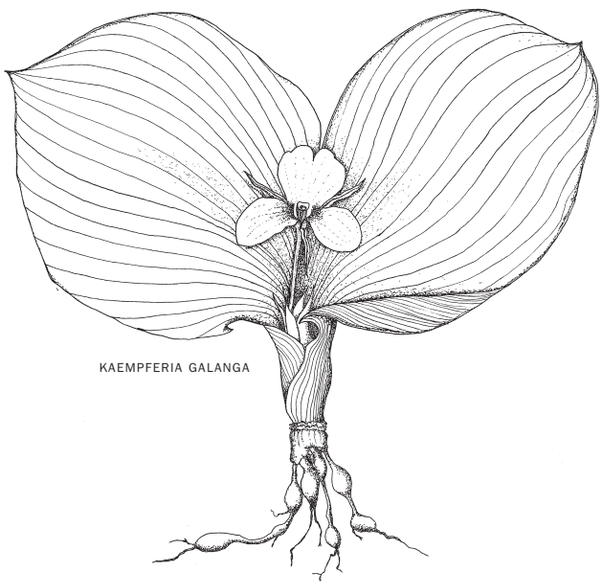
J. prostrata has yielded *carpacin* (Harborne & Baxter ed. 1993).

Justicia pectoralis is a compact herb to 30cm high; stems ascending, sometimes rooting or prostrate at base, subquadrangular, alternately bisulcate, glabrous, pilose from bud, strongly decurrent; internodes short, usually less than 2cm. Leaves numerous, glabrous on both sides, narrowly lanceolate, attenuate, entire, base acute, cuneate; petioles slender, to 6mm long. Inflorescences terminal spikes up to 10cm long, dichotomous, glandulose-pubescent, hairs filiform; bracts and bracteoles setaceous; flowers distant, secund; calyx 5-fid, lacinia slightly subcapillary above, subulate, c.2mm long, 0.25mm wide, puberulous; corolla white or violet, sometimes purple spotted, c.7-8mm long, slightly pubescent externally; stamens exserted c.1mm beyond corolla throat; style c.7mm long. Capsules clavate, c.8mm long; seed flattish, c.15mm wide, rough, reddish-brown.

Eastern Colombia, adjacent Amazonian Brazil; often semicultivated (Fridericus & De Martius ed. 1965-1975; Schultes & Hofmann 1980).

KAEMPFERIA and ALPINIA

(Zingiberaceae)



KAEMPFERIA GALANGA

Kaempferia galanga *L.* – galangal, maraba, shannai [rhizome in TCM], kuunkuun, sidhoul, camphor root, gisol, spice lily

Alpiniablepharocalyx *(J.C. Wendl.) K. Schum.* **(Languasblepharocalyx** *(K. Schum.) Hand.-Mazz.***)**

Alpinia galanga *(L.) Sw.* **(A. galangal** *(L.) Willd.***; Amomum galanga** *(L.) Lour.***; Am. medium** *Lour.***; Languas galanga** *(L.) Stuntz***; Maranta galanga** *L.***)** – galanga, galangal, galanga major, greater galanga, Siamese ginger, Laos root, da gao liang jiang [rhizome in TCM], rieng, rom deng, kha ta deng, pa da goji, sugandhavacha, kulinjana

Alpinia kumatake *Makino* **(A. formosana** *K. Schum.***; A. hokutensis** *Hayata***; A. intermedia** *Gagnep.***; A. kelungensis** *Hayata***; A. koshunensis** *Hayata***; A. oblongifolia** *Hayata***; A. satsumensis** *Gagnep.***; Languas formosana** *(K. Schum.) Sasaki***; L. hokutensis** *(Hayata) Sasaki***; L. intermedia** *(Gagnep.) Sasaki***; L. kelungensis** *(Hayata) Sasaki***; L. koshunensis** *(Hayata) Sasaki***; L. oblongifolia** *(Hayata) Sasaki***)** – Taiwan galangal, ginger lily, pinstripe ginger, shell ginger, shellflower ginger, Formosan ginger, mei-shan-jiang

Alpinia officinarum *Hance* **(Languas officinarum** *(Hance) Farw.***)** – galangal, lesser galangal, Chinese ginger, gao liang jiang [rhizome in TCM]

Alpinia speciosa *(J.C. Wendl.) K. Schum.* **(A. zerumbet** *(Pers.) B.L. Burtt et R.M. Sm.***; Languas speciosa** *(J.C. Wendl.) Small***; Zerumbet speciosum** *K. Schum.***)** – light galangal, shell ginger, shellflower ginger, Queen's candle ginger, pink porcelain lily, China lily, shan-jiang

As 'maraba', the rhizomes of K. galanga are consumed in the Morobe and Fore regions of Papua New Guinea [PNG], being chewed and swallowed, or made into a drink; it is thus said to be entheogenic, aphrodisiac, euphoric, and productive of pleasant and prophetic dreams. It is also used as an entheogen by the Bimin-Kuskuskmin of PNG, in the final 3 stages of their initiations. For this purpose, it is eaten with **Boletus** sp., **Heimiella** sp., **Russula** sp. and **Psilocybe** mushrooms, and is said to bring about a detached, dream-like state on its own. The Jamu of India add it to powders used as stimulants, aphrodisiacs, or elixirs of longevity (Hamilton 1960; Paijmans ed. 1976; Poole 1987; Rätsch 1992; Schultes & Hofmann 1980).

K. galanga rhizome has also been used in India to treat food poisoning, tetanus, inflammation of the mouth, abscesses, coughs and colds, and is considered to be a stomachic, carminative and cholagogue. Powdered and mixed with honey, it is used to treat coughs; boiled in oil, it is applied externally to a blocked nose. Sometimes, the rhizome is chewed with betel nut [see **Areca**]. In much of s.e. Asia, it is a popular flavouring and stimulant; the leaves are also cooked as a vegetable, or added to curries. The rhizome juice may also treat sore throats, headache, birthing pain and skin conditions; it has antibacterial properties. In Malaysia, it is added to an arrow poison made from Antiaris toxicaria (Bremness 1994; Emboden 1979a; Kirtikar & Basu 1980; Nadkarni 1976; Perry & Metzger 1980; Tewtrakul et al. 2005). To the Akha of n. Thailand, Kaempferia spp. are very important in warding off malicious spirits (Anderson 1993). The African K. ethele is said to have produced stupor in a horse (Watt 1967).

The rhizome of K. galanga is also used in TCM in small amounts, and is considered to be warm, fragrant, and pungent in quality, with an affinity for the lungs. It is used to treat vomiting, diarrhoea, toothache, intestinal parasites, and cold pain in the chest and abdomen. The Chinese prepare it after collection from December-March. The rhizome is washed, cut into 1cm-thick slices, bleached over sulphur fumes for 1 day, and dried on a bamboo screen (Hsu et al. 1986; Perry & Metzger 1980).

A. galanga rhizome is considered in Ayurvedic medicine to be pungent, bitter, hot and stomachic; it is used to improve appetite, taste and voice, and to treat bronchitis and heart disease. In the Unani system, it is considered aphrodisiac, tonic, diuretic, expectorant and carminative, and is used also to treat headache, lumbago, rheumatism, sore throat, chest pain, diabetes, tuberculosis, burning sensations in the liver, and kidney disease. Hakims consider it disinfectant, and use it to treat impotence, nervous debility, bronchitis and dyspepsia. The rhizome is also added to 'bazar' spirits, to make the liquor more intoxicating (Frawley & Lad 1986; Kirtikar & Basu 1980; Nadkarni 1976). Its essential oil is the source of 'Essence d'Amali' (Bremness 1994). A. malaccensis is also a source of this perfume, and its rhizome is chewed in n. India and Malaysia as a betel nut substitute [see **Areca**] (Usher 1974).

A. officinarum is lesser used in Indian medicines, though it is known as a stimulant, stomachic and carminative (Nadkarni 1976). Its rhizome is used in TCM as a stomachic (Huang 1993). The rhizomes of A. speciosa have been used as a substitute for both A. galanga, and ginger [Zingiber spp. – see *Endnotes*] (Kirtikar & Basu 1980). Alpinia spp. rhizomes are much used in s.e. Asian cooking as a spice [especially as an ingredient of some Thai curries], and are commonly available in grocers, either fresh or sliced and dried [usually labelled simply as 'galangal'] (pers. obs.).

An Alpinia sp. known as 'khraanik' is eaten peeled and crushed with salt as one of the psychoactive ginger types consumed in stage one of the Bimin-Kuskuskmin initiation rites (Poole 1987), mentioned above and further under other entries [see *Endnotes*]. The Nkopo of PNG use an Alpinia sp. ['yoma kaa'] in rituals to achieve a harmonious state ['gisam'] with natural forces (Schmid 1991).

Modern experimentation with galangal has been clouded with widespread confusion regarding the identity of rhizome material. In many cases, people seeking K. galanga have purchased and used A. galanga or A. officinarum, without knowing there is more than one plant known as 'galangal'. These latter two species are the ones more commonly sold in Asian groceries and used in cooking. Though K. galanga is used for these purposes, it is less commonly encountered in Western countries. However, the **Alpinia** spp. do seem to share some similar psychotropic effects with K. galanga. Several dosage recommendations have been suggested [eg. 6cm fresh rhizome; 60g fresh; 1 heaped tsp dried and powdered]. It is usually eaten, though the juice may be drunk if using fresh rhizomes. One in-

ternet psychonaut claimed to have successfully prepared a smokeable petroleum-ether extract [dried], from a defatted, basified syrup prepared by water decoction. The material was smoked by vapourisation in a free-base pipe. The effects for some people [such as the aforementioned psychonaut] can manifest as mild euphoria and stimulation, with mild 'LSD-like' sensory distortions lasting several hours or more. Others have achieved no effect at all, except for gastric upset and diarrhoea (pers. comms.). One person who ingested 1 cubic cm of fresh rhizome [definitely identified as K. galanga] on numerous occasions reported a pleasant stimulating and euphoric effect. Higher doses were not attempted due to fearing the potential toxicity of *borneol*, which he believed to be a major component of the essential oil [see below] (theobromus pers. comm.). Animal studies using an ethanol extract of the rhizomes observed CNS depression and analgesia, but no toxicity (Kanjanapothi et al. 2004).

K. galanga rhizome has yielded large quantities of essential oil [1.11% v/w in one analysis], containing *borneol* [2.87%], camphene [2.47%], l-Δ3-carene, carvone [11.13%], methyl-cinnamate [23.23%], ethyl-cinnamate, ethyl-p-MeO-cinnamate [31.77%], p-MeO-styrene [may be an artefact of extraction], α-*pinene* [1.28%], eucalyptol [9.59%], kaempferol [see below], kaempferide, p-MeO-cinnamic acid, ethyl p-MeO-transcinnamate, methyl p-MeO-cinnamate, pentadecane [6.41%], benzene [1.33%], alpinetin, α-terpineol, β-phellandrene, dihydro-β-sesquiphellandrene, 3-caren-5-one, 3-(4-OH-phenyl)-2-propenoic acid, p-methylcumaric acid ethylester, and cinnamic aldehyde. Constituents and their proportions appear to vary in nature. A fraction from the rhizome was shown to inhibit MAO; this has been attributed to ethyl-p-MeO-transcinnamate, which also has some anti-cancer effects (Buckingham et al. ed. 1994; Hsu et al. 1986; Noro et al. 1983; Panicker et al. 1927; Rastogi & Mehrotra ed. 1990-1993; Tewtrakul et al. 2005). Some MAOI activity might also be attributable to the flavonoid kaempferol, which has recently shown MAOI activity, as well as acting as a neuroprotectant against NMDA-induced neurotoxicity (Sloley et al. 2000).

A. blepharocalyx seeds have yielded 4'-OH-*5,6-dehydrokawain*, phloroglucinol, and a variety of diarylheptanoids (Ali et al. 2001).

A. galanga rhizome has yielded *eugenol*, 1,8-cineole, *pinene*, linalool, cedrol, *camphor*, methyl cinnamate, quercetin, kaempferol, quercetin-3-methyl ether, isorhamnetin, kaempferide, galangin, galangin-3-methyl ether, galanal A & B, galanolactone, 1,5-bis(4-OH-phenyl)-1,4-pentadiene, 3-(4-OH-phenyl)-2-propenal and 8(17),12-labdadiene-15,16-dial (Buckingham et al. ed. 1994; Rastogi & Mehrotra ed. 1990-1993; Schermerhorn et al. ed. 1957-1974).

A. kumatake rhizomes have yielded *5,6-dehydrokawain* and dihydro-*5,6-dehydrokawain* (Kimura et al. 1966).

A. officinarum rhizome has yielded 0.5-5% essential oil, containing *eugenol*, *pinene*, cineol, cadinene and methylcinnamate (Keys 1976), as well as kaempferol, kaempferide, galangol, galangin, alpinin, and a variety of sesquiterpenes (Buckingham et al. ed. 1994; Rastogi & Mehrotra ed. 1990-1993; Schermerhorn et al. ed. 1957-1974).

A. speciosa rhizomes have yielded *5,6-dehydrokawain* and dihydro-*5,6-dehydrokawain*, flavokavain B, dihydroflavokavain B [see **Piper 2**], cardamomin, alpinetin, and methyl trans-cinnamate; cardamomin and alpinetin have also been found in the seeds (Itokawa et al. 1981; Kimura et al. 1966); dihydro-*5,6-dehydrokawain* has also been found in the leaves (Tawata et al. 1996).

Alpinia galanga is a perennial herb with elongate, leafy stems and horizontal tuberous rootstocks, slightly aromatic. Leaves 23-45 x 3.8-11.5cm, oblong-lanceolate, acute, glabrous, green above, paler beneath, with slightly callous white margins; sheaths long, glabrous, ligule reaching 10mm long, usually shorter, rounded. Flowers greenish-white, in dense-flowered terminal panicles 15-30cm long; branches short; rachis pubescent; pedicels 3-4mm long; bracts 10mm long, ovate-lanceolate; bracteoles large, sometimes enveloping buds; calyx 10mm long, tubular, irregularly 3-toothed; corolla 2-3cm long, tube cylindric, 13mm long, lobes oblong, obtuse, subequal, 6mm wide, the upper usually broader and more convex than the lateral; lip 2.2cm long; claw green, 6 x 2.5mm; blade white striated with red, rather more than 13mm long, broadly elliptic, shortly 2-lobed at apex, with a pair of subulate glands at base of claw; stamen 1, perfect, 2cm long; filament flattened; anther cells diverging at top, occasionally with an orbicular crest; lateral staminodes minute or obsolete. Ovary 3-celled; ovules few or many on each placenta; style filiform; stigma subglobose. Fruit the size of a small cherry, orange-red, globose, dry or fleshy, usually indehiscent; seeds globose or angled.

Tropical forest margins; s.e. Asia, India, Ceylon, Malay Islands. Often cultivated (Kirtikar & Basu 1980).

Kaempferia galanga is a leafy, tuberous herb, aromatic; root fibres fleshy, cylindric. Leaves 2, spreading horizontally, lying flat on surface of ground, 6.3-15 x 4.5-9cm, rotund-ovate, deltoid-acuminate, thin, deep green, 10-12-ribbed, sometimes with red margin; petioles short, channelled. Flowers in terminal spikes, singly or 6-12 from centre of the plant between the leaves, fugacious, fragrant, opening successively; bracts lanceolate, green, short; calyx as long as outer bracts; corolla tube 2-5cm long, lobes lanceolate, pure white, a little shorter than tube; lateral staminodes 1-2cm long, cuneate-obovate, white; lip rather more than 2.5cm long and nearly the same wide, deeply 2-lobed, the lobes with a lilac spot at base; connective produced into a quadrate 2-lobed appendage; stamen 1, perfect; filament short. Ovary 3-celled; ovules many on 3 axile placentas; style long, filiform; stigma turbinate. Fruit an oblong capsule with thin pericarp; seeds subglobose, with small lacerate aril (Kirtikar & Basu 1980).

In grassy areas (Emboden 1979a). India, China, s.e. Asia, often cultivated; country of origin uncertain (Backer & Bakhuizen van den Brink 1968; Perry & Metzger 1980).

Cultivate by root division in spring. Not frost-tolerant – in cold areas, grow indoors in a pot with rich soil. Water heavily, less so near end of summer, hardly at all in winter (Grubber 1973).

KEISKEA

(Labiatae/Lamiaceae)

Keiskea japonica *Miq.* – shimobashira

This Japanese mint was recently discovered to be psychoactive during a small wave of experimentation with members of the family Labiatae, following discovery of the activity of diterpenes from **Salvia** divinorum. Taken sublingually, 4-5 of the large, bitter leaves were active after being held in the mouth for at least 10 minutes. The effects are reportedly similar to the other 'lesser-active' **Salvia** spp. [as opposed to the highly-active S. divinorum], and consist of a mild euphoria and '**Cannabis**-like' effects, as well as disturbing balance (pers. comm.). The herb is also mildly psychoactive when smoked, although the sample which I bioassayed was at least 5 years old. Fresher material may have been subjectively stronger in effect. The only side effect noted was a mild headache, which might perhaps have been due to the age of the sample (pers. obs.).

Keiskea japonica is a perennial herb; stems c.60cm long, 4-angled, slightly pilose or glabrous, often branched in upper part. Leaves opposite, toothed, thinly chartaceous, broadly lanceolate to narrowly ovate, 6-15(-20) x 2-5.5cm, apex abruptly long-acuminate, base long-acuminate, rarely subobtuse, margin acutely toothed except near base, puberulent on midrib above, glabrous or thinly pilose on nerves beneath; petioles 5-30mm long. Verticils 2-flowered, forming 1-sided spikes 5-12cm long, shortly pilose; bracts broadly linear, small, persistent; flowers bisexual, pedicelled; calyx deeply 5-toothed, actinomorphic, campanulate, with lanceolate lobes, hairy on throat, 3mm long at anthesis, 5-6mm long in fruit, nearly as long as pedicels, exceeding the bracts; corolla white, c.7mm long, shallowly lobed, tube broadened in upper part, with ring of hairs inside, limb slightly bilabiate, lower lip 3-lobed, midlobe slightly larger; stamens 4, didymous, exserted, upper pair shorter, filaments glabrous; anthers 2-locular. Ovary superior, deeply 4-lobed; style solitary, gynobasic; ovules 4, erect. Nutlets usually solitary, globose, dark brown, 1.5-2mm across, with darker reticulations. Fl. Sep.-Oct.

Mountains; Honshu [Kanto district and westward], Shikoku, Kyushu [Japan] (Ohwi 1965).

KOCHIA

(Chenopodiaceae)

Kochia scoparia *(L.) Schrad.* **(K. parodii** *Aellen***; K. scoparia var. alata** *Blom***; K. virgata** *Kostel.***; Bassia scoparia** *(L.) A.J. Scott***; Chenopodium scoparia** *L.***)** – summer cypress, Belvedere cypress, ti fu, di fu zi, di fu dze, sao jou tsao ['broom grass'], kaura-ro

This herb is used in Polish medicine in the form of an infusion, to treat heart troubles and rheumatism (Drost-Karbowska et al. 1978). In TCM, leaves and seeds are used as a cardiotonic, and seeds as a tonic, diuretic, astringent, antiphlogistic and blood purifier, as well as to treat impotency, eczema and rubella. They are considered cold, sweet and bitter, with an affinity for the kidneys. A leaf decoction may be used as an eyewash to improve night vision, or as a body wash for skin disorders; shoots and stems also treat dysentery and diarrhoea (Kirtikar & Basu 1980; Perry & Metzger 1980; Reid 1995; Wen et al. 1995). In China and Japan, K. scoparia is also cultivated for its young shoots, which are eaten as a vegetable, and for its seeds, which are ground into flour. The related 'salt bush' [K. aphylla] is an important drought stock-feed in Australia (Usher 1974). In India, K. indica is used as a cardiac stimulant (Nadkarni 1976).

In one test, dried aerial parts of K. scoparia yielded 0.00028% *harman* and 0.00005% *harmine*, from a total of 0.06% crude alkaloids, the remainder of which was not analysed; extraction of the alkaloids may not have been complete. Flowering tops yielded 2.2% betaine (Drost-Karbowska et al. 1978). Seeds contain saponins called momordins, and triterpenoid glycosides (Wen et al. 1995).

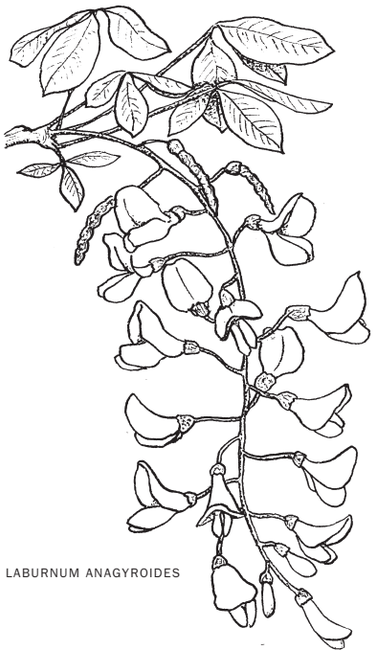
Kochia scoparia is a tall annual herb, 90-150cm high, glabrous or pubescent, strict, erect; branches erect and stems slender, white, smooth, the ultimate twigs pilose or villous. Leaves alternate, sessile, narrow, en-

tire, 2.5-3.8cm, green, linear-lanceolate, acute, midrib distinct. Flower clusters in leafy panicled spikes; flowers axillary, hermaphrodite or mainly female (rarely only male); bracts 0; perianth subglobose; lobes 5, coriaceous, incurved, closing over the utricle, girt by 5 free or confluent horizontal wings; stamens 5, usually exserted, inserted at the bottom of perianth; anthers larger, ovate. Ovary depressed-globose; style slender; stigmas 2-3, capillary; utricle depressed, membranous. Fruiting perianth very variable, wings short, semicircular, scarious, nerved, entire, shorter than the diameter of the disc. Seed horizontal, ovoid or orbicular; testa membranous; albumen scanty; embryo annular.

Central Europe west to Spain, east to n.w. India, north and central Asia to Japan (Kirtikar & Basu 1980), escaped weed in N. America (Usher 1974).

LABURNUM and CASSIA

(Leguminosae/Fabaceae)



LABURNUM ANAGYROIDES

Laburnum anagyroides *Medic.* **(Cytisus laburnum** *L.***; L. vulgare** *Presl.***)** – golden shower, golden chain, golden rain, common laburnum, llavia de oro, zoloti dozhd

Laburnum spp. – golden chain, golden shower

(Leguminosae/Caesalpiniaceae)

Cassia fastuosa *Willd.* – paricà

Cassia fistula *L.* – Indian laburnum, purging cassia, pudding pipe tree, golden shower, rajavraksha, nripadruma aragbhada, amulthus, sonhali

Cassia lucens *Vogel*

Cassia occidentalis *L.* **(Senna occidentalis** *(L.) Link***)** – coffee senna, negro coffee, fedegoso, kasamarda, kasondi

Cassia spp.

Laburnum spp., sometimes grown as ornamental trees, have been responsible for poisoning children who have eaten the green pods or seeds, or sucked on the flowers [usually of L. anagyroides]. There is usually complete recovery after 12 hours (Bruneton 1995; Forrester 1979; Foster & Caras 1994; Hatfield et al. 1977; Turner & Szczawinski 1991).

Related, though clearly distinct, is the genus Cassia, of which C. fistula ['Indian laburnum'] is also known as 'golden shower' in reference to the beautiful yellow inflorescence. It acts as a purgative, and the pulp from inside the seed pods has been used to flavour Bengal tobacco [see **Nicotiana**]; its flowers are also offered to some Hindu deities (Bremness 1994). Many other Cassia spp. [including C. angustifolia, C. australis, C. alata, C. pleurocarpa, C. occidentalis, C. senna] also have purgative properties in all parts, and when used as such, are usually referred to as 'senna'. Boiling destroys this property, so the herbs are usually infused in water (Cribb & Cribb 1981; Morton 1977). When roasted, the seeds lose their purgative properties, and are then sometimes used as coffee substitutes [see **Coffea**]. C. pleurocarpa is also reputed to be toxic to stock animals (Cribb & Cribb 1981), acting as a purgative and sometimes causing fatalities (Gardner & Bennetts 1956). In Nigeria, the seed of C. occidentalis is used as a coffee substitute, and is considered toxic unroasted. The leaf is given with palm oil for convulsions (Watt 1967). In India, the seeds [dose – 0.3-0.8g] are given in milk for the same purpose, in children. A decoction of the roots, leaves, and flowers is also used to treat spasms and hysteria (Nadkarni 1976). In Brazil, the plant has caused intoxications in cattle, with symptoms including disequilibrium, tremors, weakness, dragging of the rear hooves and diarrhoea. If a fully-toxic dose has been consumed [c.1kg of seeds per 100kg], the animals lie down and die (Pott & Alfonso 2000).

In Brazil, C. fastuosa is referred to as 'paricà' [see **Anadenanthera** and **Virola**] (Schultes 1955a), pointing to a possible previous use as a snuff ingredient. C. closiana is known in South America as 'quebracho' ['axe-breaker' – see **Aspidosperma**] (Trout ed. 1998), probably for its hard wood. In n.w. Amazonia, the Kubeo use the dried, powdered leaves of C. lucens as a memory tonic (Schultes 1993). Aboriginal people from northern Australia have used the ash of C. artemisoides ['silver cassia', 'blue bush cassia', 'parka'] to mix with chewing tobacco (Lassak & McCarthy 1990).

L. anagyroides is considered the most toxic of the Laburnum spp., all of which contain *cytisine*-like alkaloids [see **Cytisus** and **Sophora**] which can cause drowsiness intermittent with excitement, delirium, dizziness, restlessness, incoordination, confusion, dilated pupils, burning sensation in mouth and throat, nausea, vomiting, abdominal pain, diarrhoea, rapid or irregular heartbeat, sweating, salivation, cold skin and respiratory difficulties. Via the oral route, effects manifest within 1hr, and recovery may occur after 12-24hrs. Severe poisoning may lead to more severe hallucinations, convulsions, and even coma and death from respiratory paralysis. Bark and seeds are the most concentrated in *cytisine*; 20 seeds have been lethal in children. Alkaloid content may vary considerably (Barlow & McLeod 1969; Bruneton 1995; Forrester 1979; Hatfield et al. 1977; Turner & Szczawinski 1991). Smoking a cigarette of the dried flowers might be a safer method of ingestion, to produce a sub-toxic inebriation. It may be appropriate to prepare them in a similar manner to **Cytisus** canariensis flowers (pers. obs.).

L. anagyroides contains the alkaloids *cytisine* and N-methyl-*cytisine* in all parts, as well as laburnine in the seeds; seed pods have also yielded sparteine [affects muscarinic *acetylcholine*-receptors], thermopsine and 3-OH-11-nor-*cytisine*; leaflets also yielded anagyrine [affects muscarinic *acetylcholine*-receptors]. Leaflets have yielded 0-0.55% alkaloids; shoots 0.39-0.97%; petioles 0.54%; stem bark 0.47%. Flowers have yielded up to 0.62% alkaloids [this might have used the whole inflorescence; in another assay, petals yielded 0.23%, calyx none, and remaining flower parts 0.01%]; pedicels have yielded up to 1.98% alkaloids, and central rachis 1.61%, decreasing as the seed pods develop. During development and ripening, alkaloid levels increase in the seeds and decrease in the pods; ripe seed has yielded 0.5-1.96[-2.83]% alkaloids, ripe pods 0.08%. Hydrolysed leaf has yielded the flavonoids daidzein, genistein [MAOI (Hatano et al. 1991)] and isoprunetin; flowers have yielded the terpenoids lutein, lutein epoxide, violaxanthin and β-carotene (Harborne et al. ed. 1971; Henry 1939; International… 1994; Schmeller et al. 1994; White 1943b). The plant slightly inhibited human plasma AChE (Orgell 1963b).

Some Cassia spp. contain toxic compounds; for example, C. absus yielded the terpenoid chakisine, which has similar effects to *cytisine* in animals (Watt & Breyer-Brandwijk 1962). C. alata, C. fistula, C. siamea and C. sieberiana all produce HCN (Watt & Breyer-Brandwijk 1962). C. alata leaves have also yielded [w/w] 0.0037% *tyramine* (Wheaton & Stewart 1970). Glycosides such as sennoside A and sennoside B are primarily responsible for the purgative activity of many Cassia spp. (Cribb & Cribb 1981; Morton 1977).

C. occidentalis leaves, stems and pods have yielded *choline*, betaine, stachydrine, trigonelline and unidentified bases (Ghosal et al. 1970b); the herbage has also been shown to contain *GABA* (Durand et al. 1962).

Laburnum anagyroides is a hardy shrub or small tree to 10m tall, with spreading branches close to the ground; twigs with close-pressed hairs. Leaves alternate, trifoliate; leaflets elliptical-oblong, pubescent underneath, subsessile to 8cm long; petioles long; stipels none, stipules minute or none. Inflorescence showy pendulous terminal or axillary racemes to 46cm long; flowers golden yellow, 2cm long, pea-like; bracts and bracteoles small, early caducous; calyx tube very short, campanulate, obscurely bilabiate, lips obtuse, short, upper lip bidentate, longer, lower lip tridentate, usually ciliate, petals free, standard orbicular or broad-ovate, upcurved, without basal ears or tubercles, wings shorter than standard, obovate, keel very short, incurved, glabrous, not beaked; stamens 10, monadelphous; anthers alternately long and short. Ovary stalked, many-ovuled; style glabrous; stigma terminal, small. Pods in clusters, to 8cm long, silky, persistent, long-stalked, linear, narrow, nearly flattened, sutures thickened or slightly winged, slightly constricted between seeds, continuous within, 2-valved, tardily dehiscent; seeds several, kidney-shaped, dark brown. Fl. spring-summer.

Native to central and southern Europe; grown as an ornamental, and an occasional garden escape (Allen & Allen 1981; Foster & Caras 1994; Tamplon 1977; Turner & Szczawinski 1991).

LACTUCA

(Compositae/Asteraceae)

Lactuca altissima *Bieberstein*
Lactuca canadensis *L.* – wild lettuce
Lactuca canadensis var. elongata *(Muhl.) Farw.* **(L. elongata** *Muhl.***)**
Lactuca indica *L.* **(L. brevirostris** *Champ. ex Benth.***; L. mauritiana** *Poir.***; Pterocypsela indica** *(L.) C. Shih***)** – wild lettuce
Lactuca sativa *L.* **(L. scariola var. sativa** *Moris***)** – garden lettuce, salad lettuce
Lactuca sativa var. capitata *L.*
Lactuca serriola *L.* **(L. scariola** *L.***)** – wild lettuce, prickly lettuce, compass plant
Lactuca virosa *L.* – wild lettuce, prickly lettuce, bitter lettuce, poor man's opium
Lactuca spp. – lettuce, wild lettuce

The narcotic properties of lettuce varieties have been known since antiquity. The ancient Egyptians considered lettuce [probably L. serriola] to be aphrodisiac, using the seed oil to treat impotence, and held it sacred to Min, the fertility god. Dioscorides recognised the plant as being soporific, cooling and emmolient, and claimed that the seeds could dispel sexual desire. The famed Greek physician Galanus used to eat lettuce leaves in the evening to help himself sleep. Aphrodite was said to have lain the dead body of Adonis on a bed of lettuce leaves, according to Greek mythology. The herbs have also been added to witch's flying potions for their psychotropic properties in Europe. In Lebanon, powdered lettuce seed is used to calm feverish patients, and to deter boys from masturbating excessively! Lactuca spp. are also used by some Native Americans in ritual smoking blends (Bremness 1988; Duke 1983; Harlan 1986; Rätsch 1992; Von Bibra 1855).

The Cherokee use L. canadensis as a calming sedative to induce sleep [and also, paradoxically as a stimulant], and as an analgesic. Like other Lactuca spp., it is also cooked and eaten as a vegetable (Hamel & Chiltoskey 1975). The latex from L. canadensis, in large doses, has been reported to cause "delirium, confusion of the brain, vertigo and headache, dimness of vision, salivation, difficult deglutition, nausea and vomiting, and retraction of the epigastric region, with a sensation of tightness; distension of the abdomen, with flatulence; urging to stool followed by diarrhoea; increased secretion of urine; spasmodic cough, oppressed respiration, and tightness of the chest; reduction of the pulse 10 to 12 or more beats; unsteady gait; great sleepiness; and chills and heat, followed by profuse perspiration" (Millspaugh, in Pammel 1911).

In India, L. serriola is sometimes used for its leaves and sap, as a sedative, hypnotic, and expectorant (Nadkarni 1976). Likewise, in Indo-China the latex of L. indica is used as a narcotic sedative. In Papua New Guinea, the seeds of L. indica are chewed alone as a betel nut substitute [see **Areca**] by the Kukukuku (Paijmans ed. 1976; Perry & Metzger 1980). In n. Thailand, L. sativa seeds are eaten by hill-tribe shamans, to gain the cooperation of spirits when attempting to heal intestinal pains [see also **Petroselinum**] (Anderson 1993).

Culinary types of lettuce common on western tables have had most of their medicinal properties bred out of them to make them more tender and less bitter, and hence more palatable. These properties are concentrated in the milky sap or latex of the herb. Wild lettuce latex has long been used to adulterate opium from **Papaver** somniferum, and by the late 1700's it was in common use in its own right in European medicine, as a sedative relaxant (Von Bibra 1855). In medicine, the dried latex extract of wild lettuce has been known as 'lactucarium'. There were two main varieties used, French lactucarium [derived from L. sativa var. capitata], and German lactucarium [lactucarium germanicum; derived from L. virosa] (Budavari et al. ed. 1989; Felter & Lloyd 1898).

Several decades ago, it began a small 'counterculture' resurgence of use, with 'lettuce opium' being sold in health stores and through 'underground' magazines. However, much of this product appears to have been of low quality [made from garden lettuce] and was not satisfying to heroin addicts, who were used to 'harder stuff' (pers. comms.).

Lactuca spp. latex is collected when the plant is in flower, or just before. The tops of the plant are cut off with a sharp blade, and the latex collected and scraped off to be dried; this latex is milky-white and bitter, and in a couple of days dries to a light-brown colour. After a rest of 1-2 days or more, the plant can be cut again, a little lower on the stem, and this process continued until no more latex is yielded. The latex may then be smoked or decocted in the same manner as opium (pers. obs.). For internal medicinal use, the suggested dose of lactucarium is 0.3-1.3g (Felter & Lloyd 1898). Giorgio Samorini recently found latex of L. serriola [presumably taken orally] to be sedative and analgesic at a dose of 1g, but stimulating at doses of 2-3g. Samorini attributed these stimulant effects to the tropane alkaloids possibly present [see below] (Lorenzi 2005). Alternately, leaves and roots may be smoked for a weak effect, or the whole plant can be heated in water for up to 8hrs before being strained and reduced to a gum (Miller 1985). L. virosa is generally said to be the most potent, with L. canadensis var. elongata and L. altissima also held in high regard. L. sativa and L. serriola, when allowed to grow to maturity, are still active, but much less potent (Cribb 1981; Felter & Lloyd 1898).

The most important active components of Lactuca spp. are sesquiterpene lactones concentrated in the latex, such as *lactucin* and lactucopicrin [lactupicrin, intybin], which are very bitter (Sessa et al. 2000). These active principles reside mainly in the water-soluble portion of the latex; this portion, as well as pure *lactucin* and lactucopicrin, shows CNS-depressant activity in animals. Lactucopicrin is less toxic than *lactucin* [see *Chemical Index*], with an oral LD50 in mice of 12-20mg/g (Forst 1941). Although the presence of traces of *hyoscyamine* and *morphine* has been reported [see below], this is strongly doubted, largely on the grounds that these or similar compounds have not been detected elsewhere in the Compositae.
